Table 2. EFFECT OF ADMINISTRATION OF NORMAL AND IRRADIATED BONE-MARROW SUSPENSION ON LIVER REGENERATION OF NON-IRRADIATED ANIMALS

No. of exps.	Group	Mortality (per cent)	No of animals	r./100 g	Per cent	Note	
1	Partially hepatectomy	10	27	2·27 ± 0·08	89·7	—	
2	Partially hepatectomy + administration of bone-marrow suspension	8	11	2·82 ± 0·10	104·8	$t_{36} = 6{\cdot}170$	$P < 0{\cdot}01$
3	Partially hepatectomy + administration of irradiated bone-marrow suspension	11	15	1·51 ± 0·08	58·3	$t_{40} = 10{\cdot}250$	$P \ll 0{\cdot}01$

the lower thoracic and lumbar vertebræ or the lower ribs against irradiation.

The bone-marrow extract was obtained from the femur and tibia of one rat, and suspended in sodium chloride solution. This was injected into the femoral vein of one rat. The injected suspension contained $2{\cdot}1 \times 10^7$ cells on the average. The injection was carried out within 2 h after irradiation.

These experiments have again shown that treatment with bone-marrow extract decreases the number of deaths caused by irradiation.

Table 1 shows that under the effect of X-irradiation the loss in weight in the hepatic regenerate remains significant even if the liver is protected during irradiation of the whole body. At the same time when protecting the bone-marrow, that is, when the liver is subjected to X-rays, though the weight of the regenerate is smaller than that of the normal one, it surpasses significantly the weight of the liver regenerate exposed to the irradiation of the entire body. Injection of bone-marrow suspension being administered, regeneration of the liver continues with maximum intensity. The bone-marrow extract exposed to irradiation *in vitro* is ineffective. The results of our experiments are supported by mathematical calculations.

On the basis of the 117 appreciable experiments performed on rats it can be stated that the speed of hepatic regeneration decreases during irradiation and this effect can be explained not only by the direct influence exerted on the liver but also by the general reaction of the whole organism. An important component of this system, exerting a general reaction, is the bone-marrow.

The ineffectiveness of the X-ray-treated bone-marrow can be explained in two ways: (1) the supposed protecting material of the cell elements becomes inactive under the effect of irradiation; (2) under the effect of ionizing radiation toxic elements are produced which prevent the regeneration of the liver. The first possibility has already been shown by the protecting effect of bone-marrow suspension. The second possibility has been investigated through the effect of intact and irradiated bone-marrow on regeneration of liver in rats not exposed to X-rays. The results of these experiments are shown in Table 2.

It appears clearly that while regeneration of the liver of rats not exposed to irradiation is significantly advanced by normal bone-marrow suspension, the bone-marrow exposed to X-rays causes inhibition as if the whole body of the animal had been irradiated. Hence, when explaining the effect of bone-marrow, both possibilities (the protecting and the toxic effect) have to be taken into consideration.

In the course of our experiments we have noticed several phenomena little understood so far. One is that irradiation of the whole body hinders hepatic regeneration even if the region of the liver itself is protected against irradiation with lead plates. The other is that besides the protecting functions of the bone-marrow (prolongation of life and rapid regeneration of the lesions of bone-marrow and the alimentary canal) a further effect exercised on hepatic regeneration has been discovered, and at the same time also the toxic effect of the X-ray-treated bone-marrow has been noticed. It is also interesting that in the course of the research for the ætiology of pernicious anæmia, the effect of the liver on the bone-marrow has been recognized, and we have now found that both normal and irradiated bone-marrow also have a certain effect on the liver.

A SEX-ASSOCIATED PROTEIN IN LIVER TISSUE OF THE RAT AND ITS RESPONSE TO ENDOCRINE MANIPULATION

By Dr. H. E. BOND*

Biology Division, Oak Ridge National Laboratory†, Oak Ridge, Tennessee

SEXUALLY associated protein differences in animal tissues have been recognized for some time. Reports of these differences have related chiefly to enzyme activities[1,2] or to certain yolk proteins[3]. A protein in the serum of pregnant and fœtal rats has been described[4] which persists for the first three weeks of post-natal life, and the suggestion has been made that this protein may be a growth-associated substance which occurs in either sex in the presence of rapidly growing tissues. In this article, further work on a protein of unknown function, normally present in high concentration in the liver of the male rat (but absent from female liver[5,6]) will be described, together with observations on the effects of endocrine manipulation.

A sub-Wistar strain maintained at this laboratory was used for correlations of the sex-associated protein with age. The remainder of the investigations were carried out with Sprague–Dawley rats 4–5 months of age. No protein differences were observed between the two strains.

The effects of endocrine disturbances were examined on 10 groups of animals (castrated and uncastrated of both sexes) using commercial preparations of testosterone propionate, testosterone phenylacetate, and œstradiol dipropionate (Ciba preparation of 'Perandren' and 'Ovocylin').

To assay for the sex-associated protein, rats were stunned and decapitated, and the liver perfused, homogenized, and the soluble phase prepared as previously described[7]. Low molecular weight materials were removed by passage through a 'Sephadex *G*–50' (Pharmacia, Uppsala, Sweden) column equilibrated with 0·01 M *tris* chloride buffer at *p*H 8·4. 15 ml. of the Sephadex column effluent of known optical density at 280 mμ were transferred to a 2 × 25 cm column of DEAE-cellulose and chromatographed at 6° C. The column had been previously packed with DEAE-cellulose in the hydroxide form under 15 lb. air pressure and equilibrated with 0·01 M *tris* chloride buffer at *p*H 8·4. Proteins were eluted from the column with the same buffer at a flow-rate of 1·5 ml./min. The column had a hold-up volume of 42 ml. and 59 theoretical plates. The effective distribution coefficient for the male protein was 0·09. The column eluant was analysed continuously and the data recorded automatically at 260 and 280 mμ (Fig. 1) using an automatic analytical system[8].

Since the area under the sex-associated protein peak was found to compare favourably with the results from Kjeldahl nitrogen determinations, all chromatographic data presented here are based on the spectrophotometric measurements.

Mobility and sedimentation measurements were made in Miller–Golder[9] buffers at an ionic strength of 0·1. Amino-acid analyses were conducted on 24-h acid and base hydrolysates using a Spinco amino-acid analyser.

The sex-associated protein rechromatographs as a single component. Preliminary immunochemical experiments, however, show at least two other components present in small amounts in the purified material. An $S_{20,w}$ of 2·6 has been found for the protein isolated by improved techniques as compared with the value of 3·13 previously reported. The material appears to be homogeneous in the ultracentrifuge. The mobilities observed at *p*H 7·48, 8·12, and 8·59 were $-1{\cdot}6$, $+1{\cdot}8$ and $+2{\cdot}1 \times 10^{-5}$ cm^2 V^{-1} sec^{-1}. In each instance only one peak was observed. The isoelectric point obtained by interpolation is *p*H 7·7. The dry protein contains 15·5 per cent nitrogen and approximately 1 per cent amino hexose. The amino-acid chromatogram contains a peak suggesting the presence of galactos-

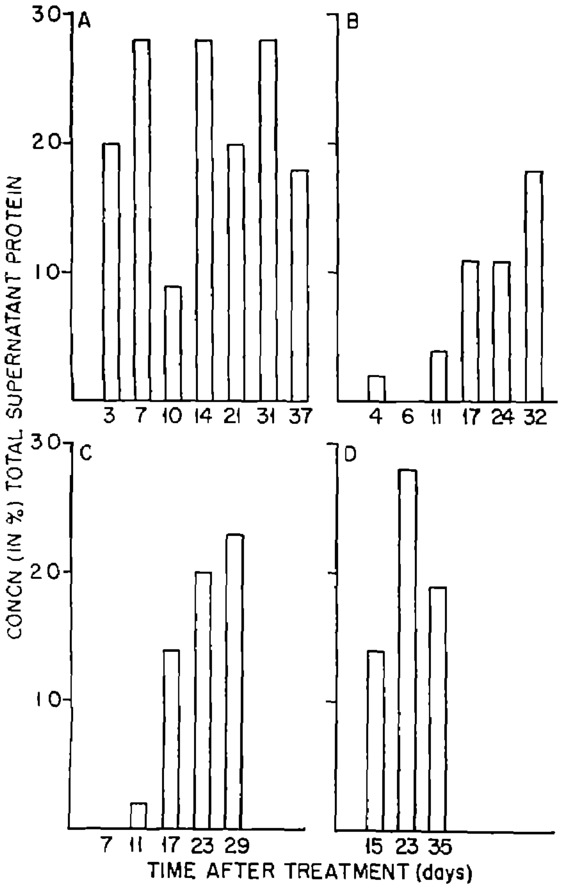

Fig. 3. Changes in the sex-associated protein component with respect to experimental treatment with testosterone. One animal was used for each analysis. *A*, male castrates treated with testosterone after being castrated 84 days. Time with reference to hormone treatment; B, females treated with testosterone, *C* spayed females treated with testosterone, *D*, normal males treated with testosterone

amine. Only a trace of cystine was observed which may have come from the minor contaminants suggested by immunochemical studies. The sex-associated protein has not been observed in male rat kidney, brain or testis.

The concentration of sex-associated protein observed in the soluble phase of the normal adult male liver has a mean value of 3·2 ± 0·3 per cent. This is a lower value than obtained previously[5], the difference being the result of improved chromatographic methods.

The effect of castration in the male was followed for 89 days (Fig. 2*A*). While considerable individual variation was seen, the concentration of the protein tended to be reduced to about 1·5 per cent Changes in the concentration of sex-associated protein in males given 2 mg œstradiol dipropionate intramuscularly immediately after castration were studied at intervals for 25 days (Fig. 2*B*). Little change was seen during the first 3 days. The concentration of sex-associated protein declined abruptly between the seventh and eleventh days, giving a total change much greater than was observed with castration alone.

To examine changes in the concentration of sex-associated protein as a result of female sex hormone treatment. normal male rats were given one intramuscular injection of 2 mg of œstradiol dipropionate (Fig. 2*C*). Observations were not started until the ninth day, at which time the concentration of sex-associated protein had already dropped to 1 per cent. Three subsequent determinations confirmed the pronounced reduction.

The effect of male sex hormone on males which had been castrated for 84 days was examined after injection of 10 mg each of testosterone propionate and testosterone phenylacetate. The results are shown in Fig. 3*A*. While the results of this experiment are inconclusive, there is some evidence for protein restoration. When female rats were given the same hormone treatment, sex-associated protein appeared and gradually increased in concentration during the 32-day observation period (Fig. 3*B*). It was of interest to see if the presence of ovarian tissue was important in the production of sex-associated protein in females treated with male sex hormone. The experiment was therefore repeated on spayed females (Fig. 3*C*). The results were similar to those observed in intact females. A somewhat higher concentration of sex-associated protein was eventually attained, although the onset of the response was slower. In control experiments on spayed females given no hormones, no evidence of sex-associated protein was observed.

To see whether excess male sex hormone increased the amount of sex-associated protein, normal males were given 15 mg of testosterone phenylacetate intramuscularly. The first observations (Fig. 3*D*) were made at 15 days and the last at 35 days. The only effect observed was a slight depression in the amount of the protein.

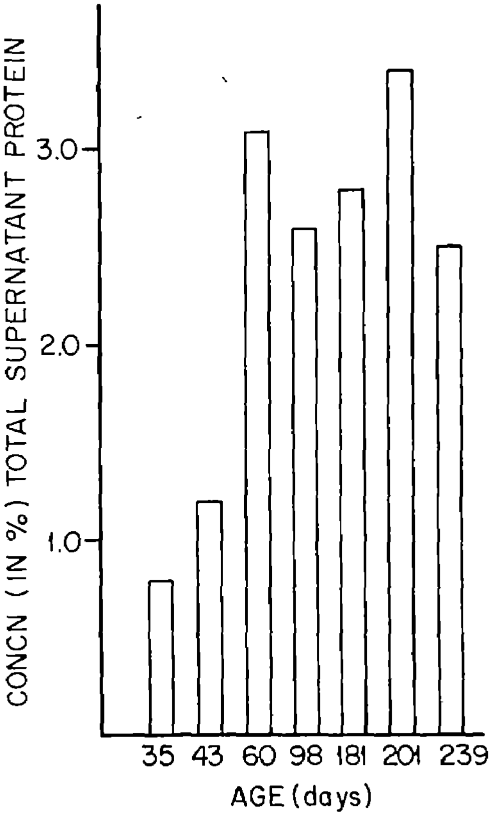

Fig. 4. Concentration of sex-associated protein component with respect to age. Pooled samples from 3–4 animals were used for each analysis at 98 days or less; one animal was used for each of the remaining analyses

The effect of age on the concentration of sex-associated protein was studied using livers of male *WR* (a sub-Wistar stock) rats. As shown in Fig. 4, animals 60 days of age and older gave similar values, whereas the composite samples tested at less than 60 days have lower concentrations. The protein is present in considerable amount at 35 days of age, however, and apparently increases rapidly in concentration between days 43 and 60.

These investigations demonstrate that the sex-associated protein of the male rat is susceptible to endocrine manipulation. The most striking instance is the female rat treated with testosterone. Here the previously absent protein appears and reaches an appreciable concentration. Results based on testosterone treatment of male and male castrates are less conclusive (but suggest that testosterone causes the production of the protein and that œstradiol has the opposite effect). Other androgens and œstrogens may be similarly effective but have not been tested.

The possibility exists that the hormones used may have exerted their effect through complex interactions with other endocrine systems. The presence of the protein in moderate concentration in the immature male rat is one such suggestion as is also the persistence of a considerable amount of the material in the castrated male. The treatment also of the long-term castrated male with testosterone appeared not to have restored the protein to levels found in the normal male. The inhibiting effect of large doses of testosterone in 2 of 3 intact males could also have involved indirect mechanisms, interactions with the pituitary gland or with the liver metabolism of adrenal hormones, for example. The pursuit of these and other interesting aspects involving the sex-associated protein are being deferred pending development of more precise and less time-consuming analytical techniques.

Evidence of a dose-dependent response of the sex-associated protein to hormone treatment has been shown in additional studies not reported here. Consequently, any attempt to obtain statistically valid results would have been complicated by the necessity of testing both the dose response and the animal variability in each group. The experiments described here were designed to show that there is a relation between male and female hormones and the existence of the sex-associated protein. The results show this unequivocally but do not explain the nature of the interactions demonstrated.

I thank Dr. Norman G. Anderson for advice.

FATAL INFECTION OF NEW-BORN HAMSTERS BY AN ADENOVIRUS OF HUMAN ORIGIN

By H. G. PEREIRA, A. C. ALLISON and JANET S. F. NIVEN

National Institute for Medical Research, Mill Hill, London, N.W.1

LACK of pathogenicity for laboratory animals is generally accepted as one of the criteria for the characterization of adenoviruses of human origin[1-3]. However, symptomless infection of rabbits by adenovirus type 5 has been described by Pereira and Kelly[4] and evidence that several adenovirus types may cause inapparent infections in guinea pigs, cotton rats, hamsters and dogs has been presented[3-6]. Furthermore, Hull *et al.*[7] showed that intracerebral inoculation of certain types of human adenovirus into monkeys may give rise to inflammation of the choroid plexus. More recently, the pathogenicity of human adenoviruses for new-born pigs has been demonstrated by Betts *et al.*[8].

In the investigation reported here adenovirus type 5 is shown to cause fatal infections when inoculated subcutaneously into new-born hamsters.

The virus inoculum used in these experiments was obtained from HeLa cells infected with the prototype strain of adenovirus type 5 and was partially purified by treatment with a fluorocarbon compound[9] as described by Pereira and Valentine[10]. This virus material contained $10^{10\cdot5}$ TCD_{50}/ml., estimated by titration in HeLa cell cultures incubated for 4 weeks.

All of 35 one-day-old hamsters inoculated subcutaneously with 0·05 ml. of undiluted virus material died within a period of 31 days. No deaths were observed during the first 3 days following inoculation. The number of deaths after this period showed a sharp rise between 4 and 10 days, involving 23 (65·7 per cent) of the 35 animals under examination. Between the 11th and the 27th days, only 4 deaths were observed, and all the remaining animals died during the following 4 days.

Inoculation of a 10^{-3} dilution of the same virus material into 11 new-born hamsters resulted in 5 deaths, the first occurring on the 9th day and the remainder between the 19th and 27th days after inoculation. The survivors showed retarded development when compared with uninoculated litter mates (Fig. 1), but were still alive 4 months after the inoculation.

No post-mortem examinations could be carried out either because of cannibalism or because the animals could not be examined shortly after death. However, 3 animals from the group inoculated with undiluted virus material and not included in the percentages given here were killed and examined for histological changes and for the virus content of various tissues.

A part of each tissue collected from these animals was homogenized, centrifuged and the supernatants titrated in HeLa cell cultures. From the results shown in Table 1 it is seen that the virus was present in all tissues examined although the titres showed

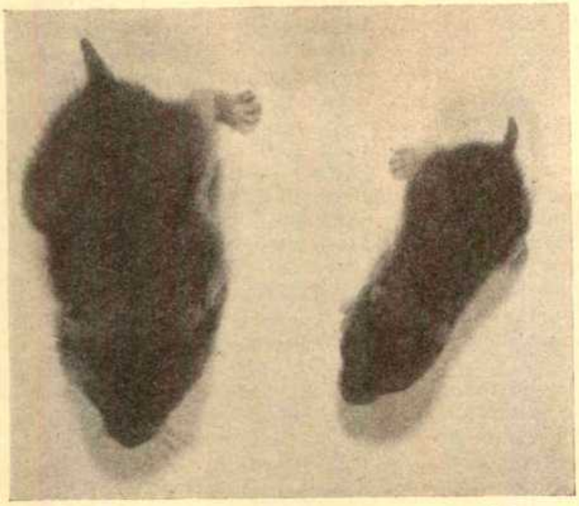

Fig. 1. 20-day-old hamsters. The animal on the right was inoculated one day after birth with 0·05 ml. of a 10^{-3} dilution of the virus material. Uninoculated litter mate on the left

considerable variation from tissue to tissue and from animal to animal.

Table 1

Hamster No.	Time (days) after inoculation	Virus content* Liver	Spleen	Kidney	Lung	Thymus
101	5	$10^{6\cdot5}$	$10^{5\cdot7}$	$10^{4\cdot3}$	$10^{5\cdot6}$	$10^{2\cdot8}$
102	6	$10^{5\cdot0}$	$10^{5\cdot6}$	$10^{2\cdot7}$	$10^{3\cdot0}$	$10^{1\cdot2}$
103	12	$10^{4\cdot6}$	$10^{3\cdot5}$	$10^{3\cdot7}$	$10^{4\cdot0}$	$10^{2\cdot3}$

* TCD_{50}/ml. of supernatant of 10 per cent tissue suspensions.

Histological examination revealed varying degrees of abnormalities, the most striking occurring in the liver tissue of hamster 101 (Fig. 2), which showed many parenchymatous cells with nuclear changes characteristic of adenovirus infection, that is, condensation of chromatin into a basophilic central mass surrounded by vesicular spaces. There were also cells with very shrunken pyknotic nuclei. However, actual necrosis of the liver was slight. Lesions seen in the remaining tissues consisted mainly of necrotic cells with pyknotic nuclei, but the extent of these alterations was extremely variable and their significance remains to be determined.

Although the present findings demonstrate the pathogenicity of adenovirus type 5 for new-born hamsters they do not allow a categorical statement to be made regarding virus multiplication in this host. The latter is, however, likely in view of the characteristic histopathological lesions correlated with the high virus content found in some of the tissues examined.

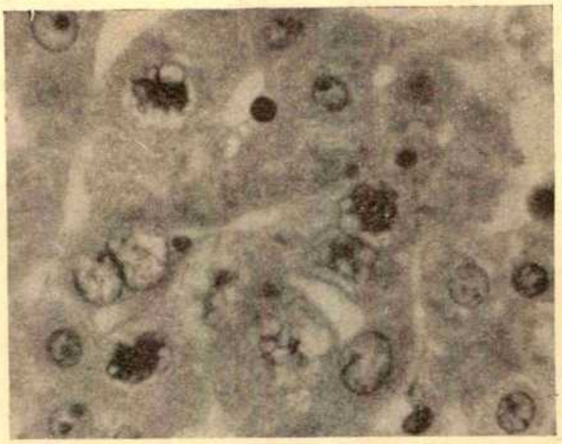

Fig. 2. Section of liver tissue from hamster 101. (Hæmatoxylin–eosin × c. 950)

The irregular results regarding the extent of lesions and virus content in different animals suggest that new-born hamsters may react in different ways to infection. This is also suggested by the apparently bimodal distribution of survival times, especially notable among the animals inoculated with the larger virus dose.

Note added in proof. Since this communication was submitted for publication it has been observed that human adenovirus types 12 (Trentin, J. J. Yabe, Y., and Taylor, C., *Science*, **137**, 835; 1962) and 18 (Huebner, R. J., personal communication) are capable of inducing malignant tumours in new-born hamsters.

PATTERN AND MECHANISM IN THE REAGGREGATION OF SPONGES

By Dr. A. S. G. CURTIS

Department of Anatomy and Embryology, University College, London

WHEN the various types of cell of an organism reaggregate from a mixture of cells they tend to sort out so that those of each tissue group together. This sorting out demonstrates a specificity which it has been usual to regard as being due to the specific adhesion of cells of like type. The concept of specific adhesion has greatly influenced theories about the nature of cell adhesion. However, as I have pointed out[1,2], since the various tissue masses in reaggregates are always positioned in definite relationships to one another the sorting out would result equally well from a mechanism which determined the general position of a given cell type in the reaggregate without the existence of any form of specific adhesion.

To enlarge on this point: it is not a sufficient explanation of the pattern of tissues found after sorting out to invoke a hypothesis of specific adhesion because, although this might sort out the cell types, it would not arrange the tissues in any given pattern. On the other hand, any mechanism controlling the position in the tissue pattern taken up by a given cell type would automatically sort out the cell types as well. For these reasons examination of the pattern found in reaggregates may be most informative about the nature of mechanisms of reaggregation. When mixtures of the cells of two species of sponges and other animals have been allowed to reaggregate, each cell type tends to form separate reaggregate bodies, as Wilson[3] first pointed out. Nevertheless de Laubenfels[4] stated that he had succeeded in obtaining interspecific mixtures of sponge cells in single reaggregate bodies, though unfortunately he gave few details of the experimental technique used. Sara[5] found that two closely related species of *Leucosolenia* do not show any sorting out in mixed reaggregates. Among vertebrates Moscona[6] has shown that mouse and chick cells do not sort out if they come from homologous organs, though mixtures of cells from two newt species do sort out[2]. In view of such exceptions, it seems that the mechanism for sorting out species is not developed universally.

In general, it has been assumed that the same type of mechanism is responsible for both the sorting out of tissue types and of different species. The experiments to be described here are directed to test whether the two types of sorting out are alike and whether specific adhesion or some other mechanism can account for sorting out and pattern formation in reaggregates. In reaggregation, phenomena other than adhesion play a considerable part. During the period when the cells are coming together they crawl over one another rather than on the surrounding substrate—a form of behaviour called 'contact promotion'[2]. Although movement is obviously related to adhesiveness it is not related in a linear manner, for extreme lack of adhesion will defeat movement owing to the resulting slip and likewise extreme adhesion will prevent movement owing to there being too much grip on the substrate for the cell to overcome. Later in reaggregation the cells become less mobile, and there is some evidence[1,2,7] that this happens at differing times for each cell type. Possibly the cells become 'contact inhibiting'[8] before they become immobile. Thus it seems that several types of cell behaviour are involved in the sorting-out process and that they involve movement as well as differences in adhesion. This argument suggests in itself that a specificity of adhesion is not a sufficient mechanism to account for the sorting out. Extensive cell movement is required for sorting out, and large differences in adhesiveness will be required to produce any marked specificity in the process. Yet these differences in adhesiveness will make some cell types less mobile so that their movement and thus the sorting out will be impeded.

For these reasons it seems that the sorting-out mechanism might depend on the control of the types of cell behaviour shown by cells. Evidence that this was so was found for the sorting-out of tissue types in amphibian reaggregates[1]. These results supported the following hypothesis: during the various stages of reaggregation the cells pass through a sequence in time of types of cell behaviour. Different cell types, which separate out in reaggregation, pass through this sequence at differing rates. There is thus a temporal specificity in the types of behaviour shown by each cell type. Any two cells which show the same types of behaviour at the same time associate together, but those which do not, become separated in the reaggregation process.

This hypothesis has been tested for sponge reaggregation by the following method, which, in addition, tests whether the species specificity and the tissue specificity are brought about by the same mechanism. Four species of sponge were used, *Halichondria panicea*, *Hymeniacidon perleve*, *Microciona sanguinea* and *Suberites* (*Ficulina*) *ficus*. Of these, *M. sanguinea* cells reaggregate most rapidly, taking about 3 h to form rounded bodies at 16°–17° C, *H. panicea* cells take about 8 h to reach the same stage at 16°–17° C and *S. ficus* and *H. perleve* cells reaggregate more slowly, taking some 15 h to reach this stage. Disaggregation was carried out by immersing fragments of the sponge bodies in 0·004 M ethylenediamine tetra-acetate (EDTA) in 0·55 M sodium chloride buffered with 0·004 M 2-amino-2-hydroxymethyl 1,3-propanediol–hydrochloric acid (*tris*-hydrochloric acid buffer), for 24 min. At the end of this period the fragments were pressed slightly and a dense suspension of cells formed. The cells were diluted with filtered (sterile) sea-water to give suspensions of 0·7–0·9 million cells per mm^3. For each reaggregate 5 ml. of this suspension was mixed with 10 ml. of sterile sea-water and the cells were then allowed to settle down on a coverslip. After 1 h the medium was replaced with more filtered sea-water. These cultures were grown for 20 h at 16°–17° C and then fixed and stained either as whole mounts or in section.

If a temporal specificity exists it would display itself by leading to the sorting out of those pairs of species which reaggregate at different rates. This in itself is little proof of the existence of such a mechanism: but if, when one of these species is started reaggregating and after an interval the cells of the second species are placed on top of it, so that they are initially 'sorted out', they become intermingled during the course of reaggregation; then this is strong evidence for the existence of a mechanism controlling sorting out by the timing of some process. In order to check intermingling, it is necessary to be able to identify the species type of cells. In live reaggregates the colour of masses of cells is a rough guide to cell type, but the degree of hæmatoxylin staining is a most satisfactory guide. By these means it is fairly easy to identify the main species type of a mass of cells. Control reaggregates of the four species each cultured alone were made. Mixed reaggregates were made from the following pairs of species: *M. sanguinea* and *Halichondria panicea*, *M. sanguinea* and *S. ficus*, *Hymeniacidon perleve* and *S. ficus*, and *Halichondria panicea* and *S. ficus*. These reaggregates were prepared with 0, 2, 4, 6, 8 and in some cases 10 h between the start of reaggregation of the first species and the start of the second, placed on top of the first.

When the reaggregate has been completed and sufficient time for any sorting out that might occur has passed (20 h) one or other of the following four types of pattern of separation of the various cell types in the mixed reaggregates can be recognized (see also Fig. 1).

(1) Complete separation of the reaggregates of each species. This was found when cells of *Microciona*, *Suberites* and *Halichondria* taken in pairs were started reaggregating simultaneously.

(2) Chain aggregates: though separation of the cells of each species occurs, reaggregates of each

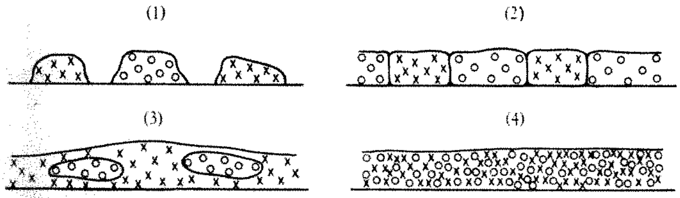

Fig. 1. The four types of reaggregate seen in idealized section. (1) Complete separation of 2 cell types; (2) chain aggregates: types separate in groups, but each group adheres to another; (3) concentric coating: one cell type invests the other; (4) intermingling. ○, Cells of one type; ×, cells of second type

species can adhere to those of another, frequently a 'segmented' chain of aggregates forms. This was produced when *Halichondria* cells were added to *Suberites* cells after the latter had reaggregated for 2 h, when *Microciona* cells were added to *Suberites* after 6 h reaggregation, when *Microciona* cells were added to *Halichondria* cells after 2 h and when *Hymeniacidon* cells were added to *Suberites* cells after the latter had reaggregated for 4 h.

(3) Concentric coating: one cell type forms a layer, coating a core of the other type. *Microciona* cells formed the coat when they were added to *Suberites* cells after the latter had reaggregated for 8 h; they also formed the coat when added to *Halichondria* cells which had been reaggregating for 4 h, and *Halichondria* cells formed the coat when added to *Suberites* cells after 4 h.

(4) Intermingling: complete or nearly complete intermingling of the cells resulted when *Hymeniacidon* and *Suberites* cells were reaggregated simultaneously, when *Microciona* cells were added to *Halichondria* cells after 8 h reaggregation, when *Halichondria* cells were added to *Suberites* after 6 h reaggregation and to a considerable degree, though some coating occurred, when *Microciona* cells were added to *Suberites* cells after 10 h reaggregation.

Those pairs of species which sort out completely if reaggregated simultaneously are those in which reaggregation proceeds at different rates. The pair of species which intermingle under such conditions are those which reaggregate at much the same rate. If the patterns of reaggregation in pairs of mixed species are considered it can be seen that there is a sequence (types 1–4), which is shown by those three pairs when the faster reaggregating species is added to the slower after successively longer intervals. With a sufficiently long interval before the addition of the fast type to the slow one both species will presumably show the same type of cell behaviour during the period when sorting out would normally occur and thus they associate together, type 4 behaviour. Thus the pattern of separation of two cell types and even its occurrence at all can be controlled by the timing of some phase of cell behaviour in the two types. The experimental results strongly suggest that if the behaviour shown by two cell types can be synchronized (at least at some crucial stage of the process) they will not sort out. With increasing desynchronization sorting out will produce varying different patterns which show greater and greater degrees of separation (coating, then segmentation, then complete separation). A further point in support of this interpretation is that the pair of species which do not normally sort out can be made to do so by delaying the addition of one species (*Hymeniacidon* and *Suberites*).

Thus a variety of 'tissue' patterns can be built up presumably by difference in the timing at which cells show certain types of behaviour. The four 'tissue' patterns found in these experiments are also widely spread in the animal kingdom, and it is probable that the same specific timing of the appearance of various different types of cell behaviour is responsible for the building of such structures during embryogenesis. It is interesting that one of the patterns is a segmental one, for Deuchar[9] has suggested that aggregation phenomena occur during the process of somite formation. It appears that a mechanism of temporal specificity operates both in tissue separation in amphibia and in species separation in sponges. There is some evidence, due to Gaze and Jacobson[10], that the regenerating optic nerve of the frog re-acquires functionally adequate central connexions by means of some sort of temporal specificity in the timing of the growth and movement of the various optic axons. If the timing of a type of cell behaviour does not coincide in two cell types they will separate out, and this may occur either with cells of different species or of different histological type. This explains why some workers have reported that the sorting-out specificity is displayed on the histological level[6] and others that it is displayed between species[3]. With several cell types of two species mixed together it might be expected that on occasion some of the cells would associate though of differing species and cell type and that others would separate out: there is some evidence that this has occurred in the *Microciona–Suberites* mixtures. The origin of the timing specificity must lie in some physico-chemical property of the cell—a possible suggestion is that the cells contain some class of grouping which reacts with a component of the medium as reaggregation proceeds; differing tissues having differing velocity constants for this reaction.

These experiments have a considerable bearing on the mechanism of cell adhesion. The specific adhesion of cells, or any other individual property of a given cell type, cannot explain these results by any but a most complex theory; for example, *Microciona* cells added after 8 h to *Suberites* coat the latter, but if they are added after the same interval to *Halichondria* cells they intermingle. Thus the sorting out or otherwise appears to be due to a mutual interaction between two cell types. In consequence it seems improbable that there is any mechanism involving the specific adhesion of members of a cell type to one another (egg and sperm may be an exception). If this is so, we can discard hypotheses of cell adhesion such as those of Steinberg[11] or Moscona[12] in which the specificity of adhesion forms the main feature of the theory. Moscona[12] has suggested that there are specific cementing substances which cause like-cell types to adhere together, formed by cell metabolism. Subsidiary experiments suggest that a specific cementing substance is probably not involved in the adhesion of *Suberites* or *Halichondria*. For if such a substance exists it would be dissolved during disaggregation. Washing away the disaggregation medium would remove the substance and if the cells were prevented from reforming it metabolically, for example, by culturing them cold, they should not reaggregate from cooled washed cell suspensions, though cooled unwashed suspensions might contain sufficient substance with which to re-adhere. However, cells of these two sponges will slowly reaggregate at 3° C even after such extensive washing that the concentration of any possible 'cement' would be reduced to 0·00001 of its original concentration.

It can be concluded that: (1) the pattern of separation of cell types or even its occurrence at all in reaggregates of mixtures of two species of sponges can be controlled by a mechanism involving the timing of certain types of behaviour in each cell type; (2) that this 'temporal specificity' can act in both the separation of reaggregating cells of different histological or different species type; (3) that a hypothesis of the 'specific adhesion' of cells does not explain the sorting-out processes in reaggregation; (4) that there is no evidence for the existence of specific materials cementing cells together in the reaggregation of these sponges.

I thank Prof. J. Z. Young for his advice, Dr. F. S. Russell, director of the Marine Biological Laboratory, Plymouth, for providing me with facilities for work in his laboratory, and Mr. G. R. Forster for arranging the collection of material and for identification of the species. This work was supported by grant *C*–04847 from the U.S. National Institutes of Health.

A MECHANISM FOR THE DISSOLUTION OF GROUND QUARTZ POWDERS IN DILUTE HYDROFLUORIC ACID: AN 'EASILY SOLUBLE CORE' AND ITS RELATION TO THE 'EASILY SOLUBLE LAYER'

By I. BERGMAN, J. CARTWRIGHT and R. A. BENTLEY

Safety in Mines Research Establishment, Ministry of Power, Sheffield 1

INVESTIGATIONS of the rate of dissolution of ground quartz powders of graded size in the respirable range (particle diameter $<5\mu$ (particle sizes are given in the form of Stokes's diameters)) in dilute alkali[1] and hydrofluoric acid[2] have confirmed that the early stages of dissolution occur at a rate of an order of magnitude greater than that for the remaining material. The material dissolved during these early stages has been termed the 'easily soluble layer'. The amount of easily soluble material present in the powders of diameter $>3\mu$ was small enough (about 0·2 per cent at 4μ) to be explained in terms of a surface monolayer solubilized by hydration. Once the easily soluble layer had been removed, the dissolution rate fell to a low and fairly constant level. With powders of smaller initial particle size, however, the amount of easily soluble material was too great (about 8 per cent at $0{\cdot}3\mu$ diameter) to be explained entirely by surface hydration, and there was no clearly defined transition between successive stages of the dissolution, for the rate of dissolution decreased gradually as the material was etched away.

The examination of these and similar quartz powders by X-ray diffraction[3] has shown an increase in the line-broadening of diffracted X-rays with decreasing initial particle diameter below 4μ; this increase runs parallel to that in the easily soluble layer. With powders of diameter $<1\mu$, the line broadening was not completely removed by etching, even when the greater part of the material had been dissolved. These powders also showed a generally higher dissolution-rate; both this and the line-broadening are believed to be due to disturbance of the crystal structure of the material by the grinding process. The disturbance appears to be intense near the surface, and decreases slowly towards the core.

On this assumption, the quartz powders can be regarded as made up of three types of material: ordered crystalline, disturbed crystalline, and hydrated quartz. The powders of particle diameter $>3\mu$ would consist of a disturbed and afterwards hydrated layer on an ordered core; those $<3\mu$ of a hydrated layer merging into a disturbed crystalline material through which the intensity of disturbance decreased gradually towards the core.

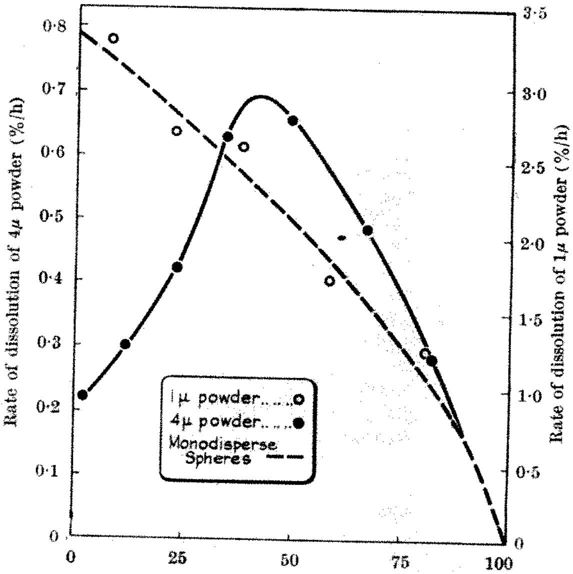

Fig. 1. Variation of dissolution-rate with amount dissolved for 1μ or 4μ powders and for monodisperse spheres (fitted to 1μ curve)

This explanation is considered in the light of further evidence from studies of dissolution in dilute hydrofluoric acid beyond the stage required to remove easily soluble material. These experiments revealed that, for a number of ground quartz powders of particle diameter $> 2\mu$ which had already lost about 5 per cent of their material, the rate of dissolution (expressed in terms of a percentage of the initial amount of material) increased gradually until it had more than doubled, as if the particles had an 'easily soluble core'. Such a dissolution-rate curve is shown for a 4μ diameter quartz powder in Fig. 1. Now, in general, the rate of dissolution should decrease gradually with the depletion of available surface area. For a homogeneous, monodisperse and isotropic powder the dissolution-rate would decrease as the 2/3 power of the volume remaining, unless the dissolution process had resulted in a significant change in the average particle shape. A dissolution-rate curve, calculated for the ideal case of monodisperse spheres, fitted to the experimental points for a 1μ diameter powder, is shown in Fig. 1; the points lie fairly close to the calculated curve. In order to facilitate comparison of the shapes of the dissolution-rate curves for the two powders and the calculated curve, the scales for the 1μ and 4μ powders have been adjusted to bring the curves together at about 90 per cent dissolved.

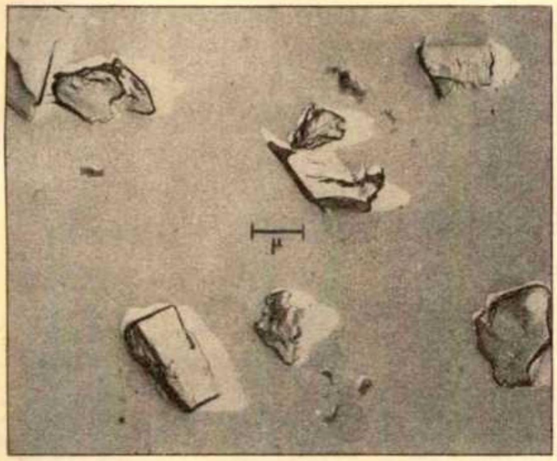

Fig. 2. 1μ diameter powder before etching

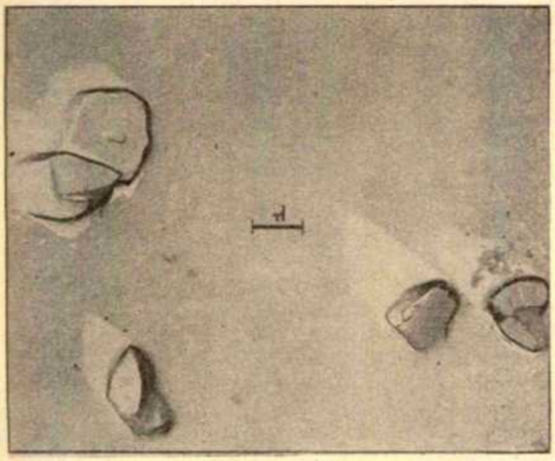

Fig. 3. 1μ diameter powder after etching

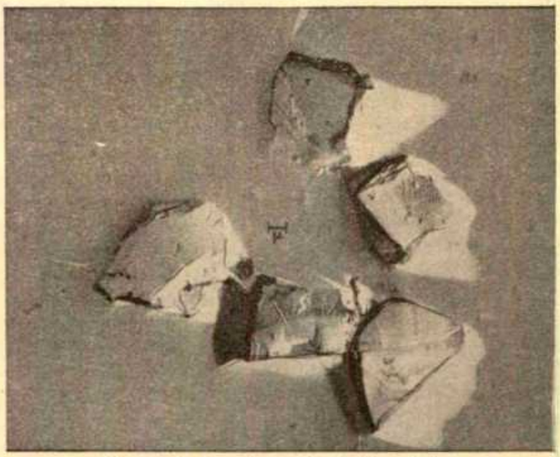

Fig. 4. 4μ diameter powder before etching

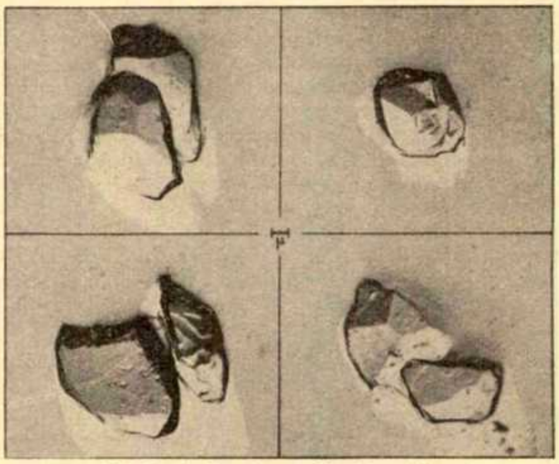

Fig. 5. 4μ diameter powder after etching

The increasing dissolution-rate of the 4μ sample up to 50 per cent lost could conceivably have been due to shape changes; but measurements of the specific surface areas of etched quartz powders by gas adsorption, and of their particle shapes by microscopy, revealed no change in shape after etching sufficient to account for such an increase. Since the increase in rate for these powders was not due to an increase in available surface, the indication was that there must be a change in the mechanism of the dissolution, or in the nature of the dissolving material, once 5 per cent had been dissolved. It was thought that either of these two effects might show up as a change in the structure of the etched surface. The fine detail of the particle surfaces is not revealed by transmission electron microscopy; a technique was therefore developed to prepare replicas of surfaces of the particles for study by electron microscopy.

The powder, in suspension in ethanol, was sprayed on to a glass microscope slide, while another slide was coated with a thin film of gelatin. The two were pressed together, partially embedding a number of particles into the gelatin. The specimen was gold palladium shadowed, and then coated with a carbon film by evaporation[4]. This film was stripped from the gelatin in hot water, and the quartz particles were dissolved in concentrated hydrofluoric acid. Figs. 2–5 show electron micrographs of replicas of quartz powders of 1μ and 4μ diameter, before and after dissolution of about 50 per cent in dilute hydrofluoric acid. The unetched powders (Figs. 2 and 4), show gently curving surfaces with fine stepped striations (characteristic of conchoidal fracture) which are occasionally observed on particles of < 2μ but more frequently seen on particles of ground quartz powders above this size. The etching process has had little effect on the particle shapes of the 1μ diameter powder (Fig. 3), but appears to have led to the development of plane faces with straight edges on the 4μ powder (Fig. 5); often three faces meet at a point, at angles to each other which appear to the eye to be consistent with the trigonal crystal structure of quartz. On such faces occasional etch pits, often triangular in outline, are observed, rather than striations. On the remaining surfaces, the irregularities are unchanged in appearance.

The mechanism of the dissolution of ground quartz powders of particle diameter > 2μ appears, therefore, to be one of preferential dissolution in directions normal to a number of crystal planes. The rates of dissolution of these faces must be similar; otherwise, particles shaped like needles or plates would be formed, and both the specific surface and the average particle shape of the powder would change in an obvious manner. The fact that fine striations characteristic of an unetched surface are still present on some parts of the particle surface even after 50 per cent has been dissolved is consistent with the idea of a much slower dissolution of surfaces not parallel to the preferred crystal planes. All the experiments so far have yielded clear evidence of the formation of these flat etch faces on > 2μ particles. The assumption that these faces are the result of etching in preferred directions seems reasonable and offers an explanation for the increased dissolution-rate associated with their formation. Once the faces were formed, their areas would tend to increase during dissolution and an increasing fraction of the particle surface would consist of preferred faces; hence there would be an increasing rate of dissolution (per unit area) until all the faces consisted of preferred planes and the remainder of the particle constituted an 'easily soluble core'. Thus the growth of etch faces might be the primary mechanism controlling the dissolution-rate of particles > 2μ.

With < 2μ particles the observed results are different and suggest a different mechanism. Etch faces do not form to any marked extent, and the rate of dissolution decreases with time as would be expected of a material dissolving by an isotropic etching mechanism. These results suggest that the disturbance of the bulk of the material, though not intense enough to increase the dissolution-rate appreciably, is sufficient to inhibit the anisotropic mechanism of dissolution, that is, to prevent the development of faces parallel to well-defined crystal planes. Thus, compared with the larger particles, those of < 2μ diameter have a slowly dissolving core.

THERMAL AND PHOTOLYTIC DECOMPOSITION OF THE LEAD AZIDES IN AIR

By Dr. G. TODD and E. PARRY

The War Office, Royal Armament Research and Development Establishment, Fort Halstead

The thermal decomposition of α-lead azide in air has already been investigated by Todd[1] using X-ray diffraction methods. It was shown that the ultimate product was lead oxide and that the decomposition proceeded through a number of intermediates none of which could be further identified at that time. The similarity between the diffraction pattern of the first emergent phase and that of basic lead azide I (several basic azides probably exist) was, however, demonstrated and the relative diffraction data are now collated in Table 1. On this basis it was suggested that the first emergent phase might prove to be a dehydrated basic azide I or oxy-azide, and recent gravimetric work[2] showing a loss in weight of 12 per cent for its formation by oxidation from normal lead azide appears to substantiate the formula $PbN_6.PbO$.

It has not yet been found possible to assign unit cell data to this oxy-azide but the second emergent phase of the decomposition series has now been identified as a tetragonal phase with parameters $a = b = 11{\cdot}3$ Å and $c = 11{\cdot}2$ Å. Pattern spacings and intensities are shown in Table 2. The second phase appears to degenerate to a crystallographically similar phase with a single resolved line at 7·7 Å.

The decomposition sequence has been studied gravimetrically by Stammler *et al.*[2], who have noted arrest-points in the weight-loss curves corresponding with formation of these intermediate phases. They have also characterized a further phase (termed phase 3) not observed in the earlier work and therefore probably occurring between the 5 and 65 h heating arrests at 240° C (Fig. 1, ref. 1). It is interesting to note that the weight-loss arrests at 15 and 15·5 per cent (Fig. 1, ref. 2), and which probably correspond with the second and third emergent phases of the X-ray work, can be explained by transitions of the type:

$$3PbN_6 \rightarrow PbN_6.2PbO.\tfrac{1}{2}H_2O \rightarrow PbN_6.2PbO$$

indicating formulæ for these phases.

Preparation and formula of basic lead azide I. Basic lead azide I may be prepared by the double decomposition of soluble azide and lead salt. Six preparations were attempted as shown in Table 3. M and 2 M solutions of salt and alkali respectively were used, volumes being adjusted to give the equivalents ratio shown. The arrow indicates order of addition.

—	2·33	—	< 10	1·52	—	1	—
2·31	2·31	5	< 10	1·50	1·50	3	< 10

Diffraction patterns of the six products are shown in Fig. 1. Preparation *BLA* 11 alone appeared to onsist of a relatively pure sample of basic azide I. *BLA* 9 and *BLA* 13 contained amounts of basic lead arbonate and α-lead azide whereas *BLA* 10, 12 and 2*A* contained varying amounts of a phase with diffraction maxima at 7·7, 3·10 and 3·15 Å. This has been prepared in another context[3] by the photo-ysis of α-lead azide and basic azide I in moist atmopheres, and does not appear to be a hydrate of lead xide, most of which we have now examined by X-ray diffraction. Its similarity to the second and hird emergent phases of the α-lead azide thermal series suggests that it may be a further basic azide of formula $\mathrm{PbN_6 . 2PbO} . n\mathrm{H_2O}$.

The empirical formula for basic azide I was obtained by dissolving a sample of *BLA* 11 in aqueous ammonium acetate and estimating lead as lead sulphate, and the azide as silver azide. The respective figures of 80·2 and 15·5 per cent compare with mean figures of 79·2 and 15·3 per cent obtained by Feitknecht and Sahli[4] for crystallographically similar preparations and an empirical formula for basic azide I of $\mathrm{PbN_6 . PbO} . n\mathrm{H_2O}$ is indicated. n is in the range 0·5–1·0.

Thermal decomposition of basic lead azide I. A sample of basic lead azide I (preparation *BLA* 11) was decomposed as in the normal lead azide experiments by heating in air at 240° C and changes studied by diffraction analysis. Certain of the diffraction maxima were observed to weaken and thereafter the phase appeared to decompose directly to the second emergent phase of the normal azide thermal series and thence through the third phase to lead oxide. No diffraction evidence for the first oxy-azide of the normal series was obtained, but the oxy-azide pattern is so similar to that of the basic azide I that small transient amounts could easily pass undetected.

Table 2. OBSERVED DIFFRACTION DATA OBTAINED WITH COBALT $K\alpha$ RADIATION FOR THE SECOND EMERGENT PHASE OF THE α-LEAD AZIDE THERMAL DECOMPOSITION SERIES

Indices of the planes have been assigned as shown on the basis of a tetragonal unit cell with axes $a = b = 11{\cdot}3$ Å and $c = 11{\cdot}2$ Å

BLA 12*A*	1 × sodium azide	→	2 × lead acetate 2 × ammon. hydroxide
BLA 13	1 × sodium azide 1 × ammon. hydroxide	→	1 × lead acetate

In this connexion, it should be noted that the reverse is also true and small amounts of basic azide I are undetectable by X-rays in the presence of large amounts of emergent phase 1. Whereas no basic

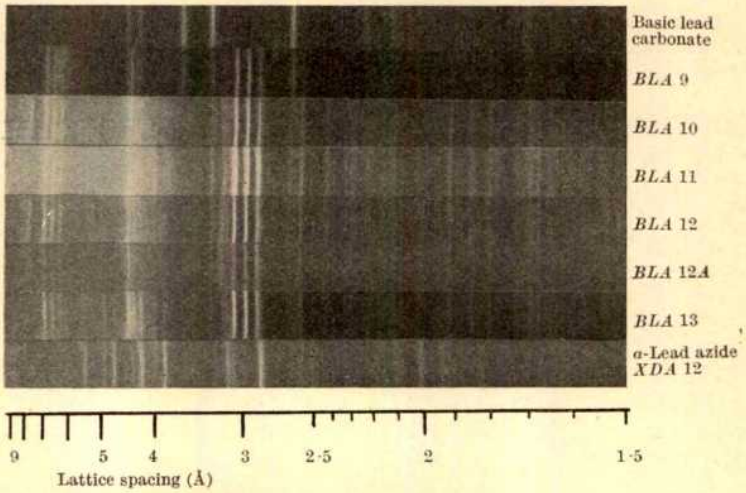

Fig. 1. Taken with a focusing camera using cobalt $K\alpha$ radiation, these diffraction results show the impurity content of basic lead azide samples. *BLA* 9 and *BLA* 13 are heavily contaminated with basic lead carbonate and normal lead azide respectively. *BLA* 10, *BLA* 12 and *BLA* 12*A* contain an unknown impurity with diffraction lines at 7·5, 3·1 and 3·15 Å. (*Crown copyright reserved*)

azide I is detected by X-rays in the thermal breakdown of α-lead azide, there is gravimetric evidence (Fig. 1, ref. 2) for an arrest at a loss of weight of 5–10 per cent corresponding with transient formation of basic azide I.

Comparison of the thermal decomposition of normal α-lead azide and basic lead azide I. In order to avoid confusion, a notation based on the sequence noted in the original paper[1] will be used. If the first, second and third emergent phases of the decomposition of α-lead azide are designated [1], [2] and [3] the three decompositions so far studied may then be stated as follows:

$$\begin{array}{llcl}
(A)\ \text{Normal } \alpha\text{-lead azide} \xrightarrow{\text{heat}} & [?] & \rightarrow & [1] \rightarrow [2] \rightarrow [3]\ \text{etc.} \\
(B) & \begin{array}{c}\text{basic}\\ \text{lead}\\ \text{azide I}\end{array} & \xrightarrow{\text{heat}} & [?] \rightarrow [2] \rightarrow [3]\ \text{etc.} \\
(C) & \begin{array}{c}\text{basic}\\ \text{lead}\\ \text{azide I}\end{array} & \xrightarrow[\text{vacuum}]{\text{heat}} & [1]
\end{array}$$

It is now evident that all sequences can be taken as interpolations of the general sequence *A* in which basic azide I can be inferred as a transient phase undetected in the presence of larger amounts of [1]. Similarly in sequence *B* transient amounts of [1], which is readily hydrolysed to [2], go undetected in the presence of large amounts of basic azide I.

In sequence *A*, on the other hand, [1] is able to accumulate because α-lead azide is a stronger 'getter' for water and frustrates the next hydrolysis stage so long as it is present in any amount.

Mechanism of the thermal and photolytic decomposition of the lead azides in moist atmospheres. Todd and Parry[3] have previously examined the photolytic decomposition in various atmospheres of α-lead azide and basic lead azide I and have shown that the process is essentially through a basic azide sequence to the azide-free product basic lead carbonate $2PbCO_3.Pb(OH)_2$. This in our experience takes the place of the fully hydrolysed and hypothetical $Pb(OH)_2$ in slow-rate reactions where basic lead is the end product.

The thermal decomposition now appears to be of essentially the same type except that oxy-compounds or oxy-hydroxy-compounds take the place of corresponding hydrates unstable at the higher temperatures.

Whatever the electronic detail, the primary process of decomposition of lead azide, both photolytic and thermal, consists of loss of electrons by adjacent ions which then interact to liberate nitrogen and create negative ion vacancies[5]:

$$\underset{\text{(azide ion)}}{2N_3'} \rightarrow \underset{\text{(gas)}}{3N_2\nearrow} + \underset{\text{(electrons—usually trapped)}}{2e}$$

Lead nuclei are formed later in the process when such gas evolutions have occurred at adjacent sites and liberated lead ions are able to collect electrons and collapse to assume the periodicity of lead.

Interface decomposition is, however, only slightly greater than elsewhere in the crystal, and lead nuclei, once formed, show little tendency to grow. The fundamental process still continues as the liberation of nitrogen gas and the creation of negative ion vacancies throughout the crystal.

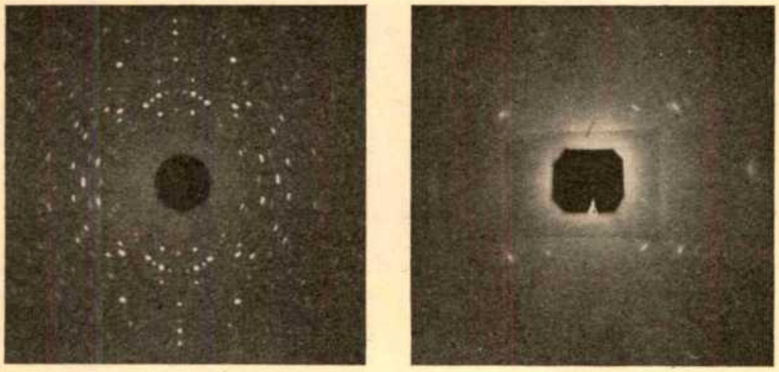
Where decomposition takes place in a vacuum or explosively so that no atmospheric components can reach and react with the decomposing lattice, the products of decomposition can only be lead and nitrogen. However, when water and carbon dioxide are present we show that this is not so, and it is now necessary to suggest a mechanism for the formation of the complex azides which are in fact observed.

Although it is doubtless in principle possible for these complex phases to form as a result of reaction of reactive lead nuclei with other residues in the decomposing crystal, there appear to be a number of arguments against this. For example, if lead azide is decomposed by heat or X-rays in both wet and dry atmospheres, the lead azide diffraction pattern disappears much faster when water is present. If the effect of water were solely to destroy lead nuclei, electron traps would be thus removed and one would expect the rate of decomposition of the lead azide to be, if anything, retarded.

It seems likely, therefore, that metallic lead is not directly involved in the formation of the basic azides, and since the chemical reactivity of *F*-centres is already well known[6] it is suggested that these are in fact the functional groups involved in the generation of basic azides. Although their existence in the thermal case can only be implied theoretically and has not been established experimentally, colour centres can be detected readily in the X-ray case where material removed from the irradiation chamber exhibits delicate colours which fade rapidly in light.

The general reaction of an *F*-centre to water is as follows:

$$e + H_2O \rightarrow OH' + H$$



Before irradiation

After irradiation

Fig. 2. X-ray Laue photographs of the *b*-axis projection of an α-lead azide crystal undergoing X-ray decomposition. Unlike the thermal case (Fig. 2, ref. 1) where the azide appears to decompose directly to a disoriented product the material here shows evidence of disoriented breakdown. (*Crown copyright reserved*)

Gas evolved when irradiated azide is exposed to water has been analysed and found to contain mostly nitrogen with little or no hydrogen. The hydrogen as released is, however, atomic and will not escape as hydrogen gas unless it can find and combine with an equivalent hydrogen atom. It is more likely to react with azide residues and to reduce these to ammonia, nitrogen and hydrazoic acid.

Such an *F*-centre mechanism would explain why both photolytic and thermal decomposition of lead azide via the basic azides, oxy- and otherwise, is so apparently dependent on water, conversion to the oxide being essentially a hydrolysis followed by dehydration. In the photolytic case no dehydration occurs and it is probable that the defect azide lattice may acquire a considerable quota of hydroxy-ion before breakdown and reorientation to the basic azide lattice occurs. Such a situation would lend itself to a measure of oriented breakdown and may account for the anomalous *b*-axis expansion of the decomposing crystal[3] together with certain features revealed by X-ray Laue studies and not found in the thermal case (Fig. 2).

We thank the Ministry of Aviation, Explosives Research and Development Establishment, Waltham Abbey, for the supply and analysis of azide samples.

IONOSPHERIC EFFECTS OF NUCLEAR EXPLOSIONS

By Prof. W. J. G. BEYNON and E. S. O. JONES

University College of Wales, Aberystwyth

In a recent communication Dieminger and Kohl[1] described some ionospheric phenomena observed at Lindau, Germany, on October 30, 1961, following a large nuclear explosion at Novaya Zemlya in the Arctic. The Lindau ionospheric recordings were made at ½-hourly intervals and, as the authors point out, this limited the determination of the precise time of the onset of the disturbance. For a large part of the day concerned recordings were made at Aberystwyth at ¼ hourly intervals, and these provide some interesting additional information on the ionospheric effects at a distance of 3,570 km from the source.

Fig. 1 shows the variation in the peak electron density of the *F*2-layer at Aberystwyth on the day of the explosion, expressed as a percentage deviation from undisturbed conditions on a group of six control days. Hourly data only are available until 10 U.T. with ¼-hourly data thereafter until 1745 U.T. It will be seen that between 09 and 10 the peak electron density of the *F*2-layer fell to some 50 per cent below normal and in the succeeding hour rose to 50 per cent above normal. Then followed two further oscillations with a period of about 1 h and with diminishing amplitude. The amplitude of the second peak (marked *b* in Fig. 1) is about 60 per cent that of the first. From about 1445 onwards the electron density remained well below average. The large initial fall in electron density was not observed at Lindau, but it seems probable that this 50 per cent decrease at Aberystwyth is significant and related to the explosion. Support for this suggestion is provided by data for certain other stations and by other data in the Aberystwyth records.

In Fig. 2 corresponding data for Dourbes (Belgium), Prague and Genoa are plotted. It will be seen that all three curves show a depression in *F*2 peak density with a minimum near 10 U.T. and the magnitude of the depression recorded at Dourbes between 09 and 10 is comparable with that observed at Aberystwyth. A decrease of electron density of this sort at temperate latitude stations is typical of a magnetically disturbed condition, but there seems to be no clear evidence for a widespread magnetic disturbance at this time. Further supporting evidence that these changes in electron density were due to the explosion is provided by an analysis which we have made of the electron density/true height ($N(h)$) profiles deduced from our ¼-hourly ionograms. In Fig. 3 the variations in the true height of reflexion of a radio wave of frequency 4·4 Mc/s (corresponding to an electron density of $2\cdot4 \times 10^5$ e/c.c.) on October 30 and 31, 1961, are shown. In this case the oscillations between 10 and

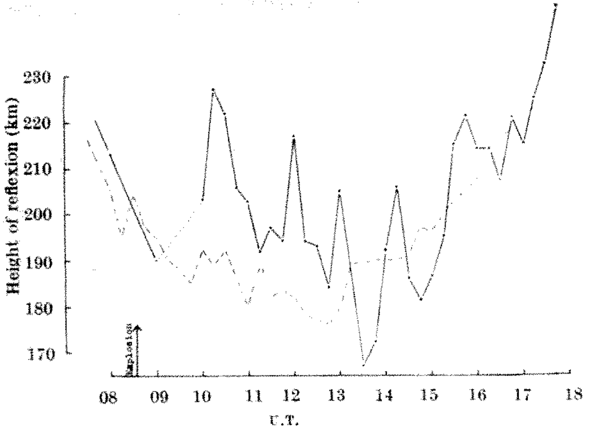

Fig. 3. Variation in true height of reflexion at 4·4 Mc/s observed at Aberystwyth. –, October 30, 1961; – – –, October 31, 1961

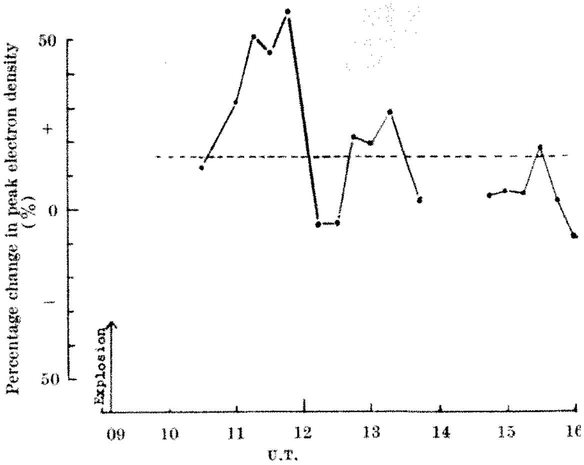

Fig. 4. Variation in peak electron density of region $F2$ observed at Aberystwyth on August 5, 1962, expressed as a percentage deviation from undisturbed conditions on five control days

16 h in the height of reflexion show up very clearly and there seems little doubt that the first peak at 1015 is a real consequence of the explosion and that the onset of the disturbance occurred at, or before, 10 U.T. It is to be noted that Dieminger and Kohl comment on the fact that in their records an unusual $F1$ stratification showed up at 10 U.T., indicating that at Lindau, too, the ionosphere at this level was being disturbed at this time.

We have examined the electron density variations at four levels in the ionosphere above Aberystwyth (220, 200, 180 and 160 km) and find that there is a progressive decrease in the magnitude of the disturbance towards lower levels. On the average, a change of 100 per cent at the 220 km-level is accompanied by changes of 70, 35 and 20 per cent at the 200, 180 and 160 km-levels respectively. This decrease in the magnitude of the disturbance at the lower, denser levels in the ionosphere is confirmed by our normal E layer observations which refer to a level of about 120 km. During the morning period the normal E-layer trace was obscured by sporadic E echoes, but the ¼-hourly measurements between 1230 and 1500 U.T. appear quite normal whereas the F layer was certainly very disturbed at this time.

The marked maximum in the $F2$ peak electron density within 2–2½ h after the explosion (marked a in Fig. 1) is a clear feature in all the data considered here and, for the Aberystwyth observations, the time-interval between this maximum and the explosion corresponds to a travelling disturbance with a mean velocity of about 410 m/sec. We find that when due consideration is given to the uncertainty in precise timing, a mean velocity of this magnitude will fit all the observations of this first maximum by the group of stations considered here. This maximum represents the onset of the first pressure maximum at this level with a time delay of about 150 min, and it is of interest to note that after a further interval of this magnitude the F layer was again very disturbed (between 1315 and 1345). We feel that this second marked disturbance some 5 h after the initial explosion may be significant since we have clear evidence for a very similar sequence of events after a recent Soviet nuclear test on August 5, 1962. Fig. 4 shows the perturbation in peak electron density of the $F2$-layer following this explosion. (The layer electron density seems to have been generally higher than normal on this day and the ordinate scale should probably be displaced upwards as indicated.) Unfortunately, we do not have records before 103 U.T. but between 1030 and 1345 there are two clea oscillations which can be ascribed to the effect of th nuclear explosion. The amplitudes are only abou one-half those observed for the October 1961 test an indicate that the energy of the explosion was considerably smaller. The explosion is reported to have take place at 0908 U.T. and the mean velocity of a disturbance which would give the first observed $F2$ maximu at Aberystwyth lies between 380 and 420 m/sec depending on whether the maximum is assumed to b at 1145 or 1130 U.T. The amplitude of the secon maximum in Fig. 4 is again about 50 or 60 per cen that of the first. The oscillations on October 30 1961, are distinctly sharper in character than thos on August 5, 1962, as might be expected from th relative magnitudes of the two explosions. It wil be noted that in Fig. 4 no values are given betwee 1345 and 1445. This gap in the data is again due t the very disturbed records at this time, which ar particularly characterized by a marked elevation i the height of the $F2$ trace. This disturbance agai occurs some 5 h after the time of the explosion and as before, has a time-delay of approximately twic that of the first pressure wave.

In the case of the large explosion of October 30 1961, we feel that the minimum in electron densit observed some 1½ h after the explosion at four widel separated stations, ranging in distance 3,300–4,25 km from the source, marks the initial onset of th disturbance in the ionosphere. In this connexio it is interesting to note that the time delay involve is just that to be expected for a rarefaction travellin at high level in the ionosphere from above the sourc with a sound-wave velocity appropriate to the mea temperature in the height-range 160–220 km. O the occasion of the test on August 5, 1962, our recordings only commenced some 1½ h after the explosio and consequently any initial minimum may hav been missed. Alternatively, it may be that thi phenomenon in the ionosphere, at large distance from the source, is only a feature of very larg nuclear explosions and it may well depend too o the height at which the explosion occurred.

We thank the International Geophysical Yea World Data Centre C, Slough, for the supply certain ionospheric data.

LETTERS TO THE EDITOR

ASTRONOMY

Tensional Stress and Lunar Patterns

Warner and Fielder[1] have referred to their conclusion that the lunar surface was under overall tensional stress at the time of cratering. I have approached the problem of the mode of origin of the lunar surface patterns from a different, purely geological point of view, but my conclusions might perhaps be relevant to the conclusions of these authors.

Geological investigations in the rift valleys of Kenya, carried out over the past decade, have led me to the conclusion that in these particular anorogenic zones the lunar patterns are more nearly duplicated than in any other terrestrial field—though the patterns are scaled down and the volcanic products associated with them are not, for the most part, comparable with those likely to have been erupted on the Moon. Firsoff[2,3] has used terrestrial patterns from Tanganyika for comparative illustrations in his penetrating studies of selenology, but, in my view, the patterns in Kenya, to the north, are both more complex and more strikingly 'lunar'. The rift valleys in Kenya seem to have originated as linear undations or volcano-tectonic upswellings, in Miocene times: in central Kenya a second and comparable undation occurred towards the end of the Pliocene. The two undations were each followed by a related recessive phase, during which collapse on normal faults occurred along the zones of undation. Each cycle of activity involved a distension accompanied by vulcanicity followed by either simple subsidence or drawing down of the surface-levels with an actively receding magma-level (as in some calderas[4]). The collapse was mainly on linear fractures, but calderas, associated with the recessive phase, show an integral relationship to the linear fracture patterns in exactly the same way that the larger lunar craters are integrated with the linear trends of the Moon.

The rift valley system as a whole forms a complex continental anorogenic zone: such zones have much in common with oceanic ridges, and indeed the rift valley system of eastern Africa goes out to sea as an oceanic ridge off Mozambique. Further, the geophysical and petrological evidence shows them to be closely related. Chenoweth[5] has recently noted the similarity between ocean floor and lunar surface patterns.

To me it seems that this is not simply coincidence. The concept is entertained that the lunar surface is essentially anorogenically moulded, and expresses volcano-tectonic undation patterns akin to the continental linear anorogenic zones and oceanic ridges. Because of the limitations imposed by the Moon's lower size and density, no atmosphere of light gas or surface hydrosphere could be held at the lunar surface, and this, it is suggested, resulted in complete inhibition of geosynclinal processes—infilling and overdeepening leading to orogenesis. Crustal depressions which were formed complementary to the undational swellings would not have been subject to sedimentation.

The vulcanicity of the Moon is reflected in essentially the same fundamental patterns as are seen in terrestrial volcanic fields; but it is in an extreme senescent stage, and must, when fully active, have possessed a quite different character to the most usual manifestations of terrestrial vulcanism. The differing physical controls operating—lower volume and density, greater curvature of the surface, lack of atmospheric pressure, hydrosphere or continental rafts, etc.—have resulted in much larger crateroid forms[6]. The products of lunar vulcanism were, in all probability, dominantly gaseous. The solid rock at the lunar surface, though almost entirely of volcanic origin, may yet show little resemblance to terrestrial lava fields. Encrustations including sublimates are likely to have predominated—material brought up to the lunar surface by the agency of gases rising up fracture conduits in exactly the same manner as volcanic gases stream up the fracture zones in senescent terrestrial volcanic fields such as the central rift valley of Kenya[7]. The resemblance of the apparently fragile linear and annular ridges of the Moon to the patterns of fumaroles and encrustation in terrestrial solfatara and mofette fields is striking. Water-soluble salts and mineral deposts will have formed permanent rocks on the Moon, and there will have been preserved a more substantial reflexion of gas activity in solid rock form than is the outcome of terrestrial fumarolic activity. Another interesting effect, consequent on the near-vacuum or complete vacuum conditions at the surface, will have been a lowering of boiling-points so that substances molten at the Earth's surface may have been volatile at equivalent temperature on the Moon. Silicate melts may never have reached the lunar surface, and if they did their nature is likely to have been that of vastly expanded filamentous pumices. The dark areas of the lunar surface (lunabase) are frequently equated with basalt, but the existence of such a basic igneous rock type at the lunar surface seems to me highly improbable. Crystallized rocks derived from silicate melts probably have no place there, and the dark areas of the maria and crater bottoms are probably covered with a late stage oozing of a material resembling obsidian: the pattern seen in lunar photographs clearly reflects a plastic response to stress, and the retention of a plastic character is typical of volcanic glasses which have retained some volatiles in solution[8]. The fact that this material seems to have oozed out in the topographic 'lows' of the lunar surface suggests some form of 'hydrostatic' restriction on its uprise.

The major eruptions of the Moon, which produced the great craters, are envisaged as having resulted from the sudden and explosive release of gas from an ascending magma, triggering being effected when the retaining pressure dropped below a critical limit. Such point-focus explosions of a truly magmatic character are evidenced in terrestrial ring complexes of the Kavirondo rift valleys of Kenya[9,10] and of Sweden[11-13]. The volatiles will have burst away from the magma and emerged at the lunar surface through fractures dominantly concentrically arranged, but associated with radial and strongly linear patterns the latter reflecting the overall lunar grid. The point focus explosions will have been deeper than on the Earth because of several physical controls operating—the lack of continental rafts or oceanic cover will in itself have facilitated bursting away of the gas at an earlier stage. A deeper focus leads to cone-fracture patterns of greater diameter at the surface. Cauldron subsidence (of a sort) is clearly reflected in many of the larger lunar craters and this is a logical successor to the positive phase of tumescence, fracturing and explosive gas release. It indicates subsidence or actual drawing down of the surface as the subjacent body of magma contracts. The main body of magma will have congealed in depth, and will not have moved upwards once the sudden bursting-out of the volatiles deprived it of fluidity, but, as already noted, a limited late-stage oozing probably ensued. This ooze may conceivably be of basic composition, but the dark colour is a poor criterion—quartz trachytes in Kenya show deep-black on air photographs where they present absolutely fresh surfaces.

The concept expressed briefly here—that of volcano-tectonic undation—has been derived primarily from terrestrial field and laboratory studies, the results of which have been compared with lunar photographs[14]. It is, of course, not an entirely original concept, and leans heavily on other workers (in particular Jeffreys[15], Spurr[16], Firsoff[2,3], Green and Poldevaart[17]). I have never observed the Moon through a telescope and have little specialized knowledge of astronomy. It is perhaps interesting that this concept, worked out from purely geological and geophysical considerations, is entirely in accord with the deduction that the lunar surface was in an overall state of tension at the time of cratering, made by Warner and Fielder[1] from an entirely different point of view—though perhaps the process is better termed distension, if, as seems likely, it involves dominantly vertical upward pressures.

To me the obvious integration of the crater patterns with the lunar grid alone makes attribution to impact unacceptable, and complex cirques such as Ptolemeus, in which the rim is composed of ridges of short length strongly reflecting the dominant grid trend, and also the annular trace of the cirque at its rim, in which the short ridges are frequently capped by summit craters and must be some form of volcanic mound and in which the floor is so little depressed, seem only explicable in terms of dominantly gas-erupting vulcanism. The existence of cirques in which the crater floor is not depressed and the distinction between floor and surround is only established by an annular line of depression (14, *B7a*, *B8a*, Janssen) again seems otherwise inexplicable.

In his comments on the morphological comparison between terrestrial and lunar surface features, Dr. McCall has made a number of interesting points. It should be noted, however, that Fielder and I only concluded that the lunar surface was tensionally stressed at the time when certain lunar craters were formed. These craters in question all appear to be 'young'. Full details of our work have now been published[1].

I have recently published work[2–4] relating to the morphology and origin of the lunar grid system. Therein it is maintained that the present alignment of ridges, rilles, crater walls, etc., has been caused by the action of stresses after many craters had been formed, that is, the lunar grid system as seen at present is the result of secondary activity[5]. In the hypothesis of magmatic explosions developing through fractures, as suggested by McCall, the shape of a lunar crater is a property of its origin. The question arises whether this latter theory can account for the differing shapes of lunar craters, and in particular the apparent correlation of percentage distortion with age noted by Fielder[6]. On the other hand, there are difficulties associated with the assumption that the crater walls and ridges were moved bodily after their formation[4].

Working from an observationalist's point of view, I have maintained[7] that the dark material composing the maria and certain crater floors is a superficial covering and should not feature in any theory of the origin of the maria and craters.

Finally, there is evidence indicating that the individual maria and craters were formed by slow processes rather than during catastrophic events[4,6].

RADIOPHYSICS

Increase in Maximum Usable Frequency for Two-hop Transatlantic Propagation due to Horizontal Gradients

It has frequently been noted that in long-distance high-frequency communication the actual maximum usable frequency (MUF) may be as much as 40 per cent greater than would be predicted from vertical soundings. One explanation for this has been given by Warren and Hogg[1], who showed, by means of an oblique incidence ionogram, that single-hop propagation could occur on a transmission path of 5,300 km, whereupon the resultant MUF exceeds that predicted by a two-hop mode calculation. A calculation by Kift[2] gives good agreement with this experimental result. The possible occurrence of layer tilts and *M* and *N* reflexions has also been advanced to account for the high MUF's obtained in practice[3,4].

An examination of the records of oblique incidence recordings, taken over a 5,600-km link between Ottawa and Den Haag, has revealed that the increase in MUF is strongly correlated with the horizontal ionization gradient. This can be seen from Figs. 1*a* and *b*, which give four typical cases for different times of the year. In making this comparison one-hop modes were rejected from the analysis. Plotted against Greenwich mean time are the critical $F2$ frequencies for vertical incidence as measured at Ottawa (O) and de Bilt (B) (about 60 km. east of Den Haag). It is apparent that, when these cross over, the measured 2-hop MUF is close to the predicted value—as based on interpolated f_0F2 values for the reflexion points. However, as the ratio of these two critical frequencies increases so does the ratio of measured to calculated MUF.

For the month of February 1961 there were 10 good recordings and every one of these has the characteristic shape of the February 26 record shown in Fig. 1*b*. The average curve for this month is shown in Fig. 2. Some 3·5 h before the cross-over point the f_0F2 value of Ottawa is half that of de Bilt. This results in a measured MUF which is 40 per cent greater than the calculated value. About four and three-quarter hours after the cross-over, the Ottawa f_0F2 is double the de Bilt value and now the measured MUF is 30 per cent greater than calculated.

These results can be explained on the basis of 'tilts' in the $F2$-layer due to the horizontal ionization gradients. In the absence of such gradients, each hop of 2,800 km would be made with rays the angle of elevation of which was about 10° and the angle of

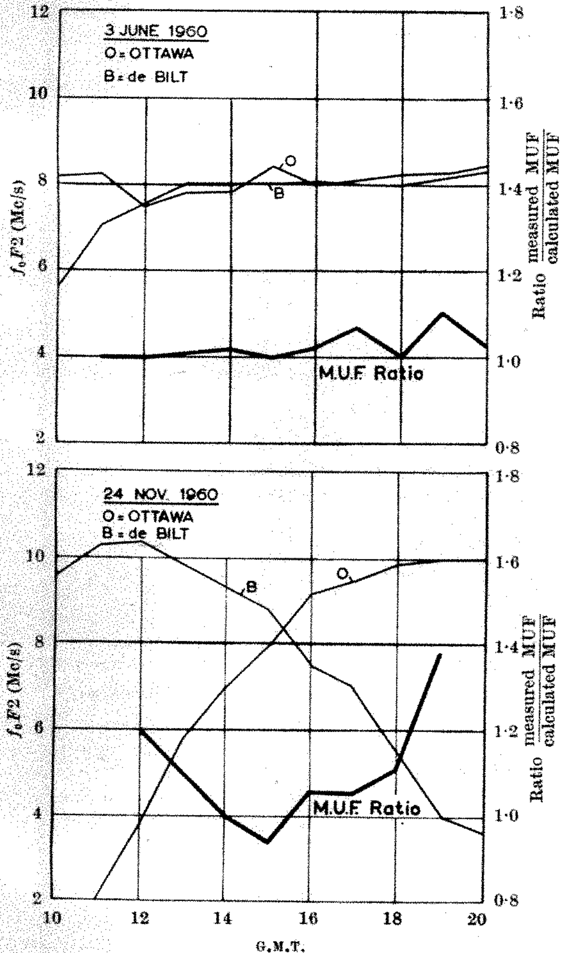

Fig. 1. *a*, Ratio of measured 2-hop MUF to calculated value based on f_0F2 records (Ottawa–Den Haag)

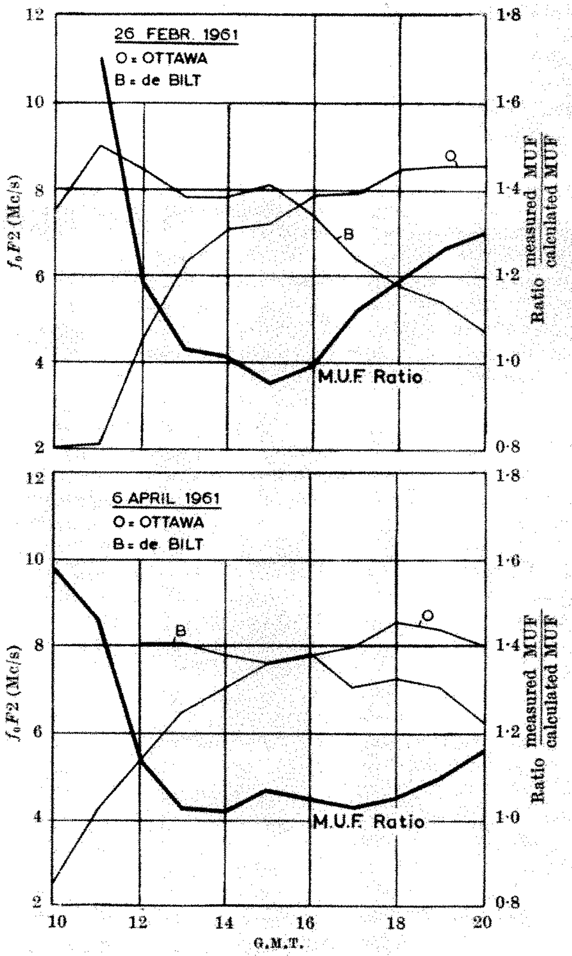

Fig. 1. *b*, Ratio of measured 2-hop MUF to calculated value based on f_0F2 records (Ottawa–Den Haag)

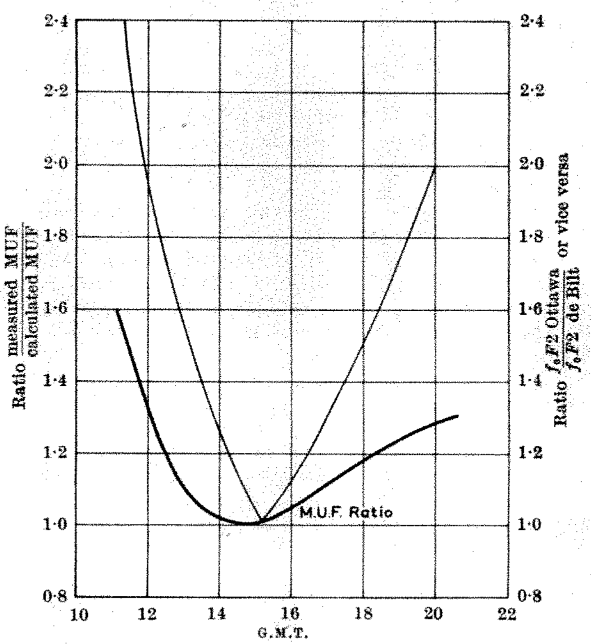

Fig. 2. Ratio of measured 2-hop MUF to calculated value based on f_0F2 records, Ottawa–Den Haag (average of 10 recordings for February 1961)

incidence of which on the ionosphere was about 70°. With a 2 : 1 ratio in the f_0F2 values at the terminals of the link there will be a gradient in the critical frequency of about 25 per cent per thousand km in the middle of the hop with the lower MUF value. Assuming a parabolic distribution of ionization in the vertical direction, this gradient is equivalent to a tilting of the layer by about 6°. Thus the angle of incidence increases by this amount, and application of the secant law shows that the MUF is increased by 23 per cent. The measured values show even greater increases in the MUF, namely, 30–40 per cent.

The foregoing simple argument ignores the fact that the reflexion point will have shifted in the direction of greater ionization and that the hop will now be asymmetrical. Because of the asymmetry the angle of incidence will be slightly reduced (though not to the extent that the angle of elevation of the steeper side is increased). The first of these effects results in an increase in the MUF, but the second will decrease the MUF. Attempts at more refined calculations have not yet proved satisfactory. However, the evidence obtained so far clearly indicates that the substantial increases in MUF found in practice on a Trans-Atlantic route are the results of horizontal gradients in the ionization of the ionosphere.

GEOPHYSICS

Spread *F* Development associated with a High-Altitude Nuclear Explosion

AT 0900 U.T. July 9, the American Atomic Energy Commission exploded a thermo-nuclear device of megaton yield some hundreds of kilometres in the atmosphere above Johnston Island (16·7° N., 169·4° W.). In order to observe any ionospheric phenomena which might be associated with the blast, the event was monitored at Sydney (34·05° S., 150·66° E.) by using a panoramic ionosonde previously described[1], providing ionograms made by a 15-sec linear scan over a frequency-range 0·5–9·5 Mc/s at the rate of 1 every min. Fig. 1 shows an ionogram taken immediately prior to the explosion, the blast occurring immediately at the end of this particular scan. Fig. 2 shows an ionogram taken 2 min later, the first ionogram following the explosion having been lost by equipment malfunction. It is apparent that *F* region frequency spreading, which before the blast covered a range of 0·2 Mc/s, had extended considerably after the event and in fact on the extraordinary ray there is evidence of spreading over a range of at least 1·5 Mc/s. At 1000 h U.T., frequency spread had decreased to 0·7 Mc/s and was still evident at 1100 h U.T.

A study of ionograms recorded on the previous day shows that spreading over a range of 0·2 Mc/s was present at 0820 h U.T. but took 70 min before increasing to cover a range of 0·6 Mc/s at 0930 U.T. Moreover, rapid-sequence ionograms taken at this laboratory and studied to observe rate of growth of spread *F* have never disclosed a rapid increase comparable with that shown in the figures.

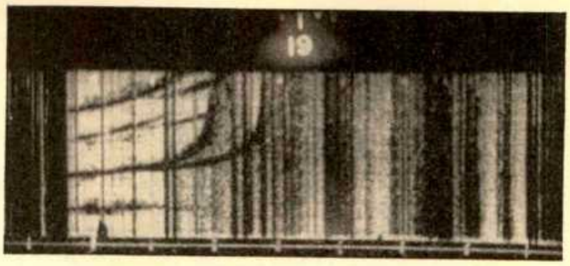

Fig. 1. Ionogram taken at Sydney at 0900 U.T., July 9, immediately prior to the H-bomb explosion

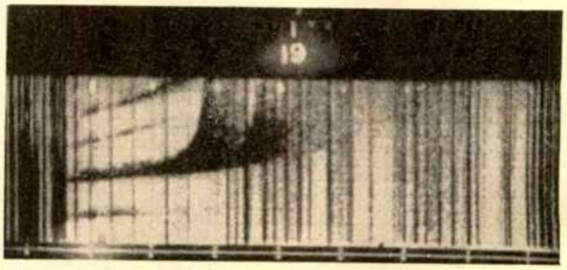

Fig. 2. Ionogram taken at Sydney at 0902 U.T., July 9, showing development of spread *F*

There is every indication, therefore, that the development of spread *F* was directly associated with the nuclear explosion. It is difficult to ascribe an explanation to the phenomenon, but undoubtedly the increased ionospheric turbulence producing the spreading must be related to some geophysical phenomena possessing a high velocity outward from the blast centre. It seems probable that the phenomenon could be associated either with variations in the Earth's magnetic field as observed by Newman[2] during the *Argus* experiments or the influx of high-energy particles into the observed ionospheric region. It is intended to monitor future explosions by means of ionograms with a more rapid sequence in an endeavour to obtain an accurate measurement of elapsed time between *H* hour and the recorded event. It is hoped that this may provide some information on the general mechanism of spread *F* formation.

A Resonance Property of the Ionosphere due to its Anisotropic Conductivity

SEVERAL years ago A. A. Ashour and V. C. A. Ferraro (private communication, 1955, and following communication) discovered that certain distributions of freely decaying currents in a non-isotropic spherical shell model of the ionosphere would rotate about the geomagnetic axis. More recently we have considered the induction of currents by an oscillating field of external origin in a similar (though not identical) model, and have found that, for frequencies greater than a certain value, the currents induced in the shell are actually greater than those which would be induced in an isotropic shell of infinite conductivity.

In seeking an explanation of this remarkable result, we have been led to examine a particular kind of resonance, which may be produced in the ionosphere by fluctuating magnetic fields of suitable distributions and periods, the periods being of the order of a few minutes. This resonance is caused by the non-isotropic nature of the conductivity and is associated with Ashour and Ferraro's rotation phenomenon.

We treat the ionosphere as a thin spherical shell (of radius a) in which the relation between electric intensity (E_θ, E_φ) and current density is given by:

$$\begin{aligned} E_\theta &= R_{\theta\theta}J_\theta + R_{\theta\varphi}J_\varphi \\ E_\varphi &= R_{\varphi\theta}J_\theta + R_{\varphi\varphi}J_\varphi \end{aligned} \qquad (1)$$

The values of $R_{\theta\theta}$ etc. (in e.m.u.) are assumed to be

$$R_{\theta\theta} = 10^7\,(\xi + \cos^2\theta),\ R_{\theta\varphi} = -R_{\varphi\theta} = 10^7\,\eta\cos\theta,\quad R_{\varphi\varphi} = 10^7\zeta \qquad (2)$$

$$\text{with } \xi = 0{\cdot}5,\ \eta = 7{\cdot}0,\ \zeta = 1{\cdot}5 \qquad (3)$$

These values give a conductivity distribution roughly the same as that produced by a dipole field in a uniformly ionized shell, when the contributions from ions as well as electrons are included. It is similar to that used by Fejer in his discussion of the effect of anisotropy on the magnetic daily variations.

We find that an oscillating magnetic field the potential of which is:

$$\Omega_0 = r^n a^{-n+1}\,P_n^m(\theta)\cos m\varphi\cos\alpha t \qquad (4)$$

gives rise to an induced field inside the shell the potential of which can be written in the form:

$$\Omega_i = r^n a^{-n+1}\,P_n^m(\theta)\,R(t)\cos\{m\varphi + \tfrac{1}{2}(\delta+\varepsilon) + \psi(t)\} \qquad (5)$$

$$\text{where } R(t) = \{\beta^2 + \gamma^2 + 2\beta\gamma\cos(2\alpha t + \varepsilon - \delta)\}^{1/2} \qquad (6)$$

$$\text{and } \psi(t) = \tan^{-1}\left\{\frac{\beta-\gamma}{\beta+\gamma}\tan(\alpha t + \tfrac{1}{2}\varepsilon - \tfrac{1}{2}\delta)\right\} \qquad (7)$$

The constants β, γ, δ, ε are algebraic functions of α, ξ, ζ, η and a.

When the actual Fejer model is used, other spherical harmonics also appear in the expression for Ω_i, but they are small compared with the P_n^m term and disappear if $\xi - \zeta = -1$. To simplify the mathematical problem we have adopted this relation in (3) above.

The expression (5) shows that the resultant field is a P_n^m field of variable magnitude rotating with variable velocity about the dipole axis. The maximum value of $R(t)$ is $\beta+\gamma$, and $\psi(t)$ is then zero. Our calculations show that $(\beta+\gamma)$ rises from zero at $\alpha = 0$ to a maximum which is greater than unity, and then tends to unity as α tends to infinity. Thus for each harmonic there is a resonance frequency which corresponds to the position of this maximum. For a uniform inducing field (P_1^1) the values of $\beta+\gamma$ and $\frac{1}{2}(\delta+\varepsilon)$ are shown in Fig. 1. In this case the maximum induced field is 2·06 times that of the inducing field and the corresponding period ($2\pi/\alpha$) is 7·7 min; the field then makes an angle −152° with the inducing field. Larger induced fields would be obtained for larger values of η.

It follows that the total field inside the shell will also rotate, and its component parallel to the inducing field of external origin will in general be of opposite phase.

The above enhancement of the induced field is associated with the rotation of decaying current systems, discovered by Ashour and Ferraro. For the particular model we have chosen, the decay of the current system corresponding to a single harmonic P_n^m is given by:

$$\Omega_i = r^n a^{-n+1}\,P_n^m(\theta)e^{-pt}\cos(m\varphi - qt) \qquad (8)$$

where

$$\begin{aligned} \lambda p &= (2n+1)\{\zeta - m^2/(n^2+n)\} \\ \lambda q &= (2n+1)\,m\eta/(n^2+n) \\ \lambda &= 4\pi 10^{-7}a \end{aligned} \qquad (9)$$

Thus the pattern of the decaying current system rotates with angular velocity q/m.

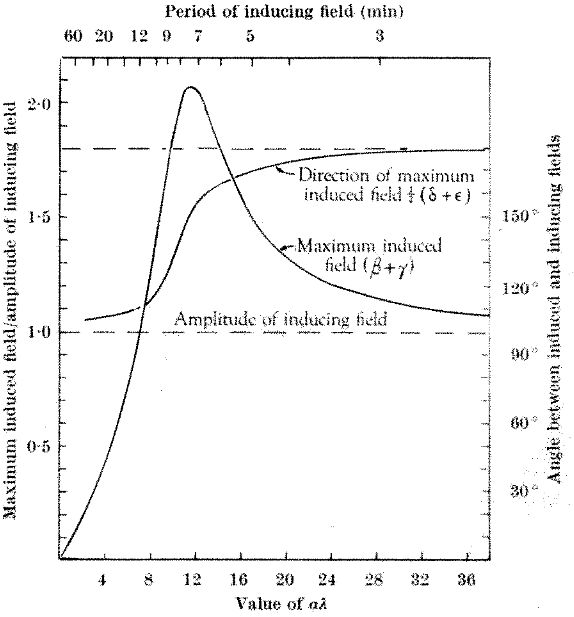

Fig. 1. Maximum induced field and its direction for a periodic uniform inducing field

Considering now a periodic inducing field P_n^m of period $T = 2\pi/\alpha$, the pattern of induced currents, brought into existence by the increase of the field during some short time-interval, will have rotated through an angle $\frac{1}{2}qT/m$ from west to east after time $\frac{1}{2}T$. At this later time the inducing field will be decreasing, so that if the current pattern has rotated through an angle π/m in the half period the induced currents now being produced will supplement those produced half a period ago, instead of subtracting from them, as would be the case if there were no rotation. Hence the total induced currents will build up until a steady state is reached depending on their rate of decay. The greatest enhancement of the induced currents would be expected when $\frac{1}{2}qT/m$ is approximately equal to π/m, that is, when $\alpha = q$. For the uniform P_1^1 field, this makes $\alpha\lambda = 10{\cdot}5$, in good agreement with the value shown by Fig. 1 for this case. The decay factor of the currents during the half period is $e^{-pT/2}$, which for this case has the value 0·41.

The foregoing suggests, and our detailed calculations confirm, that the induced field will have a relatively large amplitude when the period T is given by:

$$T = \frac{2n(n+1)\lambda\pi}{(2n+1)m\eta}$$

and the corresponding value of $e^{-pT/2}$ is not too small. Thus the resonance periods correspond roughly to the times taken by the patterns of freely decaying currents corresponding to each harmonic P_n^m to rotate through an angle $2\pi/m$.

The fact that the intensity of the induced currents is sometimes greater than the intensity of those induced in a shell of infinite conductivity may at first sight seem unacceptable; but there is no actual conflict with physical principles. Energy is absorbed by the shell from the magnetic field and, as with all systems having resonance properties, more energy is absorbed when the period is near one of the natural periods of the system.

It is clear from the above that our general conception of the ionosphere acting as a screen from magnetic fluctuations originating outside it[1] will need considerable modification. It will still shield the Earth from the most rapid fluctuations occurring outside it, but for fluctuations having periods of the order of a few minutes or tens of minutes, there may be no shielding at all, but even an amplification of the outside field. These conclusions may of course be somewhat modified when the low ionization on the night side of the Earth is taken into account. Our detailed calculations will be published elsewhere.

Induction of Electric Currents in a Uniform Anisotropic Ionosphere

THE problem of the induction of electric currents in a non-uniform ionosphere is of interest in geomagnetism. It was first studied by Ashour and Price[1] to determine the effects to be expected from the greater conductivity of the ionosphere over the sunlit hemisphere. Some time ago we considered the electric currents induced in a uniform anisotropic ionosphere (thus ignoring the difference in conductivity between the day and night hemispheres). We found that the anisotropy modifies only that part of the inducing field which is asymmetrical with respect to the geomagnetic axis, and that this asymmetrical part rotates about the geomagnetic axis from west to east at a rate depending on the Hall conductivity.

Treating the ionosphere as a spherical current sheet of radius a, and assuming that the current arises mainly from the flow of electrons, we find that the resistivity tensor is of the form:

$$K = \frac{1}{\bar{\sigma}_0}\begin{Bmatrix} 1, \beta\cos\psi \\ -\beta\cos\psi, 1 \end{Bmatrix}$$

where $\bar{\sigma}_0$ is the integrated normal conductivity of the sheet, ψ is the inclination of the local magnetic field to the geomagnetic axis, and β is the ratio of the Hall conductivity to the ordinary conductivity at the pole.

The magnetic potentials, $\Omega^{(e)}$ and $\Omega^{(i)}$, due to the external inducing field and induced currents, respectively, are solutions of Laplace's equation and the induced field is determined from the conditions that, in passing through the current sheet, the normal resolute of the magnetic field and of the tangential component of the electric field are both continuous. Denoting by (r, θ, φ) the spherical polar co-ordinates of a field point, then assuming that an external inducing field derived from a potential:

$$\Omega^{(e)} = a\Sigma E_n^m(t)\left(\frac{r}{n}\right)^n P_n^m(\cos\theta)\exp im\varphi$$

is suddenly set up outside the ionosphere, we find that the total field inside the sheet after time t is derived from the potential:

$$\Omega = \Omega^{(e)} + \Omega^{(i)} = a\Sigma E_n^m\left\{1 - \exp\left[-(p_n^m + iq_n^m)t\right]\right\}\left(\frac{r}{a}\right)^n P_n^m(\cos\theta)\exp im\varphi \qquad (1)$$

where:

$$p_n^m = \frac{(2n+1)}{4\pi a\bar{\sigma}_0} \qquad q_n^m = \frac{(2n+1)m\beta}{4\pi a(n+1)n}\frac{1}{\bar{\sigma}_0}$$

We note that $q_n^m = 0$ if $\beta = 0$ or $m = 0$; in the former case the sheet is isotropic and in the latter case the field is axially symmetric about the geomagnetic axis. In this case, the sheet clearly behaves as if it were isotropic.

The presence of q_n^m in the imaginary part of the time factor shows first that, as was to be expected on general grounds, the Hall conductivity does not affect the rate of decay of the currents and, secondly, that the asymmetric part of the induced field rotates from west to east about the geomagnetic axis. Price and Ferris (private communication) have shown that this result is also true for a more general model of the ionosphere, and that the rotation of the asymmetrical part of the field seems likely to be of importance in causing a resonance effect in the ionosphere.

As a numerical illustration of the orders of magnitude involved, we have taken the case when $n = 1$, $m = 1$ (corresponding to a uniform field), so that:

$$q_1^1 = \frac{3\beta}{8\pi a\bar{\sigma}_0}$$

Then, taking Martyn's value of the integrated conductivity $\bar{\sigma}_0$ (= 5×10^{-8} e.m.u.) and $\beta = 7$, and putting $a = 6{\cdot}5 \times 10^8$ cm (the radius of the Earth) we find that the period of rotation of the asymmetric part of the field induced by setting up of a uniform external field normal to the geomagnetic axis is about 4 min.

ENGINEERING

Permanent Insulating Duct Walls for Magnetohydrodynamic Power Generation

MOST of the reported experimental work on magnetohydrodynamic generation using hydrocarbon and other flames has been of limited duration owing to the difficulties in providing duct and electrode materials. These must withstand very high temperature (around 2,500° C), high velocity (near sonic), corrosive (a percentage or more of potassium seeding) gas conditions.

A possible method of obtaining permanent electrodes for magnetohydrodynamic power generation under these conditions has already been proposed[1], but the problem of providing electrically insulating duct walls remains. High-temperature materials such as magnesia have been tried with limited success[2]; but they can scarcely be called permanent as yet.

At the temperatures envisaged, the products of combustion contain appreciable amounts of atomic oxygen and hydrogen in equilibrium, as well as other free radicals, and are therefore highly corrosive. All

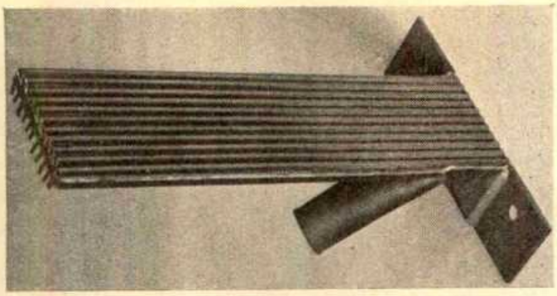

Fig. 1

known refractory materials other than the ceramic oxides (for example, graphite, silicon carbide, boron nitride, zirconium boride, tungsten) are rapidly oxidized, while the high-temperature ceramic oxides (for example, magnesia, zirconia, beryllia, thoria, hafnia) are all fluxed by the alkali metals which are present in fairly high concentrations as seeding in the combustion products. Also ceramics tend to lose their electrical insulating properties at high temperatures.

It therefore seems likely that the duct walls must be cooled, thereby producing very high heat transfer-rates, of the order of 1 MW/m². These high rates of heat loss should not prove embarrassing provided the scale is sufficiently large (of the order one thousand thermal MW), but fairly good thermal conductivity is required through the walls if adequate wall cooling is to be achieved.

The obvious materials to use are metals such as copper, nickel or stainless steel, and these have, in fact, found application in the rocket field where gas conditions are comparable; unfortunately they do not provide electrical insulation.

We have developed and tested a new type of duct wall construction which appears to overcome the difficulties mentioned here. It consists of a set of parallel metal tubes carrying cooling water (or other coolant) and insulated from each other by a thin layer of material such as sprayed alumina. The parts of the tubes facing the flame may be bare metal, and any gas penetrating to the insulating material between the tubes will presumably be cooled before reaching it. The rear faces of the tubes remain cold and can therefore be mounted in any convenient way, to provide a gas-tight seal so that hot gas does not penetrate. Our experimental section of wall consisted of ¼ in. diameter stainless steel tubes bonded with a fibre-glass reinforced epoxy resin backing, as shown in Fig. 1. The test section of wall is 30 cm × 6 cm and the total wall thickness about 1·3 cm.

This section of wall has run for about 20 min in an unseeded kerosene–oxygen flame and for a total of 3 h in a seeded flame. The seeded fuel contained about 4 per cent by weight potassium in the form of an octoate (2-ethyl-hexoate). There is no evidence of any corrosion of the wall, and the resistance between the separate tubes remains substantially unchanged.

During a run with unseeded fuel, the resistance between tubes (2·5 $k\Omega$) is substantially the same as when cold since the gas conductivity is low, but with seeded fuel the resistance drops to about 50Ω, presumably due to conduction through the gas the conductivity of which is around 30 mhos/m. In a practical generator this conduction through the boundary layer will occur even with a perfectly insulating wall, and there is no evidence that insulation between the tubes changes during a run. It therefore seems that the duct wall construction which we have investigated may provide permanent insulating duct walls for magnetohydrodynamic generators.

In conclusion, it may be remarked that an insulated tubular construction may be particularly useful when Hall effects require the electrodes to be segmented and the equipotentials to be at an angle to the direction of flow, since the tubes may be placed along the various equipotentials.

We thank the staff of D. Napier and Son, who constructed the wall, and Messrs. W. F. S. Bugden, P. G. Meier and J. A. Noé for help in carrying out the experimental work at the Central Electricity Research Laboratories. We also thank the Central Electricity Generating Board and the Manager of D. METALLURGY

Oxidation of Cupro-Nickel Alloys in Steam–Oxygen Mixtures

Wagner and Levin[1] have recently shown that metallic copper separates within the oxide scale formed on a 68/32 cupro-nickel alloy at 850° C. They considered that this was due to a reduction of cuprous oxide by nickel diffusing outward from the parent alloy. In some recent experiments, designed to investigate the oxidation characteristics of a range of cupro-nickel alloys in high-pressure steam, the authors have observed bands of copper in oxide scales formed on specimens oxidized at 275° C. It is our opinion that, at this low temperature, diffusion processes alone could not account for the isolation of such large masses of copper (Fig. 1).

The experimental conditions were chosen to stimulate the type of corrosion that occurs on cupro-nickel feed water heaters in certain generating stations of the Central Electricity Generating Board[2]. Samples of 90/10, 80/20 and 70/30 cupro-nickel alloys were heated for 1,800 h in an autoclave at 275° C containing saturated steam—800 lb./in.², with an oxygen overpressure of 250 lb./in.². Metallographic examination of the samples which had reached differing degrees of oxidation has revealed that the separation of bands of copper was initiated by the formation of a sub-scale beneath the original uniform scale. Typical micrographs illustrating sub-scale growth and copper segregation are shown in Figs. 1, 2 and 3.

It is noteworthy that the copper bands were formed in sections of scale that were directly in contact with sub-scale. It would seem, therefore, that copper is incorporated into the true oxide scale as the sub-scale is itself oxidized. The existence of a fine dispersion of copper within the sub-scale could be expected, because in a limited oxygen supply the nickel component of the alloy would be selectively oxidized owing to the higher free energy associated with the formation of nickel oxide. It is difficult, however, to understand why this dispersion should coalesce into the bands actually observed. It cannot be explained by an electrochemical reaction since the phenomenon has been reproduced under dry conditions, that is, superheated steam, at the same total pressure. Other experiments carried out in dry and wet steam at atmospheric pressure have failed to reproduce this type of oxide scale which suggests that the reaction is dependent on pressure. The authors have drawn the conclusion that under the influence of a large external pressure the copper is extruded into regions of incipient porosity. Such porous regions have been found in association with sub-scale growth on cupro-nickel alloys by earlier workers[3]. Further work is now being carried out to substantiate this hypothesis.

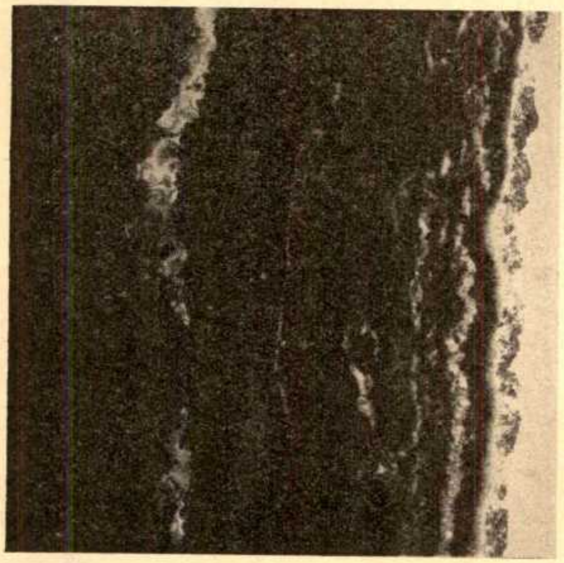

Fig. 1. Micrograph of a 70/30 cupro-nickel alloy illustrating the extent of the copper banding in the oxide scale. (× 100)

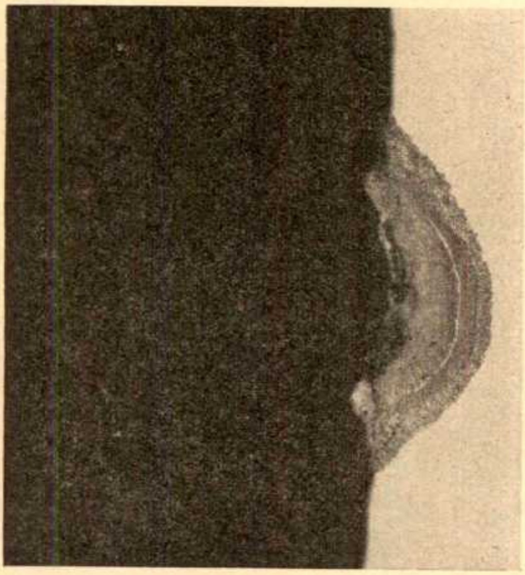

Fig. 2. Micrograph of an 80/20 cupro-nickel alloy illustrating the commencement of sub-scale formation. A thin band of copper has separated in the centre of the sub-scale. (× 150)

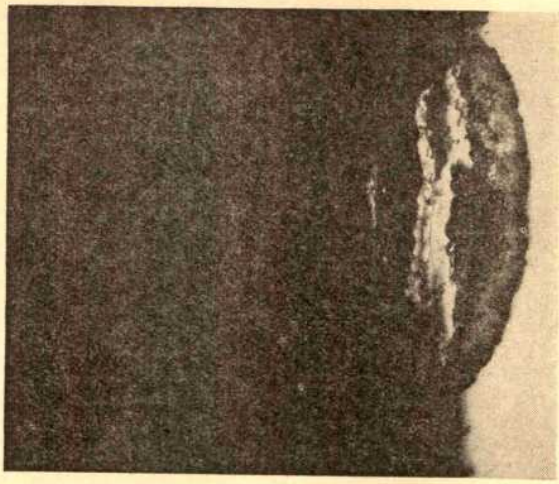

Fig. 3. Micrograph of a 70/30 cupro-nickel alloy illustrating a more advanced stage in the oxidation process than that shown in Fig. 2. The sub-scale formation and copper segregation are again apparent. (× *c.* 110)

Ternary System Copper–Zinc–Cadmium

AN isothermal section at 500° C of the ternary system copper–zinc–cadmium has been investigated. Previous work by Jenkins[1] had been carried out over a narrow range of composition, and was felt to be of doubtful value on three counts: (*a*) due to the difficulty he experienced in the metallographic identification of cadmium-rich phases; (*b*) the use of ingots from cooling curve experiments for his solid-state determination, when equilibrium had been attained only with difficulty in studies on binary alloys due to low diffusion-rates[2]; (*c*) Laves had reported the existence in the system of a ternary compound[3] which had not been described in Jenkins's studies.

In the work reported here alloys were prepared by sealing weighed amounts of the pure metals in evacuated silica tubes. The alloys were melted and then rapidly cooled to give a fine-grained structure in the alloy. The ingots were then annealed for a minimum period of 28 days (35 days for alloys close to compositions Cu_2 Cd and Cu_4 Cd_3) and water-quenched. Previous experiment had shown this time to be adequate for the attainment of equilibrium. Samples for X-ray diffraction studies were prepared from filings by annealing for 24 h to relieve strain at 500° C in evacuated sealed capsules followed by water-quenching. The average impurity content of the alloys was less than 0·05 per cent total impurities, mainly aluminium, iron and silicon.

The solid solubility of cadmium in the α-solid solution was studied by comparing the lattice parameters of binary and cadmium saturated ternary alloys. The solubility of cadmium in copper at 500° C is reported as being 2·2 weight per cent[4]. The solubility in the ternary phase was calculated on the assumption that the increase in parameter due to cadmium in copper–zinc alloys, and in pure copper, would be equal *pari passu* (Fig. 1).

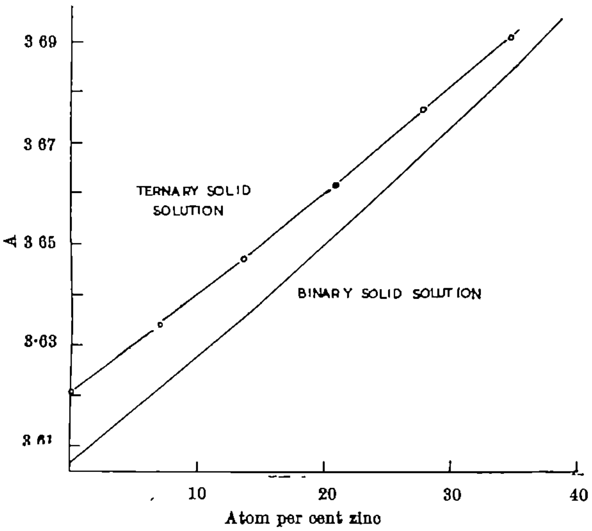

Fig. 1

The compositions of the α-solid solutions in three-phase equilibria with cadmium-bearing intermetallic compounds were determined by interpolating measured lattice parameters in the curve given in Fig. 1. Other phase boundaries were examined metallographically. The results are shown in Fig. 2.

GEOLOGY

A New Upper Old Red Sandstone Fish Locality in Scotland

With the exception of sporadic scales and plates, finds of fish remains in the Upper Old Red Sandstone of Scotland, south of the Grampians, have been limited to the abundant excavation material from Dura Den, Fife, and the more restricted productions of Bracken Bay, Clashbennie, Earlston, Jedburgh, Chirnside, etc. The discovery of two rich fish beds in the Upper Old Red Sandstone in the grounds of Duns Castle, Berwickshire, is therefore a welcome event.

The beds here consist of bright red, sometimes mottled, marls, shales and yellow or pink sandstones. The sandstone ribs have local conglomeratic bases and carry many green clay-galls. Cornstones are absent. The beds are lenticular and do not appear to exhibit the rhythmic profile seen in beds of similar age in other parts of southern Scotland[1].

The lower fish bed is some 3 in. thick and occurs at the top of a red marl. It has yielded a finely ornamented *Bothriolepis* in great abundance and may well be composed of many hundred individual fish. The plates are well articulated although somewhat flattened. The fish show a fairly consistent orientation. Areas of *Holoptychius* squamation have also been found. Unflattened plates of the same species occur in the sandstone immediately above the fish bed; but these plates are disarticulated and apparently of random orientation.

The upper fish bed occurs 20 ft. above the lower in a sandstone rib. It has yielded disarticulated plates of a coarsely ornamented bothriolepid and abundant *Holoptychius* plates and scales. The remains are disorientated and occur along with clay-galls at the base of the sandstone and are also found in the pure pink and yellow sandstone in the upper part of the rib.

It is probable that the lower fish bed has been produced *in situ* by the killing of fish in a drying pool. The remains in the sandstones may well have been washed into their present position by streams carrying the coarser sediment.

The palæontology of the fish beds with a detailed account of the locality will be published by R. S. Miles, King's College, Newcastle upon Tyne, and me. The Royal Scottish Museum thanks Colonel G. H. Hay of Duns Castle for giving access to the site. When the palæontological study is complete the Museum will be prepared to distribute excess material to interested institutions.

Dinosaur Tracks in the Lower Cenomanian of Jerusalem

As has been announced by the newspaper Press, dinosaur tracks were recently discovered in the vicinity of Jerusalem. Dinosaur foot-prints are relatively rare; at present, they are known in the world probably from no more than about thirty localities. The present discovery is the first not only in Israel but also in the whole Near and Middle East. The nearest foot-print localities are in Caucasian Georgia, the Yugoslav island of Brioni and south Tunisia. In this particular case, the dinosaur foot-prints are of Lower Cenomanian age; no more than five findings are known of this period.

The spot is situated in the village of Beit Zait, a few kilometres west of Jerusalem. It was accidentally discovered by an owner of the plot who, in order to improve his small yard, removed a thin bank of fissured limestone and thus regularly spaced marks on the rock surface were revealed. After some time, this information was passed on to me.

On an area of about 80 m^2 we can see more than 20 foot-prints in a continuous row, almost 20 m long. They belong apparently to a single individual. On both sides of this row, there are more prints, smaller and less distinct. Each of the prints in the row shows three toes, of which the middle one is 24–26 cm long, while the side toes average 20 cm in length. The angle between the toes is about 40°. The distance between the alternate footsteps is about 80 cm so that the distance between one print and another made by the same foot is around 160 cm. Evidently the animal was a bipedal reptile, with long and strong hind-feet and short fore-feet, the latter serving mainly for grasping. On the basis of these data it may be assumed that the hind legs of the reptile were approximately 120 cm high and that the length of entire body with its big tail and expanded neck was 2·5 m or more; in its normally erected posture the animal must have been about 2 m tall.

The age of the track-bearing layer is quite clearly indicated. It is situated below the Mozza marls, which present the lowest part of a fossiliferous series of Middle to Upper Cenomanian; the complex of which the dinosaur beds are part is 200–250 m thick and is underlined by marine layers of Albian age. On the whole, the Cenomanian series was considered to be of marine origin although only few beds of its lower part could be definitely indicated as such. Similarly, not many years ago, the whole upper Cretaceous series of Jerusalem region was believed to be of continuous sedimentation and of marine origin. However, it has been shown that a lacuna exists between the Upper Turonian and the Santonian–Campanian and between the Upper Cenomanian and the Upper Turonian beds[1]. The present discovery of dinosaur tracks below the base of the middle Cenomanian *Acanthoceras* beds shows for certain that at least a part of the 200–250-m thick Lower Cenomanian series is of continental origin. A microscopic examination of the track-bearing rock as well as of that immediately above it shows that both are completely devoid of any organic remnants and their texture is rather lacustrine in character.

The nearest locality which yielded bones of Lower Cenomanian dinosaur is the Baharia Oasis west to the Nile. This occurrence is stratigraphically, facially and palæontologically closely related to those of Tunisia, Algeria and Morocco, forming the upper part of the 'Continental Intercalaire'[2]. This 'Continental Intercalaire' corresponds *grosso modo* to the European Wealdian.

It seems that the foot tracks of Beit Zait belong to a theropode reptile. By the proportions of the footsteps and the calculated measures of the animal it may be hypothetically assigned to the coelurosaurian genus *Elaphrosaurus*, which is common in the deposits of the 'Continental Intercalaire'.

Three species of this genus were recognized in this formation. They are: *El. bambergi* Janensch, *El. iguidiensis* Lapparent and *El. gautieri* Lapparent. The first one seems to be, by proportions of its skeleton, the most appropriate for the Beit Zait foot tracks.

The discovery of dinosaur foot-prints in the region of Jerusalem is not only of palæontological interest; it also leads to important deductions regarding the geological history and structure of the entire area, and stresses its very close relation to the whole north African domain.

MINERALOGY

Nordstrandite in Soil from West Sarawak, Borneo

Of the three polymorphs of aluminium hydroxide—gibbsite, bayerite, and nordstrandite—only gibbsite has hitherto been known as a natural mineral, and so the discovery of well-crystallized nordstrandite in Sarawak is noteworthy. The mineral was found in red soil and was tentatively identified as gibbsite from its optical properties, but when sent to London for confirmation it was shown by X-ray examination to be nordstrandite. The following preliminary details of this discovery have resulted from field work by the Agricultural and Geological Departments in Sarawak, and laboratory studies by Miss B. B. Fox and Mr. J. A. Bain in the Mineral Resources Division, Overseas Geological Surveys, London.

The nordstrandite was found in soil at Gunong Kapor (gunong = mountain) near Bau in west Sarawak. The isolated, cliff-bounded hill is formed of limestone (kapor = lime), and the soil was collected from the edge of a large sink-hole about 350 ft. above the foot of the hill. The soil fills an irregular crevice, about 10 ft. deep, and appears to be a typical terra rossa. It resembles a dark red clay loam and contains, in the deeper parts especially, small quartz crystals and rounded pellets, some of which consist of limonite and others of nordstrandite.

The origin of the deposit is not fully understood, but it appears improbable that the soil could have been derived solely from the weathering of such pure limestone as occurs here: on the other hand, volcanic ash, which is found in some terra rossas, is unlikely to be present in substantial amounts. Wilford[1] has shown that in this region dacite intrusions and gold deposits commonly occur along the contact of the limestone with overlying shale. Sink-holes, formed in the limestone, have been filled with clay and other weathered products of the dacite, gold ore, and shale. The presence in the soil of minerals characteristic of some of the primary gold-ore deposits of the Bau district affords support for the belief that

(Assayer: F. Stacey.)

such a process has contributed to the formation of this nordstrandite-bearing soil, even though no remains of dacite or shale have yet been found.

The chemical and mineral composition of the first sample of the soil received in London is shown in Table 1. Ultrasonic dispersion in water and separation of the finer particles (nominal size < 10μ) by hydrocyclone yields a clean granular product from which the constituent minerals (except kaolinite, which is restricted to the < 10μ fraction) are readily separated and identified. The nordstrandite varies from almost colourless to coral pink and reddish-brown, the coloration being largely due to inclusions of finely divided goethite. Smaller particles are typically thick tabular crystals, from < 10μ–75μ, occasionally up to 250μ, across, which lie on the basal plane and are rhombic in plan, with angles near 60° and 120°. A perfect basal cleavage is prominent. Larger grains, up to 1 mm, are polycrystalline aggregates occasionally tubular in form. The measured specific gravity, 2·43, and optical properties, $\alpha = 1{\cdot}580$, β (calc.) $= 1{\cdot}581$, $\gamma = 1{\cdot}613$, $2V = +18°$, and $Z \wedge c \simeq 32°$, all fall within ranges reported for gibbsite. Analysis of a small sample, contaminated by included goethite and a little quartz, showed Al_2O_3 60·0, Fe_2O_3 4·35, H_2O 32·7, CaO 0·66, MgO 0·44, SiO_2 1·24, total 99·39 per cent (analyst P. J. Moore). Material of lower iron content has been obtained by magnetic separation.

X-ray powder data, obtained using a Philips 11·48-cm camera and iron radiation, are listed in Table 2, and are in close agreement with the spacings for synthetic nordstrandite grown from gels reported by previous workers[2–4]. With one exception, discrepancies occur only in weak or very weak lines, and might be due to a small amount of contaminant in the synthetic material. The exception is a line of moderate intensity at 3·18 Å reported in two of the three previous patterns but absent from our own pattern and that of Papée[3]. On the evidence of a diffractometer trace published by Lippens[4], it is not possible to dismiss this as a gibbsite line.

Of the associated minerals present in the soil, the goethite, kaolinite and manganese oxides are typical of limestone terra rossa, the quartz (in prismatic crystals), stibiconite, cinnabar and gold clearly belong to the antimony–gold mineralization of this area, but the mode of formation of the abundant nordstrandite and minor diaspore (largely euhedral) still requires elucidation. Field and laboratory investigations are continuing, and a more detailed account will be published later.

Nordstrandite from Guam

NORDSTRANDITE ($Al_2O_3{\cdot}3H_2O$), previously reported only as a synthetic product[1,2], occurs in Miocene limestone on Guam. In south Guam this limestone forms a cap several hundred feet thick, on the Mount Alifan–Mount Lamlan ridge, and overlies late Eocene and early Miocene basalt flows and volcanic conglomerates. The volcanic rocks below the limestone are deeply weathered. The nordstrandite occurs in secondary solution cavities and is concentrated mainly in the basal part of the limestone near its contact with the weathered basalt. In thin section the nordstrandite crystals are seen as flamboyant aggregates reaching lengths of as much as 0·4 mm. The optical properties of the mineral are as follows:

$\alpha = 1\ 580 \pm 0{\cdot}004$ colourless	optic sign = positive
$\beta = 1{\cdot}580 \pm 0{\cdot}004$ colourless	2 V = low
$\gamma = 1\ 596 \pm 0\ 004$ colourless	elongation = negative
$\gamma - \alpha = 0\ 016$	extinction = inclined

The hardness is about 3 and the specific gravity was determined by Edward J. Young to be 2·436.

X-ray diffractometer patterns were made of material hand-picked from the limestone and of material separated by solution of the limestone in acid. The X-ray diffraction data agree closely with those presented by Van Nordstrand *et al.*[1] and Papée *et al.*[3]. The 49 lines observed are given in Table 1.

Table 1

2·497	<1	1·8017	<1	1 4273	1		
2·480	3	1·7807	5	1·4037	1		

A chemical analysis (analyst, Sherwood, A.) of the mineral gave the following (per cent): SiO_2, 4·14; Al_2O_3, 63·97; Fe_2O_3, 0·25; H_2O^+, 29·05; H_2O^-, 1·59; Sum total, 99·00. Loss on ignition, (H_2O^-, H_2O^+), 31·92.

Because the voids containing nordstrandite appear to have formed preferentially along fissures, we believe that the deposition of the nordstrandite was a late stage in the history of the limestone, after emergence, lithification, fracturing, and subaerial solution. The nordstrandite may have precipitated from aluminous solutions leached from residual soils where these solutions migrated along the contact between the underlying basalt and the limestone. Nordstrandite would thus tend to concentrate in the basal part of the limestone near its contact with the basalt.

Infra-Red Confirmation of 6-Fold Co-ordination of Silicon in Stishovite

A SAMPLE of natural stishovite[1] (SiO_2), purified by Dr. D. J. Milton, by extensive HF digestion of Coconino sandstone, from Meteor Crater, Arizona, was studied by infra-red absorption techniques. A marked shift to lower frequencies of 400 cm^{-1} has been observed in the position of the maximum absorption peak when compared with that of the more usual tetrahedrally co-ordinated silica minerals, quartz, coesite, and fused silica.

The identity of the white powder was checked by X-ray diffraction analysis, by matching 28 of the lines on the film with those given by Stishov and Popova[2] in their 1961 paper announcing the synthesis of this high-density polymorph of silica. The line (d = 2·09 Å) was observed from our sample. Three faint lines, corresponding to the major lines of coesite, confirm the continued presence of that polymorph in the acid-leached material. Two other lines were observed.

Optical study of the natural powder (*GC* 3425) reveals that some grains are up to about 50–60μ in size. Refractive indices are close to 1·77 (fast ray) and 1·78 (slow ray). Birefringence is low (0·01) as determined from individual grains. The optical constants differ from those of Stishov and Popova for their synthetic product (N_g = 1·826 ± 0·002, N_p = 1·799 ± 0·002). Intergrown crystals with lower refractive indices appear as fine dust throughout the grains of the stishovite host, making up about 1–5 per cent of the specimen. Some isotropic material is also present with indices markedly lower than the stishovite.

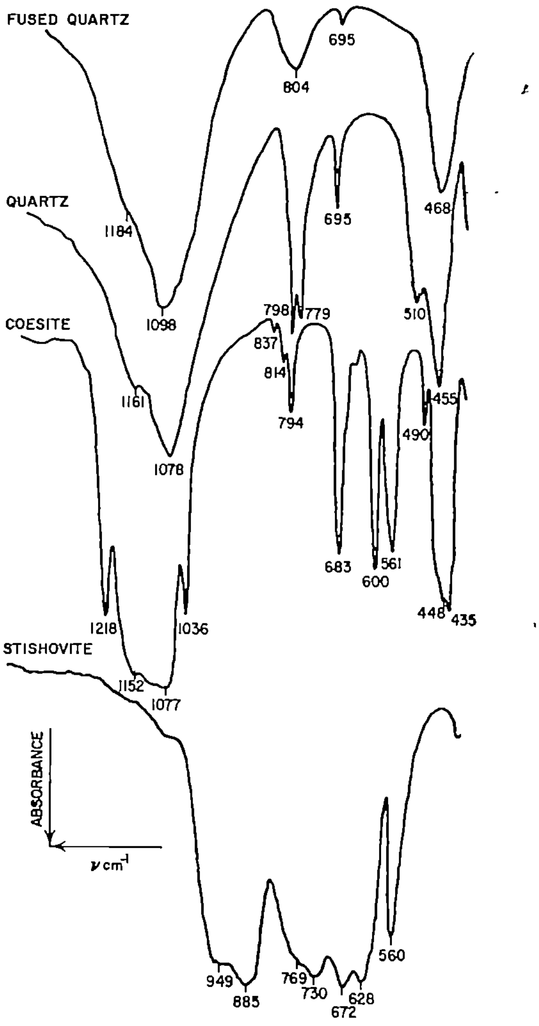

Fig. 1. Infra-red absorption curves for fused silica, quartz, coesite, and stishovite

Natural stishovite, as reported by Chao[1] *et al.* from Meteor Crater material, is in extremely fine grains mostly less than 1μ in size. The mineral has a tetragonal crystal structure, closely related to rutile. Stishovite is considered to be the first mineral discovered in which silicon occurs with oxygen in a 6-fold co-ordination (octahedral) instead of tetrahedrally co-ordinated.

Tarte and Ringwood[3] have recently directed attention to the absence of SiO_6 octahedra in silicate minerals; however, on the basis of other work in XO_4, tetrahedral and octahedral groups predicted the infra-red absorption frequencies for this octahedral configuration to be between 700 and 600 cm^{-1}. The stishovite infra-red absorption curve (Fig. 1) shows a major absorption at 769–628 cm^{-1}, effectively supporting their prediction.

The curves shown in Fig. 1 were prepared at 0·15 per cent level in potassium bromide pellets and extended over the wave-length range 4,000–400 cm^{-1}, on a

Perkin–Elmer model 221 grating-prism instrument, using both sodium chloride and potassium bromide optics. The results show a marked change in the position of the major absorption peaks when passing from the SiO_4 tetrahedral co-ordinations of quartz, coesite, and fused silica (1,098–1,077 cm^{-1}), to the SiO_6 octahedral co-ordination in stishovite (769–628 cm^{-1}; 949–885 cm^{-1}). A parallel to this has been recorded by Dachille and Roy[4] for GeO_2-quartz and GeO_2-rutile structures, which show absorption peak shifts from 870 cm^{-1} for the 'quartz' structure out to 715 cm^{-1} for the 'rutile' polymorph.

No attempt is being made in this communication to assign the various peaks in the stishovite pattern to specific Si–O bonds, particularly in view of the split maximum with the 700 and 900 cm^{-1} bands. Two slight changes in slope in the stishovite pattern around 1,070 and 1,150 cm^{-1} are probably due to the slight coesite impurity indicated on the X-ray pattern.

I thank Dr. D. J. Milton, of the U.S. Geological Survey, Menlo Park, California, for both the coesite and stishovite samples. This work was done on behalf of the National Aeronautics and Space Administration as a part of a continuing research project on the infra-red analysis of silicate minerals.

CHEMISTRY

Effect of Electric and Magnetic Fields on the Boiling Point of Alcohol

Katti and Chaudhri[1] have reported that strong electric fields depressed the boiling point of some alcohols by a much greater amount than would be expected by simple thermodynamical considerations. At 5 kV/cm they observed depressions up to 2·0° C; but, using similar electric fields and also magnetic fields, we have been unable to find any such effect.

First we examined the effect of a magnetic field by boiling methanol in a Cottrell apparatus, provided with a reflex condenser and Beckmann thermometer, and placed in a thermal bath between the pole pieces of an electromagnet; no effect was found with magnetic fields of up to 3,000 œrsteds. We then decided to repeat the measurements of Katti and Chaudhri on methanol, using this apparatus. Since they did not state the frequency of the a.c. field used, we used the following frequencies and remanent magnetic spectrographic field strengths:

Frequency (c.p.s.)	Field strength (kV/cm)
0	2·7
50	3·5
25	2·2

The field was established between two plates kept in position on the sides of the Cottrell apparatus by an external tight-fitting glass cylinder, which also acted as insulation between the plates and the thermal bath, the temperature of which was electrically controlled. On different occasions the field was applied at the thermometer bulb and at the surface of the boiling liquid. The methanol in most of the determinations was an analytic reagent with stated maximum limits of impurities: water 0·100 per cent, aldehydes and ketones 0·030 per cent, non-volatile matter 0·001 per cent.

On no occasion was any change of the boiling point due to the presence of the electric field found, although any change greater than 0·05° C would have been detected above the fluctuations of this amount, which were probably due to variations in the atmospheric pressure over the periods of up to a few hours during which readings were taken.

The results are in conflict with the previous experimental results[1], but are in agreement with the calculation of Lyon[2], who suggests that an extension of the Clausius–Clapeyron equation to include electrical energy would give an effect of less than 10^{-4} deg. C under these conditions.

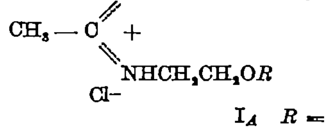
Isolation and Phosphorylation of a New Hydrolysis Product of 2-Methyl-Δ^2-Oxazoline

PORTER *et al.*[1] showed that partially neutralized aqueous solutions of 2-methyl-Δ^2-oxazoline (oxazoline) undergo transformation to yield *N*-acetylethanolamine as the final product. Two mechanisms were postulated, one involving ring opening to give first *O*-acetyl-ethanolamine, which then yielded *N*-acetylethanolamine via 2-hydroxy-2-methyloxazolidine. Based on the work of Martin *et al.*[2] with 2-methyl-Δ^2-thiazoline, a second mechanism was suggested in which oxazoline equilibrated first with 2-hydroxy-2-methyloxazolidine, which in turn is in equilibrium with both *N*- and *O*-acetylethanolamine. Martin and Parcell[3] later elaborated the mechanism derived for 2-methyl-Δ^2-thiazoline and showed that it applied to oxazoline in the *p*H range 0–6.

The decomposition of oxazoline in relatively concentrated aqueous solutions at constant *p*H-levels within the range 0–14 has been examined in these laboratories by means of nuclear magnetic resonance spectroscopy. This work has shown that the kinetic expression derived by Martin and Parcell does not apply above *p*H 6, and that a new hydrolysis product is observed between *p*H 5 and 9. If a 2·5 per cent aqueous solution of oxazoline is kept at *p*H 7 and 30° for 24 h, evaporation of the solution *in vacuo* gives an oil, the infra-red spectrum of which is unchanged after chromatography on 'Woelm IV' acid alumina. Acetylation of this oil, followed by chromatography on the same type of alumina, gave a crystalline product (m.p. 107–109°) for which analytical data indicated the molecular formula $C_{10}H_{10}O_4N_2Cl$. This substance was assigned structure I_B on the basis of nuclear magnetic resonance and infra-red data.



I_A $R = H$
I_B $R = CO.CH_3$

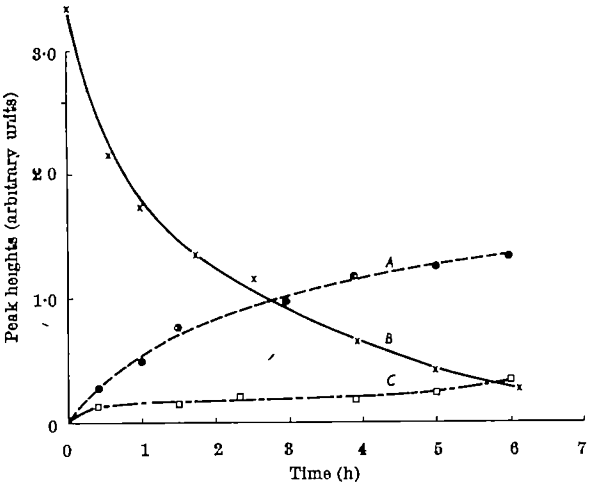


Fig. 1. Decomposition of a 2·5 per cent aqueous solution oxazoline at *p*H 7 and 30°. *A*, Peak height of the $O.CO.CH_3$ protons of *N*-2-hydroxyethyl *N'*-2'-acetoxyethylacetamidate HCL at 2·595 p.p.m up field from water, *B*, 2 × peak height of the centre band of the CH_2 triplet of oxazoline at 2 728 p.p.m.; *C*, peak height of the CH_3 protons of *O*-acetylethanolamine HCL at 2 571 p.p.m.

Comparison of infra-red spectra indicated the original oil to be the monoacetyl derivative, namely, *N*-2-hydroxyethyl-*N'*-2'-acetoxyethylacetamidate hydrochloride (I_A). The rate of formation of I_A at *p*H 7 at 30° was determined using n.m.r. spectral measurements. It is quite evident from Fig. 1 that I_A is the main product under these conditions.

Amidates are formed by the reaction of imidates with the hydrochlorides of primary or secondary amines[4]. If we consider oxazoline to be a cyclic imidate, the amine component of the reaction can be either *O*-acetylethanolamine or 2-hydroxy-2-methyloxazolidine, of which the former is favoured for this reaction. Although *N*-2-hydroxyethyl-*N'*-2-acetoxyethylacetamidate hydrochloride is relatively stable at *p*H 7 compared with oxazoline, it slowly decomposes forming *O*-acetylethanolamine, *N*-acetyl-ethanolamine, *O*,*N*-diacetylethanolamine, acetic acid and ethanolamine.

An earlier communication[5] reported the discrepancy of products obtained when oxazoline was phosphorylated with diisopropyl phosphorofluoridate (DFP) and diisopropyl phosphorochloridate (DClP). Whereas DClP reacts rapidly (1 h) to yield *N*-phosphoryl derivatives, DFP reacts slowly and after 4 days yielded two *O*-phosphoryl compounds. In a control experiment no oxazoline was detectable after 23 h and the main product was *N*-acetyl-ethanolamine. Since we have shown that oxazoline can undergo decomposition by a second mechanism the oxazoline/DFP reaction was re-examined. After 25 h, *N*-2-hydroxyethyl *N'*-2'-acetoxyethylacetamidate was isolated as its acetyl derivative in small yield, but no *O*-phosphoryl compounds were detected by paper chromatography. *N*-2-hydroxyethyl *N'*-2'-acetoxyethylacetamidate hydrochloride will react very slowly with DFP to give at the end of 4 days, 2-acetamidoethyl diisopropyl phosphate and 2-aminoethyl diisopropyl phosphate. It should be noted that under these conditions *N*-acetylethanolamine yields only 2-acetamidoethyl diisopropyl phosphate.

It has been postulated[6] that the *O*-phosphoryl derivatives of ethanolamine isolated from mixtures of oxazoline and DFP in aqueous bicarbonate solution arise from direct interaction of these two materials. However, since these derivatives cannot be detected in the reaction mixture before all the oxazoline has decomposed it would appear that an alternative explanation is required for their formation. The fact that DFP reacts with two of the hydrolytic products of oxazoline to give the observed *O*-phosphoryl derivatives offers such an explanation.

BIOPHYSICS

Action of Iodine on Strained Keratin

In earlier work on the setting of strained animal fibres in steam or boiling water it was suggested that the strained disulphide bonds of stretched fibres are more reactive than unstrained bonds[1]. Further support for this view has now been obtained in work on the action of iodine on keratin.

The relevant observations are summarized in Fig. 1, where curve 1 is the load-extension diagram of a human hair fibre in distilled water at 22·2° C. Extension was restricted to 50 per cent, and the fibre, which returned exactly to its original length on being released, was re-stretched under the same conditions as before, after a 24-h rest in distilled water. The fibre broke at about 55 per cent extension, as is usual with hair and wool, and the weakening caused by the first extension is shown by the relative positions of curves 1 and 2.

Curve 3 is the load-extension diagram of a second fibre, which was immersed in a 0·1 N solution of iodine in 0·25 M potassium iodide for 24 h at 22·2° C, before being transferred to distilled water and stretched 50 per cent while still containing the large amount of

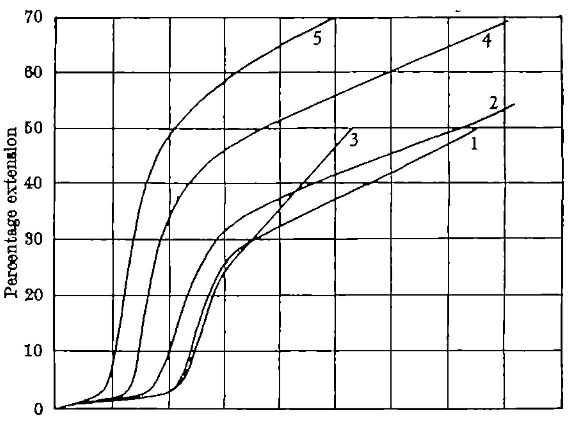

Fig. 1 (1) First fibre stretched 50 per cent in water; (2) first fibre stretched a second time in water (up to break); (3) second fibre stretched 50 per cent in water after iodination; (4) second fibre stretched a second time in water after de-iodination; (5) third fibre stretched a second time in water after iodination, stretching to 70 per cent in water, and de-iodination iodine which is absorbed[2]. Up to about 25 per cent extension, curves 1 and 3 are almost identical, but the modulus of the iodine-treated fibre at higher extensions is very much less than that of the untreated fibre. On being released, the fibre was washed over a period of 4 days in many changes of distilled water, 0·02 N sodium thiosulphate, and then water again, to remove the whole of the loosely bound iodine before being re-stretched in distilled water. Curve 4 was obtained, and it is obvious that the fibre, which broke at 69 per cent extension, is much weaker and far more extensible than if it had merely been stretched first in water (curve 2).

Even when extension is rapid, an iodine-treated fibre, unlike untreated fibres, can be stretched 70 per cent without rupture, and the weakening due to extension is then very severe. The curve for the first extension of such a fibre is not shown in Fig. 1, because it is identical with curve 3 up to 50 per cent extension, and the linear section above 30 per cent extension can be extrapolated to complete the curve. When this third fibre was freed of iodine and restretched in water curve 5 was obtained, breakage occurring at 70·5 per cent extension.

As is suggested by the similarity of curves 1 and 3 up to 25 per cent extension, both the solution of iodine in potassium iodide, and a solution of potassium iodide alone, were found to have little effect on the elastic properties of the fibres, provided that all loosely bound iodine is removed before extension occurs. It is only when the fibres are stretched in presence of the iodine that extensibility is increased and severe weakening induced.

The preceding results suggest that the bonds which oppose extension of animal fibres at extensions above 30 per cent are readily broken—but only under stress—when the fibres contain loosely bound iodine. In agreement with this deduction, paper chromatographic examination of the hydrolysate of a bundle of 100 5-cm lengths of human hair fibres, which had been stretched 65 per cent in water after being impregnated with iodine in the usual way, revealed the presence of much more cysteic acid than in the hydrolysates of similar bundles of stretched untreated fibres (50 per cent extension) and iodine-treated unstretched fibres.

Use is now being made of these observations to establish the amino-acid environment of the bonds which characterize the elastic properties of animal fibres at extensions above 25 per cent.

We thank the International Wool Secretariat and the Wool Research Organization of New Zealand for grants in aid of this investigation.

Denaturation of Deoxyribonucleic Acid of *Escherichia coli* by X-Irradiation *in vitro*

Deoxyribonucleic acid as a genetic material occupies a key position in the normal and abnormal behaviour of cells. The effect of ionizing radiation on DNA, both inside and outside the cell, is of importance for analysis of the effect of radiation on cells. Nucleic acids have absorption maxima in the range 257–261 mμ and the effect of denaturation induced by radiation would be to increase the value of the extinction coefficient in this wave-length region[1].

This communication is concerned with the effect of *in vitro* irradiation of DNA from *E. coli*, as examined from the ultra-violet absorption of irradiated and non-irradiated samples. DNA containing less than 2 per cent protein and 3 per cent RNA was extracted from stationary phase *E. coli* of 18–20 hr. growth by Marmur's method[2], and this was finally dissolved in 0·002 *M* sodium chloride solution. The concentration of the extracted DNA solution as determined by the diphenylamine reaction[3] was about 300 μgm./c.c. The stock solution was then divided into several parts, some of which were given different doses of X-rays and one was kept as control. Irradiation by 70-kV X-rays was carried out at a concentration of DNA of about 50 μgm./c.c. The dose-rate, as determined with the help of a ferrous sulphate dosimeter, was 1 krad/min.

For ultra-violet investigations both the control and irradiated solution were diluted to the same extent with 0·002 *M* sodium chloride. Ultra-violet absorption in the range 220–300 mμ was determined with a Zeiss *PMQ* II spectrophotometer (Fig. 1).

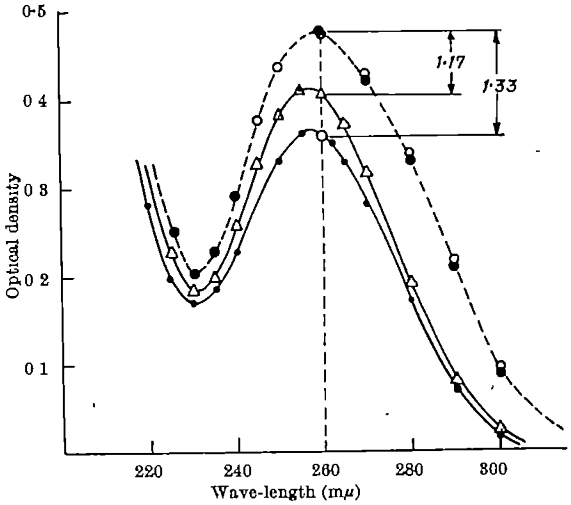

Fig. 1. Absorption spectrum of *E. coli* DNA. •, Control non-irradiated; Δ, irradiated DNA dose 9 krads, ●, control at *p*H 3·0. ○, irradiated at *p*H 3·0

Radiation-induced denaturation was estimated by the method of Fredericq *et al.*[4]. If ε_{RC} and ε_{OC} denote the extinction coefficients at 260 mμ of the irradiated and non-irradiated control DNA, then:

$$\varepsilon_{RC} = x\,\varepsilon_{OC} \tag{1}$$

where $x \geqslant 1$ is the denaturation factor from equation (1):

$$x = \frac{\varepsilon_{RC}}{\varepsilon_{OC}} = \frac{\varepsilon_{OA}}{\varepsilon_{OC}} \Big/ \frac{\varepsilon_{RA}}{\varepsilon_{RC}} = \frac{R_1}{R_2} \tag{2}$$

where ε_{OA} and ε_{RA} are the extinction coefficients of control and radiated DNA after complete denaturation by acid treatment at $p\text{H} = 3·0$ and $\varepsilon_{OA} = \varepsilon_{RA}$.

Typical ultra-violet absorption curves of non-irradiated, irradiated and acid denatured DNA solutions (correcting for dilution caused by addition of acid) are shown in Fig. 1. The value of R_1 for the non-irradiated DNA was 1·33 from 6 independent determinations. The value of R_2 decreased with increasing dose of irradiation. The denaturation factor x at various doses as calculated from equation (2) are shown in Fig. 2. It may be seen that the

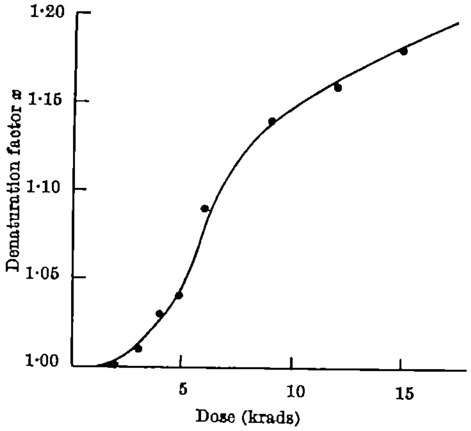

Fig. 2. Variation of denaturation factor with X-ray dose

denaturation factor increased rapidly with dose and reached a value of 1·18 at 15 krads. This was about 54·5 per cent of the maximum possible denaturation observed with acid denatured control.

The experiments recorded here indicate that there is a progressive increase in the disruption of hydrogen bonds as determined from the increase in the extinction coefficient with increasing radiation doses. This result is in good agreement with the conclusions by other workers from the electrometric titration and other studies[5,6].

I thank Prof. N. N. Das Gupta and Mr. S. B. Bhattacharjee for useful discussions and the Ministry of Scientific Research and Cultural Affairs, Government of India, for the award of a research training scholarship.

BIOCHEMISTRY

Co-ordination Compounds as Resolving Agents

IN the normal chemical resolution of amino-acids using organic bases, one optical antipode—corresponding to the less-soluble diastereoisomeric salt—can generally be obtained optically pure. The more soluble derivative remaining in the mother liquor is contaminated with a small amount of the less-soluble salt and is therefore always very difficult to obtain pure. The usual device of using both forms of the optically active base in turn is not feasible as only the natural occurring antipodes of the alkaloid bases (quinine, brucine, cinchonine, strychnine, etc.) are readily available.

We have now found that metal complex cations can be used successfully for the resolution of amino-acid derivatives. Particularly useful were the *cis*-dinitro-*bis*(ethylenediamine) cobalt(III) ion [I] and oxalato-*bis*(ethylenediamine) cobalt(III) ion [II], which wer prepared from readily available starting material and resolved to give both enantiomorphs[1]. To a aqueous solution of the sodium salt of racemic benzoy alanine[2] was added an aqueous solution of *d*-oxalat *bis*(ethylenediamine) cobalt(III) acetate [II], and th resulting diastereoisomeric salt *l*-benzoylalanine-*d* oxalato*bis*-(ethylenediamine) cobalt(III) [III], whic precipitated almost quantitatively from the solution was removed by filtration. After recrystallizatio from water, recovery of pure *l*-benzoylalanine wa effected by slurrying [III] in water and addin potassium iodide, which precipitated the insolubl iodide of [II]. The filtrate on acidification yielde optically pure *l*-benzoylalanine. The specific rotatio $[\alpha]_D$ was − 35° (0·125 g in 1 N sodium hydroxide 2 diam. tube). From the solution containing th more soluble diastereoisomeric salt, partly resolve *d*-benzoylalanine was isolated which on treatmen with the *l* antipode of [II] yielded optically pur *d*-benzoylalanine of specific rotation + 35°.

Hydrolysis of *d* and *l* benzoylalanine was effecte by refluxing in 6 N hydrochloric acid[3]. The pur amino-acids had a specific rotation $[\alpha]_D = \pm 15$ (1·5 per cent in 6 N hydrochloric acid).

The L-alanine $[\alpha]_D = + 15°$ (assayed biochemically with D-amino oxidase)[4] contained less than one part in 500 of the D antipode.

In an analogous manner phthalyl, tosyl, formyl and benzoyl derivatives of the following α amino-acids have been resolved: valine, serine, phenylalanine, leucine, isoleucine, norleucine, methionine, proline, cystine, tryptophan, aspartic acid, glutamic acid, glutamine, ornithine and tyrosine.

We thank A. H. Ennor and H. Rosenberg for biochemical assays.

Phospholipase Activity of Staphylococcal Toxin

IN view of an earlier finding that phospholipase *A* had an antagonistic effect on staphylococcal toxin in mice[1], and a later observation that staphylococcal antitoxin gave some protection in mice against phospholipase *A* (ref. 2), the possible phospholipase activity in staphylococcal toxins was investigated.

As a first approach, a batch of staphylococcal toxin derived from an αβ strain, *B.S.M.24*, of *Staphylococcus pyogenes* isolated from a case of bovine mastitis was examined as well as fractions obtained by curtain electrophoresis of the crude toxin. In this communication the action of this toxin on phosphatidyl inositol and lysophosphatidyl inositol will be described in some detail, and evidence for other phospholipase activity of staphylococcal toxins will also be reported.

A commercial preparation of soya bean phospholipids was used as substrate. This was found by paper chromatography and phosphorus analysis[3] to have the following percentage composition: phosphatidyl ethanolamine 22, phosphatidyl choline 28, phosphatidyl inositol 20, lysophosphatidyl inositol 3. Phosphorus compounds other than known phospholipids accounted for the difference between this composition and 100 per cent. The major components were identified by the standard staining procedures[4-6]. The zone migrating with R_F 0·23 was identified as lysophosphatidyl inositol in the following manner. When phospholipase *A* reacted with the soya bean phospholipids and the products were examined by paper chromatography, lysophosphatidyl ethanolamine and lysophosphatidyl choline were identified, a reduction of phosphatidyl inositol and an increase in the component with R_F of 0·23 occurred. In addition, when the area of paper occupied by the latter component was removed and placed on a blood agar plate, lysis of the blood occurred in the area beneath the paper.

The reaction between the toxin and phospholipids was studied in the following manner. Soya bean phospholipid emulsion in water (0·4 per cent) was incubated with both crude toxin and electrophoretic fractions at an optimum *p*H of 4·6 at 37° for times up to 20 h. Aliquots were freeze dried, the products were extracted with chloroform/methanol, 2:1 (v/v), and examined by paper chromatography as previously described. Reduction of the phosphatidyl inositol and lysophosphatidyl inositol spots was observed.

To identify the reaction products, aliquots of the reaction mixture were dialysed in a rubber membrane[7]. Using the method of Stern and Shapiro[8], an increase in the concentration of ester groups in the dialysate of the toxin-treated substrate was found, compared with that of the control.

Other aliquots of the reaction mixture were precipitated with trichloroacetic acid. A portion of the filtrate was extracted with diethyl ether to remove trichloroacetic acid and when examined by paper electrophoresis[9] showed a phosphorus staining[10] zone which moved in the region of an inositol phosphate control. Other portions of the trichloroacetic acid filtrate were analysed for phosphorus by the method of Brown[11]. The release of trichloroacetic acid soluble phosphorus was inhibited by commercial staphylococcal antitoxin. No significant inhibition was obtained by concentrated normal horse serum.

The relationship between water-soluble phosphorus and reaction time followed a typical enzyme reaction curve. These results suggest the following reaction:

$$\text{phosphatidyl inositol} + H_2O \xrightarrow{\textit{enzyme}} \text{diglyceride} + \text{inositol phosphate}$$

A similar enzyme occurs in guinea pig brain[12] and rat liver[13].

Preparations of rabbit red cell stroma[14] and striated muscle of the rat were similarly treated with the electrophoretic fractions of the toxin and action on phosphatidyl inositol was again demonstrated.

Evidence was obtained, however, that the phospholipase of this toxin was not directly responsible for the lethal effect in mice or the hæmolysis of rabbit red cells.

In addition, there was evidence that action on lysophosphatidyl choline was produced by another batch of crude toxin derived from the same strain, *B.S.M.*24. With toxin from strain *C.N.*56 (identical with the Wood strain) phospholipase *A*-like action, namely, conversion of phosphatidyl choline to lysophosphatidyl choline, was demonstrated. Surprisingly, there was no evidence of the action of this toxin on other substrates susceptible to phospholipase *A*. The conditions which determine these activities are to be investigated more fully. Further work on the various phospholipases released by staphylococci in relation to the pathogenicity of the strain appears to be necessary.

Urinary Excretion of Urocanic Acid and Formimino-glutamic Acid

THE major pathway of histidine breakdown is to glutamic acid, and this occurs via two relatively stable intermediate compounds, urocanic acid and formimino-glutamic acid. A competent folic-acid coenzyme is required to accept the formimino-group in the last stage of this pathway. When there is impaired, folic-acid function formimino-glutamic acid accumulates and is excreted in the urine. This has been widely used as a test of folic-acid deficiency in man[1], the urinary excretion of formimino-glutamic acid being measured after an oral dose of 15 g of histidine hydrochloride. The urinary excretion of formimino-glutamic acid after oral doses of histidine may be accompanied by the excretion of urocanic acid[2]. The purpose of this communication is to direct attention to the importance of urocanic acid in the urine of patients with megaloblastic anæmia and other disease states following oral doses of 15 g of histidine hydrochloride.

A total of 186 urine samples were examined. These were obtained from 11 normal subjects, 27 patients with megaloblastic anæmia (pernicious anæmia 10, post-gastrectomy 2, Crohn's disease 1, pregnancy 3, idiopathic steatorrhœa 6, nutritional 1, hereditary spherocytosis 1, carcinoma 2, associated with disseminated lupus erythematosis 1) and 18 patients with miscellaneous disorders associated with normoblastic hæmopoiesis (hereditary spherocytosis 2, hypochromic anæmia 6, chloramphenicol aplasia 2, carcinoma 2, acute leukæmia 3, chronic myelofibrosis 2, osseous tuberculosis 1). In the patients' serial urine samples were examined before and after treatment with B_{12} and/or folic acid.

The urine passed in the 8 h following an oral dose of 15 g of histidine hydrochloride was collected into a

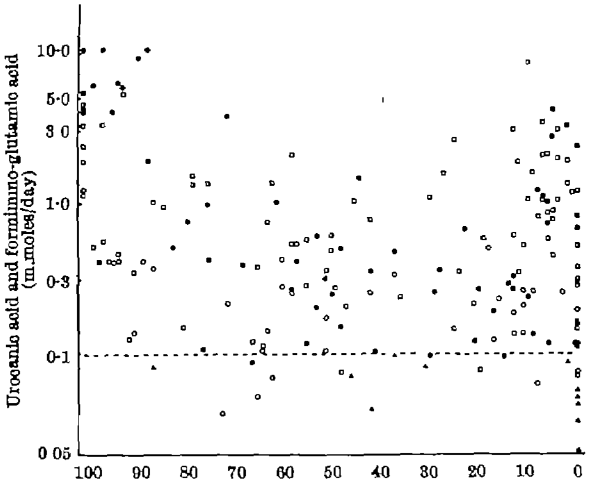

Fig. 1. Each point represents the amount of urocanic acid and formimino-glutamic acid excreted in the urine after an oral dose of 15 g (97 m.moles) of histidine hydrochloride. The proportion of urocanic acid present is shown on the abscissa. ▲, Normal subjects; ●, miscellaneous disorders, megaloblastic anæmia, ○, vitamin B_{12} deficiency; □, folic acid

container to which had been added 3–5 ml. of N/1 hydrochloric acid. An aliquot was retained for estimation of both urocanic acid and formimino-glutamic acid. A second aliquot (4·0 ml.) was brought to *p*H 9·6–10·0 with 1·5 N/1 potassium hydroxide and heated at 10 lb. pressure for 10 min. The alkali added to the urine sample was neutralized with an equimolar amount of 1·5 N/1 hydrochloric acid. This procedure destroyed all the formimino-glutamic acid present but did not interfere with urocanic acid. Recovery of urocanic acid added to urine and treated in this manner varied from 93 to 105 per cent.

Formimino-glutamic acid and/or urocanic acid were estimated by incubating the urine with folic acid, TPN and a chick enzyme preparation. This transferred the formimino group to tetrahydrofolic acid and the end-product was converted to 5–10, methenyltetrahydrofolic acid with hydrochloric acid. The latter was measured by its absorption at 350 mμ (ref. 3). Orocanic acid is fully active in this system because urocanase, the enzyme converting urocanic acid to formimino-glutamic acid, is present in the enzyme preparation.

The total histidine derivatives excreted following an oral dose of 15 g of histidine (Fig. 1) was less than 0·1 m.moles (equivalent to 17 mg of formimino-glutamic acid) in normal subjects and was more than this in all but 11 of the samples from the patients. Eight of these 11 specimens had been obtained after the patient had received either B_{12} or folic acid. The percentage of urocanic acid in these samples is also shown in Fig. 1 and in Table 1. Urocanic acid was present in 163 (88 per cent) of the urine sampl examined. In 79 urines, urocanic acid constitute more than 50 per cent of the histidine derivative present and in 10 urines, only urocanic acid wa present.

Table 1. EXCRETION OF UROCANIC ACID IN THE URINE FOLLOWING AN ORAL DOSE OF 15 G OF HISTIDINE HYDROCHLORIDE, EXPRESSED AS A PERCENTAGE OF THE TOTAL HISTIDINE DERIVATIVES APPEARING IN THE URINE

Diagnosis		$\frac{\text{Urocanic acid (m.mole)} \times 100}{\text{Urocanic acid + formimino-glutamic acid (m.mole)}}$ %						
		0	1–19	20–39	40–59	60–79	80–99	100
Normal	(11)	5	1	2	2	0	1	0
Folic-acid deficiency	(86)	7	31	6	12	9	14	7
Vitamin B_{12} deficiency	(38)	9	0	8	6	8	8	0
Others	(51)	2	12	7	11	7	9	3
Total	(186)	23	58	18	31	24	27	10
	100%	12%	28%	10%	17%	12%	15%	5%

The concentration of urocanase in the liver of foli acid-deficient rats has been found to be abnormall low[4]. Folic-acid deficiency results in an accumulatio of formimino-glutamic acid, and this in turn depresse the production of the enzyme urocanase. The en result is that urocanic acid rather than formimin glutamic acid accumulates and both appear in th urine.

Although urocanic acid is excreted by most patien who excrete formimino-glutamic acid, it is most likel to appear in large amount in patients with lon standing folic-acid deficiency. Thus two patien with hæmolytic anæmia (hereditary spherocytosis an acquired autoimmune hæmolytic anæmia) wh developed megaloblastic arrest both excreted larg amounts of urocanic acid. Formimino-glutamic ac was either absent or present in small amount. Sim larly a patient with myeloblastic leukæmia of months duration who had been treated with steroi and 6 mercaptopurine excreted between 2·3 and 4 of urocanic acid after 15 g of histidine. The excretio declined rapidly when oral folic acid was given.

We conclude that in carrying out tests for folic-aci 'deficiency' in man it is important to estimate th excretion in the urine of urocanic acid as well formimino-glutamic acid. Failure to do so may gi misleading results in many cases.

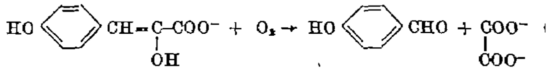
Oxidation of Phenylpyruvates to Aromati Aldehydes and Oxalate

Ewald and Hubener[1] have recently described new method for the determination of tyrosine-ketoglutarate transaminase activity. In their pr cedure, the *p*-hydroxyphenylpyruvate generated the transamination reaction was converted on stan ing in alkali to an unknown 'chromogen' absorbi maximally at 331 mμ with $\varepsilon_{334\,m\mu} = 16{,}200$. T Ewald and Hubener technique represents anoth report of the oxidative cleavage of phenylpyruvates aromatic aldehydes and oxalate according to equ tion (1) and depends on the strong absorption of t phenolate ion of *p*-hydroxybenzaldehyde.



This reaction was recognized in this laboratory[2] and preliminary reports of the Cu++ and Mn+ catalysis of the oxidation have been published[4] For pure *p*-hydroxybenzaldehyde in 0·1 N sodiu hydroxide I have found $\varepsilon^{\max}_{330\,m\mu} = 27{,}200$. Gol schmid[5] reported $\varepsilon^{\max}_{333\,m\mu} = 26{,}800$, and Do reported $\epsilon^{\max}_{330\,m\mu} = 25{,}000$. In my work, the oxidation of *p*-hydroxyphenylpyruvate in 0·1 N sodium hydroxide measured manometrically with air at 30° (0·00167 M substrate) and of 0·01 M keto-acid under oxygen was complete in less than 15 min. These reactions yielded 60–70 per cent *p*-hydroxybenzaldehyde, which is consistent with the extinction coefficient of the Ewald and Hübener 'chromogen'.

It is noteworthy that the oxidation of phenylpyruvates to aldehyde and oxalate has been reported a number of times by different investigators. The oxidation of phenylpyruvic acid was noted by Bougault and Hemmerlé[8] and described by Hemmerlé[9]. Wieland[10] observed the formation of benzaldehyde and oxalate from aqueous phenylpyruvic acid with palladium and oxygen. Cavallini and Stirpe[11] reported the alkaline oxidation of phenylpyruvate to benzaldehyde and oxalate.

The instability of *p*-hydroxyphenylpyruvate in alkali was noted by Bucher and Kirberger[12]. The formation of *p*-hydroxybenzaldehyde from alkaline solutions of *p*-hydroxyphenylpyruvate was recognized by Doy[7], who suggested a mechanism involving hydration of the enol to *p*-hydroxyphenylglyceric acid and hydrolytic cleavage to aldehyde and glycollate, a mechanism which he no longer supports[13]. The presence of *p*-hydroxybenzaldehyde in chromatograms of *p*-hydroxyphenylpyruvate was reported from this laboratory[14]. Billek[15] has also described the oxidation of *p*-hydroxyphenylpyruvate in alkali to *p*-hydroxybenzaldehyde and oxalate.

In my work and in other reports[9-11,15], the participation of the enol as the tautomer undergoing oxidation was reported.

I have found that the oxidation of phenylpyruvate, *p*-hydroxyphenylpyruvate and *p*-methoxyphenylpyruvate occurs at a negligible rate at *p*H 7 or less. The reaction is catalysed by ultra-violet light, indicating its free radical nature. At *p*H 8 and greater, the reaction is rapid enough to monitor spectrophotometrically, and its increase in rate with *p*H indicates that the enolate is the species oxidized.

In view of the numerous reports on oxidation of phenylpyruvates to aromatic aldehydes and oxalate, it is somewhat surprising that this reaction is not more generally recognized.

This investigation was supported by U.S. Public Health Service grant *A*567 and by U.S. Atomic Energy Commission contract *AT*(30–1)–901 with the New England Deaconess Hospital.

PHYSIOLOGY

Passive Transport in the Renal Re-absorption of Inorganic Phosphate in the Dog

DURING an investigation[1] on the renal effects of profound hypothermia (10° C) in the dog, the rates of renal re-absorption of filtered sodium and inorganic phosphate were found to differ markedly in their response to changing body temperature.

The dogs were cooled to an œsophageal temperature of 10° C by means of an extra-corporeal circulation and heat-exchanger. Urine was collected via uretic catheterization. Continuous urine and frequent blood samples were collected during step-wise reduction of temperature. These samples were analysed for sodium, inorganic phosphate and creatinine. The percentage of re-absorption of filtered sodium and inorganic phosphate was calculated as:

$$100\,X\left(I - \frac{U_x\,.\,V}{C_{r}\,.\,P_x}\right)$$

where U_x = urine concentration of sodium or inorganic phosphate; V = urine volume per minute; C_{cr} = creatinine clearance, P_x = plasma concentration of sodium or inorganic phosphate.

The percentage re-absorption of filtered sodium was found to decrease rapidly with a falling temperature. That of inorganic phosphate, on the other hand, showed much less reduction (Fig. 1). In a series of 6 dogs, the Q_{10} of sodium re-absorption

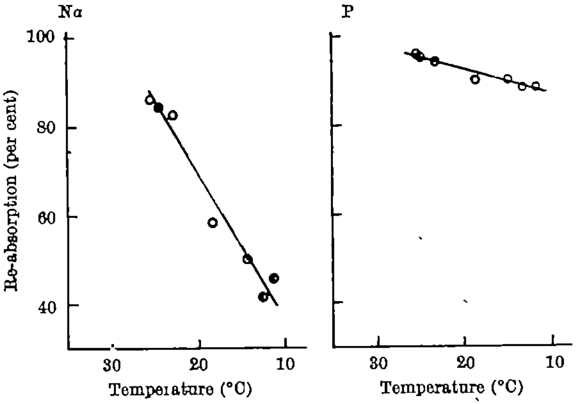

Fig. 1. Typical data for the fall in percentage renal re-absorption of filtered sodium and inorganic phosphate, on cooling a dog to 10° C

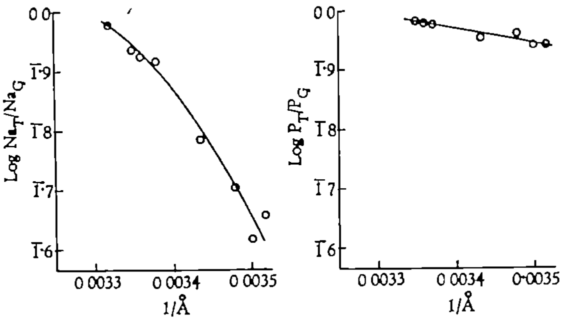

Fig. 2. The logarithms of the (corrected) rates of renal re-absorption of filtered sodium and inorganic phosphate are plotted against the reciprocals of those absolute temperatures at which the rates were determined. The slopes of the resultant curves are a measure of the apparent activation energies of the renal re-absorption of sodium and inorganic phosphate. Na_T or P_T, rate of tubular re-absorption of sodium or inorganic phosphate, Na_G or P_G, rate of glomerular filtration of sodium or inorganic phosphate

averaged 1·67, whereas that of urinary inorganic phosphate averaged 1·08.

The Arrhenius equation, $\log \frac{k_1}{k_2} = \frac{E\ (T_1 - T_2)}{2 \cdot 3\ R\ T_1\ T_2}$, was then applied to these data. (R is the gas constant, k_1 and k_2 the rate constants at the absolute temperatures T_1 and T_2, and E is the apparent activation energy.) Inasmuch as the glomerular filtration-rate, and therefore the filtered load, fell considerably during progressive cooling, the absolute rates of re-absorption were corrected for the alterations in load (Fig. 2). The mean apparent activation energy for re-absorption of filtered sodium, in a series of 6 dogs, was 8,400 cal/mol/deg, whereas that of inorganic phosphate was 1,200 cal/mol/deg.

The latter figure is well below that usually considered the upper limit (5,000 cal/mol/deg) of purely passive processes, such as diffusion[2]. This favours the hypothesis that inorganic phosphate is re-absorbed by a passive transport process in the canine kidney.

Electrophoretic Pattern of the Soluble Proteins of a Pineal Body Extract

THE possible physiological effects of the pineal body and its extracts are being re-investigated[1-4]. As few details are given about the nature of the extracts used, we studied the mobility of the water-soluble proteins of the organ.

A water extract was prepared from fresh acetone-powdered bovine pineal bodies according to the method of Kitay and Altschule[5].

Electrophoresis was performed in a horizontal tank in a veronal buffer at pH 8·6 of ionic strength 0·05 using Whatman No. 1 filter paper and a gradient of 10 V/cm for 5 h. After the run, the paper strip was dyed in amido-schwarz.

For comparison of mobilities, pineal extracts and bovine serum were run side by side on the same filter paper strip. The dyed strips, after impregnation with liquid paraffin, were scanned in an automatic densitometer. The resulting pattern was subdivided in gaussian curves and the areas determined geometrically.

For free electrophoresis, the pineal extract was dialysed against the same buffer. Analyses were performed in a Perkin–Elmer model 38 *A* apparatus, under a gradient of 10 V for two hours.

The extract from fresh pineal bodies revealed the presence of four protein fractions (Table 1 and Fig. 1).

Table 1. ELECTROPHORETIC FRACTIONATION OF WATER-SOLUBLE PROTEINS OF BOVINE PINEAL BODIES

Fraction	Relative concentration (per cent)	Mobility (cm/V/sec)
I	14·7	$6 \cdot 1 \times 10^{-5}$
II	20·8	$4 \cdot 2 \times 10^{-5}$
III	47·0	$2\ 8 \times 10^{-5}$
IV	17·5	$1 \cdot 5 \times 10^{-5}$

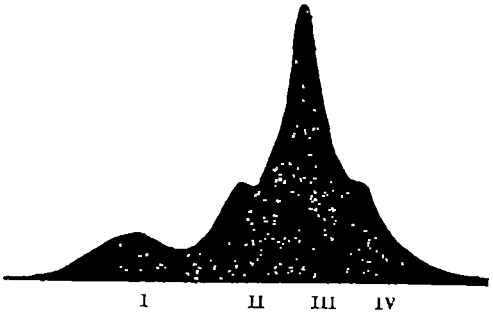

Fig. 1. Electrophoretic pattern of water-soluble proteins of bovine pineal bodies

Another extract prepared from powdered dried glands, obtained commercially, did not contain fraction 4 and only traces of fraction 1.

The fraction 1 has the same mobility as bovine serum albumin.

Immuno-electrophoretic investigation of these fractions in their relation to bovine blood proteins and their physiological actions are in progress.

Effect of Large Variations in External Potassium on the Oxygen Consumption of Rat Heart Strips

THE link between the electrical state of the cell membrane and the metabolism of the cell is unknown. High external K+, which reduces the membrane potential, causes a five-fold increase in resting oxygen consumption[1] and a twenty-fold increase in resting heat production[2,3] of frog skeletal muscle. The onset of the metabolic response (often called the Solandt effect) is so rapid that it is thought to be due to the change in potential rather than to a raised intracellular K+ (ref. 3). This communication reports our efforts to test for the Solandt effect in isolated trabeculæ carneæ from the rat heart[4].

The 24 muscles used were less than 1 mm in diameter, and about 9 mm in length. Except at one cut end, the cells were intact. Oxygen consumption was measured at 32° C by a previously described volumetric technique that allowed simultaneous measurement of the tension by means of a strain gauge[5,6]. By the time the oxygen measurements were started the tension had equilibrated at about 0·5 g. Except for an occasional test stimulus the muscles remained quiescent.

Starting with a recording of the oxygen consumption in Feigen's solution[7] the K+ concentration was raised successively to the various experimental levels. In the 'hypertonic series' this was done by injecting the proper amount of concentrated potassium chloride solution into the chambers with a micrometer syringe. Oxygen readings were begun within 2 min after injection. In the 'isotonic series' the desired final chamber K+ concentration was achieved by withdrawal of a measured amount of solution and replacement with Feigen's solution in which K+ had been substituted for part of the Na+. Thus, the total osmotic pressure of the latter solution did not change. Recording of the consumption of oxygen was begun 15 min after adding the K+. Initial experiments had shown that relatively small increases in Q_{O_2} were obtained below 20 mM/l., so that the concentrations chosen for the osmotic experiments were between 30 and 90 mM/l. of potassium. The gas phase was 98 per cent oxygen and 2 per cent carbon dioxide controlled at pH 7·4.

The oxygen consumptions for each strip at the various K+ levels were expressed as percentages of the oxygen consumptions of that same strip at 5·63 mM/l. external K+. The oxygen consumptions increased each time the external K+ level was raised (Fig. 1). The maximum increase of 73 or 82 per cent mM/l. external potassium is small compared with that seen in frog skeletal muscle. The average maximum increase in Q_{O_2} was about 2.

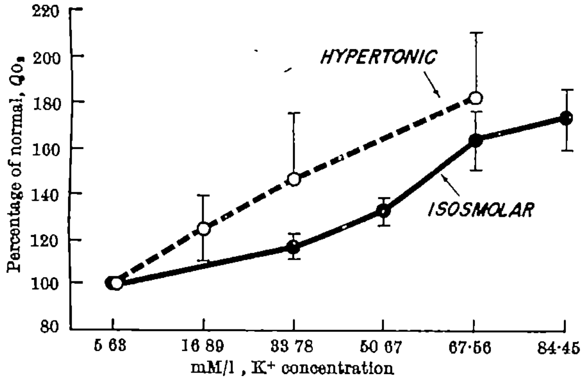

Fig. 1. Effect of variations in the external potassium concentration on the Q_{O_2} of 22 rat trabeculæ carneæ. Each point represents the mean ± 1 *S.E.* (vertical bars) of 10–12 determinations

The chambers used are capable of detecting much larger oxygen consumptions in rat heart strips of the same size[5] so that the limitation of increase in oxygen consumption would seem to have been inherent in the heart muscle strips rather than due to an experimental limitation. It is unlikely that a substantial increment in uptake of oxygen was missed due to the 2-min delay before taking readings, since the lag in the system is about 3 min. There was also little tendency for the oxygen uptake to fall with time. Finally, the small response could not have been due to calcium lack[8] since Feigen's solution[7] contains 5·58 mM/l.

The effects of K+ on metabolism vary markedly with the tissue. Not all have shown the marked increase reported for frog skeletal muscle. Gerard[9] found that high external K+ depressed the consumption of oxygen by nerve. Ashmore, Cahill, Hastings, and Zottu[10] found a depression of glycolysis and glycogenolysis in rat liver slices when K+ medium was used instead of an Na+ medium. On the other hand, Cardot, Faure and Arvanitaki[11] found that consumption of oxygen increased slightly in invertebrate heart muscle when potassium was increased relative to sodium and calcium. Thus, only in frog skeletal muscle have marked effects of the ionic medium on metabolism been seen.

HÆMATOLOGY

Effect of Carbon Dioxide and Diphenylhydantoin on the Partition of Triiodothyronine labelled with Iodine-131 between the Red Cells and the Plasma Proteins

THE uptake *in vitro* by the red blood cells of triiodothyronine labelled with iodine-131 is a useful method of evaluating thyroid function[1]. It has been shown that under the conditions of the test ^{131}I-triiodothyronine is distributed between the red cells, the α_1- and β-globulins and the binding sites on thyroxine binding protein not occupied by thyroxine (free T.B.P.), according to the relative binding powers of these substances; since the binding power of the red cells and the α_1- and β-globulins appears to be relatively constant, the test is an indirect measurement of free T.B.P. capacity[2]. It is known that an increase in the carbon dioxide tension of the blood increases the proportional uptake of ^{131}I-triiodothyronine by the red cells[3]. The uptake is also increased in patients who are being treated with diphenylhydantoin (phenytoin), an effect which may be reproduced when this substance is added to blood *in vitro*[4]. We have investigated the mechanisms whereby these agents modify the partition of ^{131}I-triiodothyronine between the red cells and the plasma proteins.

The uptake of ^{131}I-triiodothyronine by the red cells was measured in aliquots of blood from the same individual to which increasing amounts of thyroxine had been added in order to obtain a series of values for free T.B.P. capacity. The same experiment was performed: (*a*) with blood to which diphenylhydantoin had been added in a concentration of 10 mg per 100 ml. of plasma; (*b*) with blood which had been allowed to equilibrate for ten minutes with pure carbon dioxide at atmospheric pressure and room temperature. The results of these experiments are shown in Fig. 1, where for each aliquot of blood the reciprocal of the uptake of ^{131}I-triiodothyronine by the

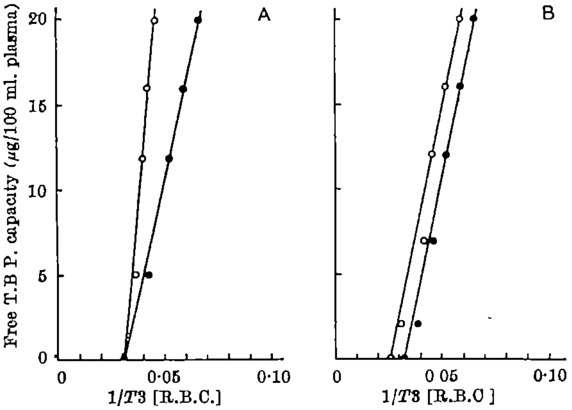

Fig. 1 Values for free T.B.P. capacity plotted against the reciprocal of $T3$[R.B.C.]. *A*, Comparison of control blood and blood to which diphenylhydantoin has been added in a concentration of 10 mg/100 ml. of plasma. The equations for the regression lines may be expressed as.

Control (●), $\frac{1}{T3[\text{R.B.C.}]}$ = 0·00175 free T.B.P. + 0 031.

Diphenylhydantoin (○), $\frac{1}{T3[\text{R.B.C.}]}$ = 0 00071 free T.B.P. + 0·031.

B, Comparison of control blood and blood which had been allowed to equilibrate in an atmosphere with a high carbon dioxide tension. The equations for the regression lines may be expressed as.

Control (●), $\frac{1}{T3[\text{R.B.C.}]}$ = 0·00163 free T.B.P + 0 032.

Carbon dioxide (○), $\frac{1}{T3[\text{R.B.C}]}$ = 0·00160 free T.B.P. + 0 0265.

red cells has been plotted against the corresponding value for free T.B.P. capacity.

The proportion of ^{131}I-triiodothyronine taken up by the red cells ($T3$[R.B.C.]) may be expressed as follows[3]:

$$T3[\text{R.B.C.}] = \frac{\text{binding power of R.B.C.}}{\text{binding power of R.B.C.} + \text{binding power of free T.B.P.} + \text{binding power of } \alpha_2\text{- and } \beta\text{-globulins}}$$

The binding power of free T.B.P. is equal to the product of free T.B.P. capacity and affinity. Hence:

$$\frac{1}{T3[\text{R.B.C.}]} = \frac{\text{free T.B.P. capacity} \times \text{affinity}}{\text{binding power of R.B.C.}} + \frac{\text{Binding power of } \alpha_2\text{- and } \beta\text{-globulins}}{\text{binding power of R.B.C.}} + 1$$

It can be seen from Fig. 1 *A* that the slopes of the regression lines for the normal blood and the blood to which diphenylhydantoin had been added are different, but that they intercept the x axis at the same point, which implies that diphenylhydantoin affects the binding power of free T.B.P. When free T.B.P. capacity is zero, diphenylhydantoin has no effect. Diphenylhydantoin probably competes with both triiodothyronine and thyroxine for binding sites on T.B.P.[4]. In the case of carbon dioxide (Fig. 1 *B*) the regression lines have the same slope but intercept the x axis at different points. According to the above formula, this must be interpreted as an effect of carbon dioxide on the binding power of the α_2- and β-globulins. The proportional effect on the uptake of ^{131}I-triiodothyronine by the red cells is of the same magnitude whatever the value for free T.B.P. capacity.

The uptake of ^{131}I-triiodothyronine by the red cells is only a valid test of thyroid function if the binding power of the α_2- and β-globulins remains relatively constant[3]. Since an increase in the carbon dioxide content of the blood diminishes the binding power of these proteins, it is advisable, when carrying out this test, to allow the blood to equilibrate with the atmospheric carbon dioxide before and during the period of incubation.

Chemical Difference between Normal Human Hæmoglobin and Hæmoglobin-I

Ingram and I have reported that a specific colour reaction on a 'fingerprint' indicated that the tryptic peptide 23 of hæmoglobin-I (Hb-I) contains tryptophan whereas the corresponding one in the normal hæmoglobin (Hb-A) does not. Ingram reported that the peptide is in the α-chain of the molecule[2]. Hill and Konigsberg[3] found that there is only one tryptophan residue in the α-chain of Hb-A; it is in a pentapeptide with valyl as the NH_2-terminal and lysyl as the COOH-terminal residues. I wish to report that it is the lysyl residue of the pentapeptide which is exchanged with aspartyl in the genetic alteration of Hb-I. It is now known that the pentapeptide is the third tryptic peptide from the NH_2-terminal end of the α-chain[4,5] and that the interchange of lysyl for aspartyl takes place at the 16th from the NH_2-terminus.

The soluble peptides were prepared from chromatographically purified Hb-A and Hb-I as previously described[1]. One-dimensional electrophoresis was adequate for the present investigation for the examination and isolation of soluble peptides. The tryptophan-containing peptides were easily located by fluorescence under an ultra-violet lamp.

Results indicate that there were three tryptophan-positive peptides in both hæmoglobins as shown in Fig. 1. The tryptophan-positive peptide which migrated the fastest at pH 6·4 towards the cathode in Hb-A vanished in Hb-I. (In our previous publication, Fig. 2, 4 tryptophan-positive peptides were shown for Hb-I; this is now known to be due to a trace of Hb-A present as a contaminant.) As it was previously reported the peptide 23 of Hb-I moved more rapidly towards the anode than the normal peptide. The peptide 23 of Hb-I contained tryptophan and an aspartyl residue (the latter accounted for its greater mobility towards the anode), whereas the corresponding peptide 23 of Hb-A did not. Because the tryptic digest of the α-chain of Hb-A contained but only one tryptophan residue the peptide with which it is associated vanished in Hb-I (Fig. 1). Thus

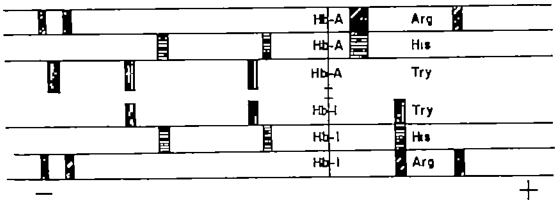

Fig. 1. Comparison by one-dimensional electrophoresis of tryptic digests of the normal and I hæmoglobins at pH 6 4. Three peptides of both hæmoglobins developed colour for tryptophan. Note that the peptide which moves the fastest toward cathode showing positive reaction for tryptophan in Hb-A is absent in Hb-I. It appears on the anode side in hæmoglobin-I

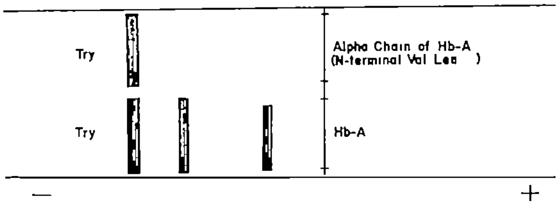

Fig. 2. Tracing of one-dimensional paper electrophoresis of tryptic digest of the normal hæmoglobin (Hb-A) and the α-chain isolated from it. The α-chain contains only one tryptophan-positive peptide. It moves the fastest towards the cathode, it is thus peptide which vanishes in Hb-I. The amino-acid interchange of this genetic alteration takes place in the tryptophan-positive pentapeptide of the α-chain

the specific chemical difference between Hb-A and Hb-I must be located in the tryptophan-containing pentapeptide.

The specific amino-acid composition of the tryptophan-positive pentapeptide of the α-chain of Hb-A was determined by the column chromatography method of Spackman, Stein and Moore[6] and found to consist of $(Ala)_2(Try)(Gly)(Lys)$; where Ala = alanyl, Try = tryptophyl, Gly = glycyl, and Lys = lysyl. In order to preserve tryptophan, leucine-aminopeptidase was used to hydrolyse the peptide which contained it. The NH_2-terminal residue of the pentapeptide was alanyl by the method of Sanger[7]. The amino-acid sequence of the pentapeptide was deduced in the following manner: the peptide was split with α-chymotrypsin and then the peptides were separated by one-dimensional paper electrophoresis; the tryptophan-positive segment behaved essentially neutral; the NH_2-terminal residue was alanyl and the amino-acid composition was $(Ala)_2(Try)$; so the sequence of the tripeptide was Ala-Ala-Try. The dipeptide contained glycine and lysine. The amino-acid sequence of the pentapeptide was deduced to be Ala-Ala-Try-Gly-Lys.

The NH_2-terminal residue of peptide 23 of Hb-I was alanyl, but it was valyl for peptide 23 of Hb-A. The amino-acid composition of Hb-I peptide 23 was identical with the sum of the tryptophan-positive pentapeptide and peptide 23 of Hb-A, however, with one exception—instead of lysyl, aspartyl residue was found. Since the pentapeptide is the third from NH_2-terminus of the α-chain, the tryptic peptide 23 must be the fourth; they are simply linked together in Hb-I through aspartyl residue.

Attempts made in this laboratory to find out whether or not other amino-acids in peptide 23 might be involved in the genetic change have not been successful; the amino-acid sequence appears to be identical with those reported by Braunitzer *et al.*[4] and by Hill and Konigsberg[5].

Schroeder *et al.*[8] reported that human hæmoglobin is composed of four polypeptide chains of two different kinds, referred to as α- and β-chains. In accordance with recommendations for the nomenclature of hæmoglobins[9] $\alpha_2{}^A\beta_2{}^A$ designates Hb-A and $\alpha_2{}^{16Asp}\beta_2{}^A$ could be used to define Hb-I.

I thank Dr. Robert J. Hill and Dr. William Konigsberg, of the Rockefeller Institute, who provided me with the α-chain of Hb-A; they also collaborated with me on the amino-acid analyses of the pentapeptide. I also thank T. Viswanatha and Mr. H. B. Marsh for assistance.

Hæmolytic Action of Mercurials

IN studying the effect of heavy metal ions on staphylococcal α-lysin it was found that whereas mercuric chloride inhibited hæmolysis at a concentration of 10^{-3} M, it became a potent lytic agent at lower concentrations: it was decided to investigate this problem.

The lytic effect of mercuric chloride, certain organomercurials, and other heavy metal ions was examined on human, sheep, guinea pig and rabbit erythrocytes. The compounds were dissolved in isotonic phosphate or acetate buffer pH 6·8–7·0 and titrated in doubling dilutions in isotonic buffer of the same pH; 0·5 ml. of a 2 per cent suspension of four-times washed erythrocytes were added to each tube. The results were read at various time-intervals after incubation at 37° C; hæmolysis was assessed visually. All chemicals were of B.D.H. 'AnalaR' or 'laboratory' standard.

Using rabbit erythrocytes, lysis began after 30 min at a concentration of $6·8 \times 10^{-5}$ M mercuric chloride. At 1 h, lysis had spread to higher and lower concentrations; the upper limit was $2·5 \times 10^{-4}$ M, the lower $1·7 \times 10^{-5}$ M, with usually a trace of lysis at $8·4 \times 10^{-6}$ M. Above 5×10^{-4} M the erythrocytes became agglutinated. On prolonged incubation lysis spread to 5×10^{-4} M and 4×10^{-6} M.

The erythrocytes of other species were found to be less susceptible than those of the rabbit. After 1 h no hæmolysis was observed. At 2 h human erythrocytes were incompletely lysed, between 5×10^{-4} M and $6·8 \times 10^{-5}$ M of mercuric chloride and traces of hæmolysis were seen with sheep erythrocytes between the same concentrations: guinea pig erythrocytes were incompletely lysed at $2·5 \times 10^{-4}$ and $1·25 \times 10^{-5}$ M. Prolonged incubation for 4–5 h led to further lysis, that of human erythrocytes spreading to almost the same limits as of rabbit erythrocytes. Mercuric chloride thus exhibits selective lysis similar to some extent to that shown by staphylococcal toxins.

The lytic effect is shared by organomercurials: *p*-chloromercuri-benzoate, ethyl mercuric chloride and thiomersal. In contrast with mercuric chloride no upper limit of hæmolysis was observed at the concentrations tested. After 1-h incubation with rabbit erythrocytes *p*-chloromercuri-benzoate and ethyl mercuric chloride caused lysis down to a concentration of 10^{-3} M and thiomersal to a concentration of 4×10^{-3} M; at 2–3 h *p*-chloromercuri-benzoate caused lysis at $1{\cdot}25 \times 10^{-4}$ and thiomersal at 5×10^{-4} M. Those compounds also lysed human and sheep erythrocytes although again not as rapidly as rabbit erythrocytes. The order of susceptibility of erythrocytes was rabbit > human > sheep.

The ability to lyse seems to depend on the number of free positive mercury charges on the compound. Mercuric chloride, which has two free positive charges, is more potent than either *p*-chloromercuri-benzoate or ethyl mercuric chloride, which have one free positive charge. These in turn are more potent than thiomersal, which although it has no free positive charge in the native state is thought to split in the presence of tissue sulphydryl groups to reveal 1 free positive charge.

Other heavy metal ions, such as copper and lead, are also hæmolytic, but less potent than mercury. Barium ions were inactive even after 19 h of incubation; it would thus appear that hæmolytic activity is not a general property of heavy metal ions.

The conditions under which lysis occurs and the nature of the hæmolytic system suggests that the mechanism of lysis probably involves the formation of a chelate or co-ordination complex of the heavy metal ion with a reactive group on the surface of the red cell membrane causing instability and subsequent lysis.

I thank the Rankin Research Fund for a grant towards the expenses of this work.

Effect of Methylene Blue on Red Cell Glutathione

An unusually high value for red cell reduced glutathione (GSH) was encountered while performing a glutathione stability test, using Beutler's[1] technique, on blood from a 2-year-old girl who developed methæmoglobinæmia and hæmolysis following the accidental ingestion of an unknown quantity of diaminodiphenylsulphone ('Dapsone'). Our range for red cell GSH in normal subjects is 78–104 mg per 100 ml. red cells (mg per cent): in the patient a value of 160 mg per cent was found. After incubation of the blood in the presence of acetylphenylhydrazine, the GSH-level was 119 mg per cent (normal range 60–94 mg per cent); red cell glucose-6-phosphate dehydrogenase activity[2] was normal.

It seemed unlikely that either the 'Dapsone' or the subsequent hæmolysis was responsible for this high value for GSH. It was demonstrated that the addition of 'Dapsone' to blood *in vitro* did not interfere with the estimation of GSH, and no difference was found in the GSH content of young and old red cells following their separation by centrifugation in bovine albumin as described by Prankerd[3]. Furthermore, normal red cell GSH-levels have been found in patients receiving 'Dapsone', even when prescribed in high dosage with resultant hæmolysis[4]. Our patient had received five intravenous injections, each of 20 mg methylene blue (1·5 mg/kg body-weight), during the 24 h preceding the withdrawal of blood for GSH estimation. We therefore investigated the effect of methylene blue on the level of red cell GSH. Two rabbits were used: the first received 10 mg (3·1 mg/kg body-weight) methylene blue, intravenously, twice daily for two days. The initial red cell GSH-level was 126 mg per cent: 18 h after the last injection this had risen to 190 mg per cent. The second rabbit received 10 mg (3·4 mg/kg body-weight) twice daily for four days. The resulting changes in the level of red cell GSH are shown in Fig. 1. It can be seen that the GSH rose from an initial level of 137 mg per cent to a maximum of 432 mg per cent; this peak was reached 18 h after the last injection of methylene blue. The red cell GSH afterwards fell, returning to its initial level 10–12 days after the last injection of methylene blue. The red cell glucose-6-phosphate dehydrogenase activity was 109 units initially, and 135 units when the GSH-level was at its peak.

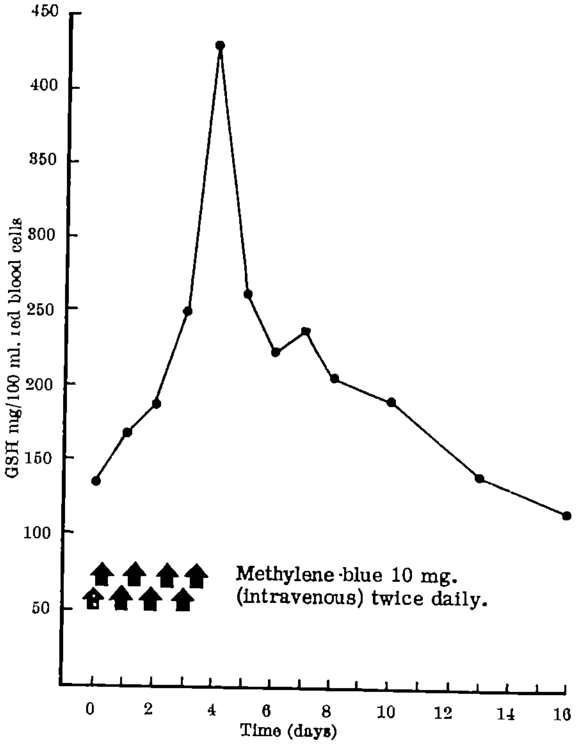

Fig. 1

It is generally accepted that oxidized glutathione (GSSG) in the red cell is reduced by the enzyme glutathione reductase, the presence of reduced triphosphopyridine nucleotide (TPNH) being essential for the reaction to proceed[5]:

$$\text{GSSG} + \text{TPNH} + \text{H}^+ \rightarrow 2\text{GSH} + \text{TPN}$$

An adequate level of red-cell TPNH depends on the aerobic breakdown of glucose to carbon dioxide and water through the hexose monophosphate pathway. In normal circumstances, however, this pathway accounts for only a fraction of the glucose utilized by the red cell: little oxygen is consumed, and the main energy source appears to be derived from the anaerobic breakdown of glucose to lactate. When red cells are incubated *in vitro* in the presence of methylene blue, their oxygen consumption is greatly increased[6]: this indicates increased activity in the hexose monophosphate pathway, and as a result, increased TPNH production and consequent reduction of further GSSG to GSH might be expected to follow. Whether our observed high GSH-levels can be explained on this basis must depend on the amount of GSSG present in red cells and available for reduction. Very few observations have been made on the level of red-cell GSSG: however, Jocelyn[7] found that less than 6 per cent of the total glutathione in normal human red cells was present as GSSG. It therefore seems highly improbable that the substantial increases in red cell GSH observed in the present study can result from the reduction of pre-existing GSSG: indeed, it is almost certain that there is also a substantial increase in the total glutathione content of the red cells. We suggest, therefore, that in the presence of methylene blue there is an increase in the synthesis of glutathione in red blood cells: this may be a consequence of the increased activity in the hexose monophosphate pathway, or the result of the influence of methylene blue on another metabolic pathway in the red cell.

Erythropoietic Stimulation in the Hypertransfused Guinea-Pig following Injections of Human Urinary Erythropoietin

CONSIDERABLE evidence has accumulated in recent years that supports the concept of a humoral component as part of the mechanism for control of erythropoiesis. The humoral agent has been termed erythropoietin or erythropoietic stimulating factor, and has been obtained from plasma and urine of various anæmic animals and from urine of patients with various hæmatological disorders. Erythropoietin does not appear to be species specific; thus, human, rabbit and sheep erythropoietin stimulate erythropoiesis in the mouse, rat and rabbit.

Reports of the effectiveness of erythropoietin obtained from various sources in stimulating erythropoiesis in the guinea pig have been variable. Gordon[1] reports that injections of urine from a child with thallassæmia major did stimulate erythropoiesis in the guinea pig, but that other urine samples which were quite erythropoietically active in rats failed to stimulate guinea pigs. Osmond[2] failed to observe erythropoietic stimulation in guinea pigs following the injection of plasma extracts from anæmic ponies. Osmond *et al.*[3], on the basis of quantitation of marrow cellularity, found that injections of human urinary erythropoietin into normal guinea pigs were not only not erythropoietic but actually granulopoietic. Van Dyke[4], using the iron-59 assay, found an absence of response in the guinea pig to human urinary erythropoietin. Keighley[5] is reported to have found that a filtrate of anæmic rabbit plasma, erythropoietically active in other species, was inactive in guinea pigs. In general, these workers conclude that failure of guinea pigs to respond to injections of extracts which are erythropoietically active in other rodents may be due to the presence in the extracts of antigens to which the guinea pig is more responsive than the other animals studied. Possibly these antigens indirectly influence the erythropoietic response by stimulating the cellular proliferation of other cell lines such as granulocytes, lymphocytes and plasma cells. This increased proliferation may compete with erythropoiesis for stem cells or essential nutrients. This competition, if it does occur, should be less in assay animals not undergoing active erythropoiesis prior to the administration of exogenous erythropoietin. Thus, in the present experiments the responsiveness of guinea pigs to human erythropoietin has been reinvestigated using hypertransfused guinea pigs.

Male guinea pigs of the Hartley strain initially weighing about 400 g were used. On each of the first two days of the experiment the animals were given intraperitoneally 10 ml. of a 60 per cent suspension of washed red cells obtained from donor guinea pigs. This was followed by 5 days of treatment with 2 mg daily of erythropoietin. The erythropoietin contained 16 cobalt units per mg dry weight. The daily dose was given in 0·5 ml. of saline, half the dose being given intraperitoneally and the other half subcutaneously. The control animals were injected in the same manner with saline. The erythropoietin was obtained from the urine of a patient with aplastic anæmia and was extracted by ultrafiltration as described elsewhere[6]. The day following the last injection of erythropoietin the guinea pigs were injected intraperitoneally with 0·5 μc. iron-59 in 0·5 ml. of saline. The animals were anæsthetized with ether 24 h later, and approximately 10 ml. of blood withdrawn from the aorta into a heparinized syringe. An aliquot of this blood was counted for radioactivity and, using a value of 5 per cent of the body-weight for the blood volume, the radioactivity in the total blood volume was calculated. This figure is given as a per cent of the iron-59 injected. Microhæmatocrits and reticulocyte counts were done on the same sample of blood. A total of 1,000 cells were counted in smears made of blood, previously incubated 20 min with 1 per cent brilliant cresyl blue in saline, for the reticulocyte determinations. The spleen was fixed in formalin, embedded in paraffin, sectioned, and stained with hæmatoxylin and eosin. Smears of the bone marrow were also examined.

The 24-h iron-59 incorporation and the reticulocyte response in the erythropoietin and saline injected hypertransfused guinea pigs is shown in Table 1.

Table 1. RESPONSE OF HYPERTRANSFUSED GUINEA PIGS TO HUMAN URINARY ERYTHROPOIETIN

	No. of animals	Weight (final) (g)	Hæmatocrit (per cent)	24-h ^{59}Fe red cell incorporation (per cent)	P*	Reticulocytes (per cent)
Control (saline)	10	472	60	2·1		0·01
Erythropoietin (2 mg/day for 5 days)	8	380	62	11·0	< 0·001	1·01

Guinea pigs transfused with a total of 11·54 ml. of packed red cells during the two days prior to treatment.

* t test.

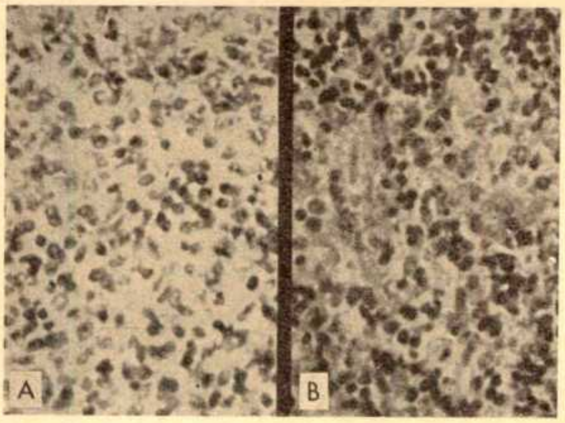

Fig. 1. *A*, Spleen of saline injected hypertransfused guinea pig; non-erythroid. *B*, Spleen of hypertransfused guinea pig injected with human urinary erythropoietin; active erythropoiesis

We observed, as did Osmond *et al.*[3], that a loss of weight occurred in the guinea pigs receiving erythropoietin. The estimated blood volume is obviously low because of the hypertransfusion and weight loss in the erythropoietin injected animals, so that the estimated uptake of iron-59 in the calculated blood volume indicates only qualitatively the nature of the erythropoietic response. These results and a comparison of the cytological changes in the marrow and the histological changes in the spleen (Fig. 1) indicate that injection of human urinary erythropoietin can specifically stimulate erythropoiesis in the hypertransfused guinea pig, that is, the marrow or spleen devoid of erythropoietic foci shows marked erythropoietic activity after erythropoietin injections.

Clotting of Fibrinogen with Aqueous Fibrin Extract

IN a previous communication[1], a clotting factor was reported to occur in aqueous fibrin extract. Chemically, it appeared to be a steroid glucuronide. It was differentiated from thrombin by greater heat stability, inactivation by oxalate and β-glucuronidase, by producing urea-insoluble fibrin clots in oxalated plasma without calcium chloride and reacting with *C* reactive protein antibody.

For a more thorough examination of certain properties of the factor, particularly its relationship to thrombin and fibrinogen, it was desirable to obtain it in higher concentration. To this end, it became necessary to let the clots decompose spontaneously. This took about 2–3 months at 5° C. In 1 per cent solutions of sodium chloride and other salts, clots broke down much more rapidly, but much of the active material remained then adsorbed to the protein residue. The aqueous fibrin extract was heated at 56° C for 30 min, a procedure which invariably destroys thrombin. Heating also precipitated out of solution certain breakdown products of fibrin. The supernatant was dialysed against distilled water to free it of any traces of calcium chloride. The dialysed solution reacted with bovine fibrinogen, 0·1 ml. producing a clot with 0·1 ml. of a 0·3 per cent solution of the substrate in 20–30 sec. Addition of 0·03 ml. of 0·1 M sodium oxalate produced a precipitate and delayed clot formation corresponding to a loss of 70–80 per cent of the original activity, but no more, regardless of length of time of exposure. The clots differed from thrombin clots in their tendency to retract readily.

Lorand[2] postulated that a heat-labile fibrin stabilizing factor present in serum and calcium ions was required to render fibrin insoluble in 30 per cent urea, but did not present data as to the relative stability of different clots in this solvent. In the present work it was found that clots made with clotting factor and fibrinogen dissolved in urea in about 45 min; with oxalated clotting factor the time was reduced to 5 min; on the other hand, when 0·03 ml. of 0·1 M calcium chloride was added to the two reactants, clots remained stable in their entirety for 2 h and parts of clots up to 8 h. The addition of serum, whether unheated or heated at 56° C for 30 min, and calcium chloride to clotting factor and fibrinogen, kept clots quite stable for at least 24 h. It would seem then that clotting factor functions in aggregating fibrinogen molecules, that calcium ions strengthen certain internal chemical bonds—merely adding calcium chloride to fibrinogen produces increased turbidity—and that serum proteins somehow give greater cohesion to the clot.

The action of clotting factor on fibrinogen is in conformity with observations by Godal[3,4] on the binding of heparin to fibrinogen in a stoichiometric relationship. In both cases, attachment to the protein may be by means of the glucuronic acid moieties of the molecules. Clotting factor has been shown[1] to counteract directly the anticoagulant effect of heparin. This suggests a competitive relationship between the two compounds for fibrinogen. The same is bound to exist between clotting factor and lytic factor, the 17-ketogenic steroid glucuronide obtained from extracts of digested fibrin[1]. It has been postulated that in the physiological process of blood coagulation, lytic factor is converted to clotting factor by the enzymes of the thromboplastin complex. So far there has been no clue to the chemical configuration of the steroid part of the clotting factor molecule. In view of its association with calcium, a relationship to vitamin D may be worth consideration.

HISTOCHEMISTRY

Histochemical Demonstration of Non-specific Esterase in Mast Cells of the Albino Rat with Properties Similar to Mast Cell Enzyme activated in Anaphylaxis

RECENT investigations suggest that release of histamine from isolated mast cells of the albino rat by an antigen–antibody reaction is due to an enzymatic process[1,2]. Further experiments with inhibitors which are more selective reveal that certain specific chymotrypsin substrates or inhibitors prevent the reaction, whereas substrates and inhibitors of carboxypeptidase, leucine-aminopeptidase or trypsin do not[3–5]. Toxic organic phosphorus compounds such as diisopropylfluorophosphate (DFP) or 'Paraoxon' also inhibit in relatively high concentration[6]. By virtue of these findings we have concluded that the enzyme responsible for the antigen–antibody reaction of isolated tissue mast cells of the albino rat is a chymotrypsin-like peptidase having pronounced esterolytic properties[5].

By means of histochemical techniques a number of enzymes can be detected in mast cells of the albino rat; in particular, one finds strong activities of leucine-aminopeptidase and adenosine-triphosphatase[7]. Benditt and Arase[8] have also demonstrated a chymotrypsin-like enzyme using naphthol-AS-chloroacetate as substrate.

I have endeavoured to discover which of the histochemically demonstrable enzymes displays properties similar to those of the enzyme responsible for the anaphylactic release of histamine. Normal isolated mast cells of the rat[9] were spread on slides and fixed by formalin vapour for 20 min. Following Pearse[10] and Löffler's[11] methods, the following histochemical tests were carried out on fixed smears: leucine-aminopeptidase according to Nachlas, Crawford and Seligman; acid phosphatase according to Gomori and Pearse; adenosine-triphosphatase according to Wachstein and Meisel; non-specific esterase according to Pearse (α-naphthyl-acetate), to Gomori (naphthol-AS-acetate), to Moloney *et al.* (naphthol-AS-D-chloroacetate) and to Holt (5-bromo-indoxyl-acetate). Comparative control tests were performed after heating slides to 90° C and with incubation mixtures lacking substrate. Several preparations were always examined simultaneously. The experiments with the inhibitors were performed according to the methods of Pearse[10], and Hess and Pearse[12].

The results are set out in Table 1. This shows that the mast cells of the albino rat, in accordance with the findings of Eder and Schauer[7], display pronounced activity of leucine-aminopeptidase, acid phosphatase and adenosine-triphosphatase. Histochemical detection of these enzymes is not influenced by eserine, DFP or 'Paraoxon' (2×10^{-6} and 10^{-3} M). The detection of non-specific esterase is unsuccessful or unsatisfactory with the substrates α-naphthylacetate and naphthol-AS-D-chloroacetate. On the other hand, the use of naphthol-AS-acetate or 5-bromoindoxylacetate results in an intensive staining which is clearly localized in the granules of the mast cells. This activity is not influenced by eserine (2×10^{-6} M), DFP (10^{-6} M) or 'Paraoxon' (10^{-6} M); however, incubation with higher concentrations of these substances (10^{-3} M) results in virtually complete loss of enzymatic activity. In addition, copper sulphate (10^{-3} M), lead nitrate (10^{-3} M), silver nitrate (10^{-2} M), and β-phenylpropionic acid (10^{-2} M) are also inhibitory. Histochemically the enzyme thus appears to be a non-specific organophosphate-resistant esterase. In so far as comparative experiments are available, its properties are identical with those of the enzyme responsible for the anaphylactic release of histamine.

Table 1. EFFECT OF VARIOUS INHIBITORS ON HISTOCHEMICALLY DEMONSTRABLE ENZYMES IN MAST CELLS OF THE ALBINO RAT

PATHOLOGY

Established Bone Marrow Cell Cultures with High Degree of Iron Incorporation

THE literature contains numerous reports of cell strains derived from normal or pathological human bone marrow or from elements of peripheral blood[1]. In the great majority, cell lines of such derivation are known to transform into fibroblastic or epithelial forms after a certain period of time[2]. Their experimental application is extensive, but almost exclusively confined to the field of virology[3].

Theoretically, it is possible to develop a permanent population of cells which would retain the basic properties of the primitive elements of normal bone marrow. With this possibility in mind, attempts were made to culture under varied conditions human bone marrow derived aseptically from surgically resected ribs. Of 19 such cultures, 17 were discarded, because of degeneration or fibroblastic transformation. The two remaining cultures derived from two young persons operated on for diaphragmatic hernias showed signs of stability.

The cells (*RI*) in these two lines were originally grown in T-flasks (60 ml.) with 25 ml. of culture medium. The culture fluid used consisted of Eagle's minimum essential medium, inactivated horse serum 10 per cent, glutamine 1 per cent, and antibiotics; it was supplemented with 0·5 ml. of folinic acid ('Leucovorin' Lederle, 3 mg/ml.) and 1 ml. of vitamin B_{12} ('Rubramin' Squibb, 3 μg/ml.). Since after 25 transfers the folinic acid and vitamin B_{12} were tested in

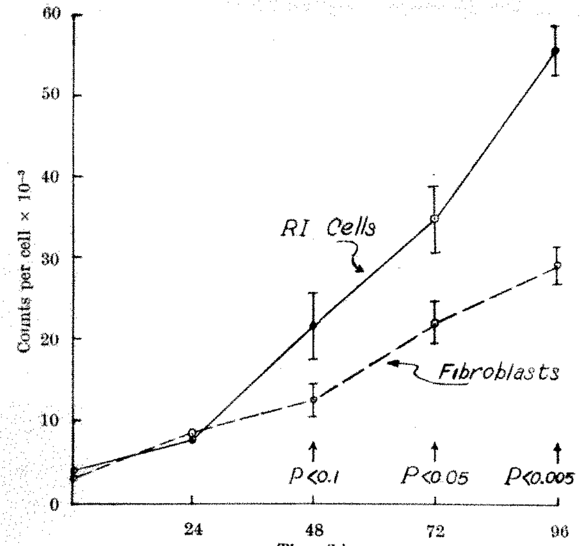

Fig. 1. Incorporation of iron-59 by *RI* cells and fibroblasts. Average of three experiments ± 1 *S.E.*

duplicate experiments, and found unnecessary, they were henceforth omitted.

Both these lines of cells grew at the same rate with a generation time of 22–24 h. The cells were best adapted in monolayer cultures. Attempts to grow them in spinner flasks gave erratic results. Cells frozen slowly kept for a period of 7 weeks at −70° C were successfully recovered. Under the phase-contrast microscope the cells appeared as round or polyhedrical elements with a large nucleus and granular, non-vacuolated cytoplasm. Numerous distinct nucleoli were present. In preparations treated with Wright's stain, the morphological characteristics were reminiscent of immature reticulum cells.

In order to study possible residual functional activity pertaining to normal bone marrow, the iron uptake of the *RI* cells was tested in short-term cultures. The cells were suspended in the described medium at optimum concentration of 7·5–10 × 10^4/ml. and incubated in a water bath shaker under a gas mixture of 5 per cent oxygen, 5 per cent carbon dioxide and 90 per cent nitrogen flowing at 2–3 lb./min. An atmosphere containing 13 per cent oxygen, 5 per cent carbon dioxide and 72 per cent nitrogen was found to be less effective for cellular growth. The *p*H was stable throughout the period of culture in a range of 7·2–7·3. Iron-59 in a citrate salt (sp. act. 20–25 mc./mg) was added in amounts of 1 microcurie per culture flask. At the end of the culture time, the radioactivity of the cells, after three washes, was counted in a well-type scintillation counter. All the cultures were run in triplicate samples. Fibroblasts from an established line were used as controls. In three experiments, the results calculated in counts/cell show (Fig. 1) that both cell lines had similar iron uptake at 24 h and were not significantly different after 48 h of culture. At 72 and 96 h, however, the *RI* cells showed significantly higher incorporation of iron. These findings were readily reproducible.

It is of interest that the *RI* cells were derived from normal bone marrow and after 85 passages had not transformed into the usual fibroblast form. The reticulum cell-like morphology was reminiscent of the stage III transformation of the Detroit line described by Berman[2], which was also derived from bone marrow. The factors arresting the usual fibroblastic dedifferentiation and stabilizing the *RI* cells are not known. It is possible that the initial addition of folinic acid and vitamin B_{12} played a decisive part. It is also possible that additional unknown factors, pertaining to either the bone marrow itself (age of the donor, state of the bone marrow at the time of implantation, etc.) or to the environmental characteristics of the culture, were equally responsible for the successful establishment of the *RI* cells.

A second point of significance is the high iron uptake of the *RI* cells. Such a quality of a cell line derived from normal human bone marrow has not been reported. At present, attempts are being made to enhance the rate of iron incorporation through hæmopoietic substances (erythropoietin) and to establish the fate of the incorporated iron. If the high rate of iron incorporation implies a retention of normal bone marrow function, the *RI* cells can prove a useful tool for future hæmatological research.

Distribution of Tritiated Thymidine about a Capillary Sinusoid in a Transplanted Mouse Tumour

DURING an investigation of the uptake of tritiated thymidine by mouse tumour tissue, fortuitous sections of tumour were found showing a large capillary sinusoid cut along its long axis for a distance of 2,000μ. Autoradiographs of these sections showed concentric zones of labelled cells, unlabelled cells morphologically intact, and necrotic tumour cells, at increasing distances from the capillary.

The tumour was a mammary adenocarcinoma which occurred spontaneously in our *C3H* mouse colony. It was designated as mammary adenocarcinoma *M2*, and has been maintained through multiple passages. It was grown subcutaneously to a diameter of approximately 0·6 cm. One hour after a tumour dose of 400 r. (250 kV constant potential, 15 m.amp, 2 mm aluminium filter added), tritiated thymidine (specific activity 0·36 c./mM) was injected intraperitoneally in the amount of 5 mc./g. The animal was killed 45 min after the injection. The tissue was cut into 5-μ sections, hydrolysed in N hydrochloric acid, and stained with Feulgen reagent. Autoradiographs were prepared by dipping in Kodak *NTB2* emulsion. They were developed after an exposure of ten days.

Figs. 1 and 2 are photographs of the autoradiographs of one of these tumour sections. The labelled cells extend on an average of 30–45μ from the capillary wall. Within this volume, cells closest to the capillary show a higher percentage of labelled cells and more label per cell. Surrounding the shell of labelled cells, a second volume is distinguishable containing unlabelled cells which show intact morphology and staining. These unlabelled intact cells lie between 45–70μ from the capillary. Beyond

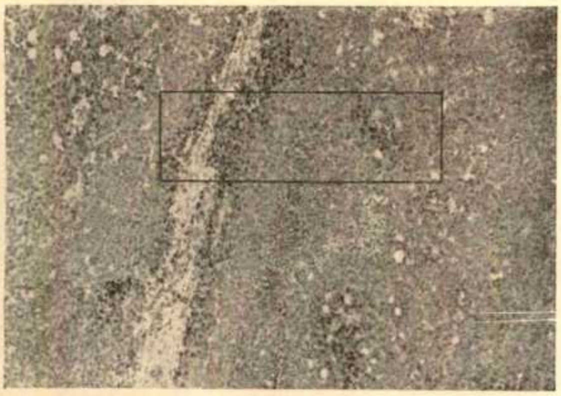

Fig. 1. Autoradiograph of mouse tumour section showing a portion of the long capillary sinusoid (just to the left of centre) surrounded by heavily labelled cells. Other capillaries cut on cross-section show the same distribution

about 70μ from the capillary are masses of necrotic cells. At greater distances from the large sinusoid and beyond the area of necrosis, other zones of morphologically intact cells without label are present. Still further, labelled cells are seen immediately surrounding other capillaries. This distribution is repeated throughout the tumour.

This observed distribution of labelled cells appears to represent a pattern of diffusion. It may be simply the diffusion of the thymidine in the 45 min following the single injection. However, Mendelsohn[1] was unable to label all morphologically intact tumour cells after continuous infusions of tritiated thymidine in tumour-bearing animals. These infusions lasted for periods up to 8 days, and autoradiographs were exposed for as long as 200 days. Cells capable of synthesizing DNA are dependent on an adequate supply of metabolites and oxygen. Therefore, the distribution in our sections may represent limited diffusion of oxygen and other metabolites. The examination of the sections themselves showing the progression from morphologically intact cells to necrosis as one proceeds peripherally from the blood vessel supports this thesis. It fits very well the diagrammatic map of a solid experimental tumour drawn by Thomlinson[2]. He attributed this progression to the drop in pO_2 as oxygen diffused through the tissue. Indeed, Johnson and Bond[3] doubled the depth of *in vitro* labelling of tumour tissue with tritiated thymidine by bubbling 95 per cent oxygen and 5 per cent carbon dioxide through the media.

We believe, with Mendelsohn, that this observed distribution of tritiated thymidine in our experimental tumour demonstrates some of the potential problems of cancer chemotherapy, and in particular the use of analogues of DNA precursors to increase radio-sensitivity of all the cells in a tumour. Also, the uneven distribution points to another pitfall in the evaluation of data obtained by autoradiography.

We thank Dr. H. Quastler, of the Brookhaven National Laboratory, for advice.

Leukæmia in the Progeny of Rats inoculated with a Leukæmogenic Virus

VERTICAL transmission of virogenic leukæmia, that is, the occurrence of leukæmia in the untreated progeny of animals inoculated with a leukæmogenic virus, has been observed with four different viruses of murine origin[1-5]. The phenomenon is not a uniform one. For example, Moloney's virus is transmitted in some strains of mice with little, if any, change of incidence through successive generations; in other strains, equally susceptible to inoculated virus, it is not transmitted at all[4,6]. Gross's virus in one strain passes with undiminished incidence to the first generation, but incidence falls off rapidly in subsequent generations; in other susceptible strains it is not transmitted[7-9].

Because of the potential value of vertical transmission as an aid in the interpretation of spontaneous leukæmia in man, it is important to know whether it occurs in genera other than the mouse. All the murine viruses referred to produce leukæmia when injected into rats as well as mice; but vertical transmission in rats has not hitherto been reported. Recently an unmistakable example of vertical transmission of leukæmia in rats occurred in this laboratory. The virus investigated was Moloney's, originally derived from mouse sarcoma 37 (ref. 10). A lyophilized sample obtained from Dr. Moloney was

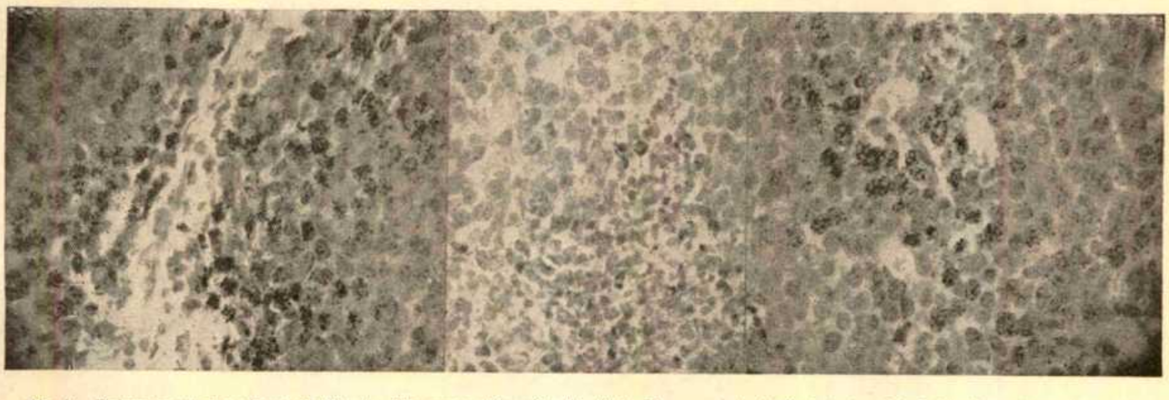

Fig. 2. Enlargement of enclosure in Fig. 1. The zones of heavily labelled cells, morphologically intact unlabelled cells, and necrotic cells can be seen at increasing distances from the capillaries on the right and left extremes of the illustration

passed twice in mouse embryo tissue cultures, and once in mice[11]. A cell-free filtrate of lymphomatous tissue homogenate from a leukæmic mouse, inoculated in infancy with infected tissue culture fluid, was injected into new-born rats of the Chester Beatty Institute albino strain (*CB*). Of 11 rats which survived for 2 months or more, 10 became leukæmic between the 11th and 20th week. A female of this group was mated when 13 weeks old to an untreated male of the same strain: she had a litter of 10, and died of leukæmia 5 weeks later. Of this litter 8 became leukæmic between 14 and 29 weeks of age. The two survivors appear healthy at 34 weeks.

The incidence of spontaneous leukæmia in the *CB* strain is very low—certainly less than 1 per cent up to 15 months of age.

The pathological changes in mice, following inoculation with Moloney's virus, are those of a generalized malignant lymphoma[12]. In rats, and in the uninoculated progeny of both genera, the changes are similar. Among the leukæmic rats of the present series, in 3 of the inoculated and in 4 of the progeny gross enlargement of the thymus (25–35 mm diameter) was the sole macroscopic abnormality. In the rest there was also enlargement of the spleen (40–60 mm long) and sometimes also of superficial and deep lymphatic nodes. Microscopically the affected organs were seen to be replaced by a dense infiltration of stem cell type, showing very numerous mitotic figures. In several, liver and kidneys were infiltrated by similar cells.

Vertical transmission of Moloney leukæmia in mice is through the maternal, not the paternal, line, and predominantly via the milk[4,6]. It is noteworthy that in the present case transmission was from the inoculated mother. Reciprocal fostering, and other tests, are in progress, with the object of determining the route of transmission in rats.

RADIOBIOLOGY

Estimation of the Total-Body Load of Cæsium-137 in Japanese People

ANALYSIS of post-mortem samples for cæsium-137 has been carried on since 1958 at this Institute. Samples were selected because a whole-body counter was not available in Japan at the start, and now such counters are limited in number and are not mobile. Breast muscles from autopsies are used for analysis and the activity of cæsium-137 is measured by a low-background β-counting technique[1] after radiochemical separation[2].

Table 1. DISTRIBUTION OF COMMON CÆSIUM IN HUMAN BODY

	Cs (mμgm/gm fresh)	Cs/K, ($\times 10^4$)
Muscle	29·5	1·32
Soft tissues	12·7	0·98
Bone (with marrow)	15·7	0·91
Total body	20	1·0

For the estimation of the total-body load, the relation between the concentration of cæsium-137 in muscle and the total-body amount must be known. It has been accepted in general that the cæsium unit (μμc. of cæsium-137/g potassium) in muscle multiplied by the total-body potassium makes the total-body load of cæsium-137 in μμc. This is not likely to be true since examination of the distribution of the stable cæsium in the human body[3] revealed the different ratios of cæsium and potassium in different tissues (Table 1). It suggests the necessary introduction of a correction factor of 0·76 in the foregoing calculation, so far as the distribution of cæsium-137 is assumed to be similar to that of the stable element. The results in Table 1 also afford another means of estimation if the body-weight of 56 kg is assumed as the average for Japanese adults; concentration of cæsium-137 in μμc./g fresh muscle multiplied by 38 gives the total-body load in mμc.

Either method of estimation can be used; however, the latter is preferable since the errors involved in the former are likely to be larger. In Table 2 are shown the estimates of the total-body load of cæsium-137 from autopsies obtained in Tokyo. The details for samples April–June 1960 are given in a previous report[4]. Measurement by a whole-body counter was made for the first time in Japan in April 1961[5] at the Japan Atomic Energy Research Institute, Tōkai, Ibaragi Pref., and the results were in good agreement with the values estimated from muscle analysis as presented in Table 2 in spite of the differences in subject and method.

Evaluation of mean levels of cæsium-137 in the human body can also be made indirectly by analysis of the diet. As previously reported[6], the factor between the total-body amount and the daily intake of the stable cæsium is 110; then the daily intake of cæsium-137 (μμc.) multiplied by 0·11 will give the total-body load (mμc.). The results of the analysis of actually consumed total diet samples collected from several sites in Japan in November 1961 showed the values of daily intakes ranging from 19 to 45 μμc. for urban adults (average, 29 μμc.) and from 28 to 52 μμc. for rural adults (average, 40 μμc.). The estimated values for the total-body load, 3·2 and 4·4 mμc., respectively, for urban and rural adults are in good agreement with the value of 3·8 mμc. in January 1962 which was obtained from muscle analysis.

In Table 2, a trend of increase in the total-body load can be observed towards February and March.

Table 2. ESTIMATES OF THE TOTAL-BODY BURDEN OF CÆSIUM-137 IN JAPANESE PEOPLE

Time		^{137}Cs in muscle (μμc./g fresh)	Total-body burden (mμc.) Estimated from muscle analysis	Estimated from diet analysis Urban	Rural
Apr.–June 1960	(27)	0·13	4·9		
Apr. 1961	(11)		4·1*		
Nov. 1961				3·2	4·4
Dec. 1961	(26)	0·10	3·8		
Jan. 1962	(20)	0·099	3·8		
Feb. 1962	(19)	0·145	5·5	5·6	5·3
Mar. 1962	(9)	0·20	7·6		
Apr. 1962	(25)	0·124	4·7		

* Measurements with a whole-body counter (ref. 5).
The figures in parentheses represent the number of samples.

This trend was also found in the daily intakes. The diet samples collected in February, 1962, showed considerable increases in the daily intakes, the values being 34–82 μμc. (average 51 μμc.) for urban adults and 40–64 μμc. (average 48 μμc.) for rural adults. This time-trend probably reflects the increase in fall-out cæsium-137 originating from the series of nuclear explosions by the U.S.S.R. in the autumn of 1961.

Examination of the distribution of the stable cæsium in the human body and diet provided a simple means of estimation of the total-body load of cæsium-137 irrespective of potassium concentration or the cæsium unit under equilibrium or near equilibrium conditions. The expression of the concentration of cæsium-137 in terms of potassium may lead to confusion because since this has been introduced another question on the discrimination between cæsium-137 and potassium arises in the various phases of biological systems.

Effect of Exposure to Ionizing Radiation on Creatine Concentration in Human and Rat Erythrocytes

ALTHOUGH several reports concerning changes in the concentration of creatine in plasma, serum, and whole blood under various pathological conditions[1] as well as after exposure to ionizing radiation[2] have been published, to our knowledge no published results with regard to changes in the creatine concentration in erythrocytes are available.

Six groups of rats of the Sprague–Dawley strain were used; each group consisted of 4 rats and each rat weighed 300–350 g. Each rat was given a single pelvic irradiation of a midline dose of 0 (sham-groups 1 and 2), 500 (group 3), 1,000 (group 4) or 1,500 r. (groups 5 and 6), through an anterior and posterior arrangements of ports measuring 4 × 4 cm. The radiation was delivered from an X-ray tube operated at 220 kV and 20 m.amp without filtration. The midline dose-rate through each port in a rat phantom of tissue equivalent substance, 3·5 cm thick, was 102 r./min. During the entire experiment the rats were kept in individual metabolism cages and on 'Purina' animal diet and water *ad libitum*. Approximately 0·3–0·4 ml. of blood was obtained at various times by transection of the tail (Fig. 1) and collected in heparinized pipettes. After separation of the blood sample into plasma and packed cell fractions, the cells were washed twice with 2·5 ml. of saline. Creatine was determined in 0·05 ml. of plasma or packed cells by the 1-naphthol-diacetyl procedure[3] after the precipitation of protein with barium hydroxide and zinc sulphate[4]. Urinary creatine and creatinine were determined by the method used by Gerber[5], but with slight modifications, namely, the *p*H of the citrate buffer was 3·9 ± 0·1 instead of 3·3 ± 0·1 and 50 mg of 'Norite' charcoal was used instead of 200 mg.

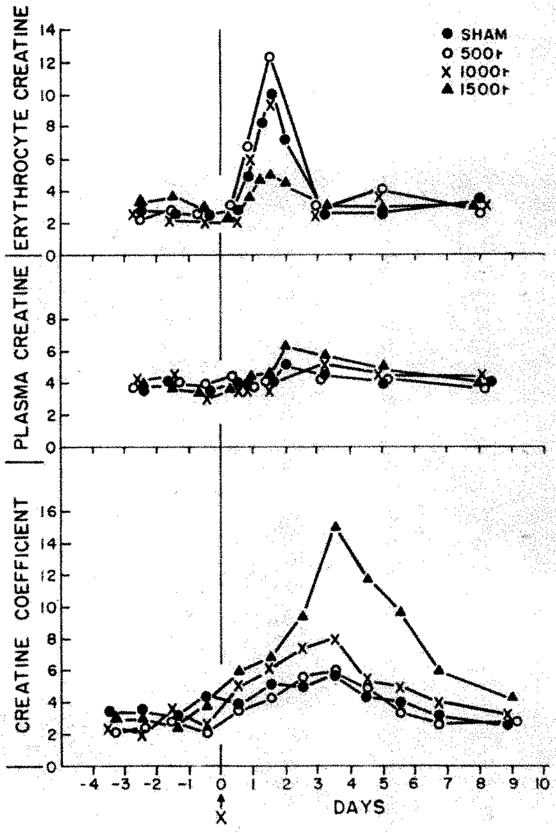

Fig. 1

In order to show that changes in erythrocytic creatine concentration also occur in irradiated human beings, serial determinations of creatine in red blood cells were made on blood samples obtained from patients before, during, and after their course of radiotherapy for various malignancies (Table 1).

Fig. 1 shows plots of erythrocyte creatine concentration, plasma creatine concentration, and urinary creatine coefficient (the ratio of the urinary creatine to creatinine concentrations) as a function of time at different doses of radiation. The means of the maximal values of the concentration of creatine in erythrocytes of the sham-irradiated group is significantly higher than that of the 1,500-r. irradiated group, whereas comparable values for the urinary creatine

Table 1. CREATINE CONCENTRATION IN ERYTHROCYTES OF PATIENTS GIVEN RADIATION THERAPY

Interval after initial irradiation (days)	Creatine concentration in mg/100 ml. of packed cells Patient No. 1	Patient No. 2	Patient No. 3
1–10	5·0	—	5·6
11–15	—	10·1*	11·2*
16–20	5·4	8·5*	6·1
21–25	7·3	8·1*	6·8
26–30	6·6	10·0*	11·0*
31–35	10·4*	*9·2**	7·3
36–40	*13·9**	—	*8·8**
41–45	19·1*	11·1*	8·4*
46–50	6·8	—	6·5
90–100	6·0	6·0	5·5

Patients No. 1 and 2 were given cobalt-60 rotational pelvic therapy with daily tumour doses of 200 r. for bladder and rectal cancers, respectively; patient No. 3 was given 2 MeV fixed beam thoracic therapy with 30 daily tumour doses of 150 r. for Hodgkin's disease.

3–4 blood samples were obtained on successive days prior to initiation of therapy from each of these patients. The mean ± standard deviation of these base-line values were: 6·32 ± 0·34 (patient No. 1), 5·80 ± 0·20 (patient No. 2) and 6·08 ± 0·38 (patient No. 3).

* Significantly elevated values at the 5 per cent confidence-level.

Figures in italics represent the value of the last sample obtained during the period of therapy.

coefficient are higher in the group irradiated with 1,500 r. than in the sham-irradiated group. The means of the maximal value of the plasma creatine concentration in the sham-irradiated and X-irradiated rats do not differ significantly at the 5 per cent level.

The results of serial determinations of creatine concentration in the erythrocytes of three patients given radiation treatments for various forms of malignancies are shown in Table 1.

These observations indicate that under the conditions of radiation therapy used here, the concentrations of creatine in erythrocytes rises after 2–3 weeks of therapy.

In the animal experiments the erythrocytic creatine concentrations rise only in the sham-irradiated rats and in rats exposed to 500 and 1,000 r., whereas in rats exposed to 1,500 r. a marked fall in the erythrocytic concentration of creatine occurred in comparison with the sham-irradiated rats. The response observed in sham-irradiated rats is probably due to the restraint imposed on the rats during sham-irradiation.

Biosynthesis of Creatine by the Kidney

THE chemical nature of the precursors contributing to the biosynthesis of creatine has been established as the result of *in vivo* experiments by Bloch *et al.*[1,2] and DuVigneaud *et al.*[3] as well as by the experiments with tissue slices and homogenates by Borsook and Dubnoff[4–6]. The last-named investigators also demonstrated that, in the mammal, the kidney is the major site of glycocyamine formation[4,5]; a slight transmethylating activity was also detected at this site. Baker and Miller[7] also reported that the kidney is able to synthesize creatine although at a level exceeding that noted by Borsook and Dubnoff. It appears to be the present prevailing point of view that the kidney does not contribute significantly to the formation of creatine from glycocyamine[8]. Evidence to the contrary, derived from experiments with perfused rat kidneys and eviscerated rats, is presented in this communication.

Rat kidneys were perfused according to a modification of the procedure devised by Weiss *et al.*[9], except that the vena cava and aorta rather than the renal artery and vein were cannulated. Eviscerated rats were prepared according to Ingle's technique[10]. L-Arginine-guanido-^{14}C and glycine-2-^{14}C were used as metabolic precursors of creatine. Creatine and glycocyamine were isolated from blood and kidneys by deproteinizing with picric acid and subsequently separating arginine, creatine and glycocyamine by paper chromatography. Arginine was separated from glycocyamine and creatine in a solvent system containing butyl acetate/acetic acid/ethanol/water, 3 : 2 : 1 : 1 (by volume)[11], and the arginine spot was cut off and eluted after development of the chromatogram. The remainder of the paper strip containing the composite spot of creatine and glycocyamine was then rechromatographed in a solvent system composed of phenol/water/acetic acid (plus a few crystals of versene), 80 : 20 : 0·6 (by volume). The creatine and glycocyamine spots were excised and eluted. The specific carbon-14 activities of the 3 metabolites thus separated were then determined. The chemical concentration of arginine and glycocyamine was determined by the method of Van Pilsum *et al.*[12] and that of creatine by a previously published method[13]. The isotope distribution in creatine and glycocyamine was ascertained as follows. (*a*) Glycocyamine was degraded to glycine, carbon dioxide and ammonia by an adaptation of the method described by Miller and Bale[14] for the degradation of the guanido group of arginine. Glycine was isolated from the reaction mixture by paper chromatography and eluted from the developed paper strip for the determination of the specific activity of carbon-14. The chemical concentration of glycine was determined by means of the ninhydrin reaction. The guanido carbon atom (carbon dioxide) was isolated from the reaction mixture as barium carbonate. (*b*) Creatine was degraded to oxalic acid and methyl guanidine by a method published elsewhere[15].

The data shown in Table 1 indicate that the activity of carbon-14 derived from the methylene carbon atom of glycine and the guanido carbon atom of arginine is incorporated by the kidney into creatine in both types of experimental preparations. The ratio of the specific activity of the guanido carbon atom to that of the methylene carbon atom is nearly identical for glycocyamine and creatine, thus lending further support to the view that the activity of carbon-14 found in creatine is the result of *de novo* synthesis. In all the experiments shown in Table 1 the specific activity of glycocyamine is several times that of creatine. This difference in specific activities, at least in the case of the kidneys, is probably largely attributable to the considerably greater size of the creatine pool (6·0 ± 3·3) as compared with the size of

Table 1. INCORPORATION OF CARBON-14 INTO CREATINE AND GLYCOCYAMINE

Type of experimental preparation	^{14}C-labelled amino-acid used	Source of creatine and glycocyamine	Creatine: Creatine	Creatine: Glycine moiety	Creatine: Guanido carbon atom	Glycocyamine: Glycocyamine	Glycocyamine: Glycine moiety	Glycocyamine: Guanido carbon atom	Arginine
Eviscerated rat	L-Arginine-guanido-^{14}C (5 μc.)*	Kidney	2,470			9,370			
		Blood	65			8,600			5,520
Perfused kidneys	L-Arginine-guanido-^{14}C (3 μc.)	Kidney	2,400			9,600			5,127
	Glycine-2-^{14}C (15 μc.)†	Blood	3,100	13	57	1,130	59	240	
	L-Arginine-guanido-^{14}C (6 μc.)‡	Blood	870	< 4	700	4,100			2,200

All values shown represent specific activities of carbon-14 expressed as c.p.m./μmole.
* This experiment was terminated 105 min. after the administration of carbon-14-labelled arginine.
† This experiment was terminated 75 min after the administration of carbon-14-labelled amino-acids.
‡ This experiment was terminated 95 min. after the administration of carbon-14-labelled arginine.

the glycocyamine pool (0·75 ± 0·24). (The values for the pool sizes are given as µmole/g net weight of tissue.) Different rates of isotope incorporation may also contribute, although to a much smaller extent, to the difference in specific activities. In comparing the two types of experimental preparations, it is noteworthy that the ratios of the specific activity of creatine to that of glycocyamine are of a similar order of magnitude.

BIOLOGY

Total Mammectomy in Female Mice and Rats

THE total removal of the mammary glands in small laboratory animals has repeatedly been tried, however without much success[1–3]. This communication describes a method for the complete ablation of all mammary glands in female mice and rats.

Female mice, 19–23 days old of the inbred strains $C_{57}BL$, WLL, O_{20}, DBA_f and the hybrids (♀ O_{20} × ♂ DBA_f)F_1 were used. The rats used were 18–20 days old F_1-hybrids between the inbred strains *U* and *R*, Amsterdam.

Bromethol in saline was used for anæsthesia with the addition of ether if necessary. The anæsthetized animals were fixed, ventral side up, on a cork board and the skin was drenched with 70 per cent alcohol. The incision was made along the ventral midline, from just above the clitoris to the root of the neck. Two lateral incisions were then made. The first was about 1 cm long from the upper end of the median incision and almost perpendicular to it, well above the first nipple, towards the right forelimb. The second started with the prolongation of the lower end of the median incision, around the vaginal and anal openings and as close to them as possible, to the base of the tail; from there laterally along the dorsomedial aspect of the thigh to about the midpoint of the hind leg. One at a time the resulting skin flaps, with all mammary glands attached, were carefully separated from the body-wall by blunt dissection. In removing the skin in the inguinal region, special attention has to be paid to the sexual fat pad. The dissection of this fat tissue from the underlying muscle layer has to be done very carefully, without damaging the very thin muscle layer, otherwise a hernia will develop. Another point which deserves careful attention is the fat tissue in the anal region. Incomplete removal of these parts of the fatty deposits may be the main source for unsuccessful operations. Finally, the fat tissue attached along the dorsomedial line of the thigh was cut off and the skin flap freed completely. This flap was then pinned to the cork board, exposing area of the nipples in the inguinal region as well as the larger part of the fat pad. The method of DeOme *et al.*[4] for clearing the fat pad of the fourth mammary gland was now used with slight modifications. The incision through the fat pad was made ventrally to the lymph node. No cauterization of the blood vessel was done; a slight pressure before cutting proved to be sufficient to avoid bleeding. The area containing the fourth and fifth glands, including the adjacent portions of the fat pads and the surrounding loose connective tissue, was now excised *en bloc* with fine scissors. The nipples were removed at the same time, leaving tiny holes in the skin.

The next step was to expose the first, second and third mammary glands. The skin flap covering these mammary glands was carefully separated from the underlying tissues. The median branch of the thoracic blood vessel was then ligated and severed. The ablation of the first mammary gland does not present difficulties, providing that the cutaneous incision is made at the proper place, that is, high enough. The second and third mammary glands were then removed *en bloc*. For this purpose an almost rectangular incision was made. Two longer arms of this incision run along and immediately ventrally to the thoracic lateral and thoracic media blood vessels, so that the latter one remains included in the area to be excised. Two shorter arms of the incision were made perpendicular to the first ones; the upper incision well above the second nipple and the other below the third nipple. The previously ligated blood vessel was removed together with both nipples, the loose connective tissue and the fat tissue from this region.

After ablation of all mammary glands from one side of the body, the exposed skin flap was moistened with saline, and put back in place. Ablation of the mammary glands on the other side of the body was then done in the same way. A non-sterile white cotton was used for sutures. No special post-operative care was necessary.

The surgical procedure in rats was essentially the same as in mice. In view of the different anatomical situation with three pairs of mammary glands in the inguinal region, a greater amount of the fat tissue had to be removed in order to assure a completeness of the operation. The incision through the inguinal fat tissue was made about 1 cm laterally from the fourth nipple. Still greater care was necessary to remove as completely as possible all the fat tissue from the sexual and anal region.

The completeness of the mammectomy was controlled at the end of the first pregnancy using the hormonal stimulus during pregnancy for the development of rests and of possible rudimentary mammary glands.

At autopsy a careful inspection for rests of the mammary glands was made. Suspected areas were dissected, stained with hæmatoxylin and examined under the dissecting microscope.

The results of mammectomy in mice and rats are summarized in Table 1. Here it can be seen that the mammectomy was complete in all but one mouse. In this case a small fragment of mammary tissue was left in the region of the third mammary gland. In the unsuccessfully operated rat, the removal of the third mammary gland was incomplete.

Table 1. RESULTS OF MAMMECTOMY IN FEMALE MICE AND RATS

Strain of mice	No. of animals operated	Successful mammectomy	Mean age when killed (days)
$C_{57}BL$	11	11	84
WLL	10	10	64
O_{20}	10	10	75
DBA_f	12	11	64
(♀ O_{20} × ♂ $DBA_f)F_1$	9	9	96
Total	52	51	
Rats			
(♀ U × ♂ $R)F_1$	10	9	81

Relationship between *in vivo* Rumen Gas Composition and Feed Efficiency of Calves

THE efficiency of feed utilization by cattle is important because feed amounts to 80 per cent of the cost of beef production[1,2]. There is a need for an improved method of estimating the efficiency of feed utilization by ruminants[1,3] because direct determinations by traditional feed efficiency studies are expensive[4,5] and subject to large errors[5,6]. Attempts have been made to estimate the efficiency of feed utilization by correlating it with physiological criteria such as blood type and composition[1,3] and *in vivo* volatile fatty acid production[7]. However, such criteria have not been adopted for one or more of the following reasons: low heritability, low association with efficiency, difficulty in obtaining and preserving samples and the cost of analyses.

Rate of digestion has been related to gas composition *in vitro*[7] and rapid digestion has been associated with high bloat incidence[12]. Therefore, when bloat scores were found to be correlated with the carbon dioxide and methane (r = 0·898 and − 0·905, P = 0·01) content of rumen gas[9], it appeared that rumen gas composition might be related to efficiency of feed utilization.

Over a two-year period, twenty-six animals, some grade beef but mostly pure-bred Jerseys of diverse genetic origin, were feed-tested from 180 to 240 days of age. The daily ration consisted of alfalfa hay fed *ad libitum*, grass and legume silage at three times the amount of hay consumed plus five pounds of mixed grain concentrate. Pounds of dry matter consumed by each animal were determined and the total digestible nutrient consumption calculated using Morrison's table[5]. Efficiency was calculated as gain in weight per pound of total digestible nutrient consumed.

At the conclusion of the feed test period the animals were fasted for 12 h and then fed alfalfa hay. One hour later a gas sample was withdrawn from the rumen at the left flank by reduced pressure and analysed by gas-solid chromatography[10]. After gas collection the animals were given silage and grain. Gas samples were taken daily from each animal for five consecutive days, and carbon dioxide, methane, nitrogen, oxygen and hydrogen were determined. Correlation coefficients were calculated between feed efficiency and carbon dioxide, methane, the carbon dioxide–methane ratio, and the carbon dioxide–methane difference. Hydrogen, nitrogen and oxygen did not show any relationship to efficiency of feed utilization.

Simple correlation coefficients between rumen gas characteristics and feed efficiency are shown in Table 1. The difference and the ratio between the carbon dioxide and methane contents were calculated, but there was no advantage from the additional calculations.

Table 1. SIMPLE CORRELATION COEFFICIENTS (r) BETWEEN RUMEN GAS CHARACTERISTICS AND FEED UTILIZATION EFFICIENCY FOR 26 6-MONTH OLD CALVES

Rumen gas characteristic	r*
Methane	−0·428
Carbon dioxide to methane ratio	0·425
Carbon dioxide minus methane	0·458
Carbon dioxide	0·458

* Significant at the 5 per cent level.

The reasons for the significant association between rumen gas composition 1 h after feeding commenced and feed efficiency have not been determined in this work. However, during the first 2 h after feeding a rapid increase in the carbon dioxide content of rumen gas[4,9] and a concurrent decrease in rumen pH, which was accelerated by feeds of higher digestibility[9,11], have been observed. The increased rate of pH drop was undoubtedly caused by increased acid production, which in turn would be accompanied by greater carbon dioxide evolution due to higher fermentation-rate[4], decreased solubility and reaction with carbonates. Accordingly a higher carbon dioxide content of rumen gas 1 h after feeding would indicate a higher rate of digestion. A higher fermentation-rate could allow an animal to increase feed intake due to a decrease in retention time, but in this group the more efficient animals had lower total digestible nutrient consumption (r = − 0·537, P = 0·01). Therefore they appeared to extract more nutrients from each unit of food consumed rather than to have consumed more feed and hence to have reduced the proportion of energy used for maintenance. Somewhat the same reasoning would apply to the association between methane and feed efficiency because the principal components of rumen gas are carbon dioxide and methane. Because the volume of methane produced followed the same pattern as the proportion of methane[4] it is possible that animals with a higher percentage of methane also produced a greater volume of methane. Accordingly some of the association between gas composition and feed efficiency might be due to a higher loss of energy as methane in the less efficient cows.

This is believed to be the first report of a significant correlation between *in vivo* rumen gas composition and efficiency of feed utilization. The collection of rumen gas from intact animals has distinct advantages over the collection of gas from artificial rumens because gas production occurs under normal conditions and hence few assumptions are required and many possible errors are eliminated. Though the heritability of rumen gas composition was not determined, the animals differed significantly ($P = 0{\cdot}01$) and gas composition rankings did not change when groups of animals were sampled at widely spaced intervals[9]. The large inherent errors in determining the efficiency of feed utilization[5,6] and factors other than digestion which play an important part in the physiology of feed utilization undoubtedly reduced the correlations.

Rumen gas analyses could be used to replace traditional feed efficiency tests on breeding animals if a higher correlation could be obtained. This would permit screening of much larger populations than is feasible with the present expensive and inaccurate method. Because rumen gas can be readily collected from intact animals, and because it can be conveniently stored and inexpensively analysed with precision, it is anticipated that this measurement will be useful in conjunction with studies concerning the efficiency of feed utilization and the causes of differences between animals.

Energy Expenditure of Grazing Sheep

THE results of several field experiments[1] have indicated that the energy expenditure of sheep at pasture in equable climates is 1·1–2·0 times larger than that of stall-fed animals. The distances travelled by grazing sheep and the energy cost of locomotion have been measured[2], and it appears that walking would increase the daily energy expenditure by 5–10 per cent. This leaves the energy cost of grazing *per se* and of the animal's reactions to its environment to be accounted for; the first measurements of the former can now be reported.

Two sheep were allowed to graze normally for a week. A patch of turf 1·0 × 1·5 m was then dug up and relaid on the floor of a respiration chamber. The sheep, which had both been trained for such work, were then, one at a time, placed in the respiration chamber (ambient temperature 22° C; water vapour pressure 10–15 mm mercury; still air) and their respiratory exchange measured by the confinement method[3] during five successive 30-min periods. The sheep were restrained from grazing during the first and third periods, usually rested voluntarily during the fifth period, and grazed during the second and fourth periods. Thus any changes of the metabolism due to time of day or to metabolism of ingested food would not affect the measurement at issue. Afterwards, the grass on a 1·0 × 1·5 m patch was cut and given to the sheep in the chamber over the course of an hour.

Five different types of pasture have been used. These ranged from one containing dry mature grass (*Paspalum dilatatum*) with a few small green clover plants (*Trifolium repens*), which was grazed slowly with an intake (estimated by clipping) of about 40 g dry matter per hour while in the respiration chamber, to one containing lush young grass (*Poa annua*), which was grazed avidly with an estimated intake of 130 g dry matter per hour.

The 'resting' metabolism of the sheep was not dependent on whether they were restrained or rested voluntarily, nor on the level of carbon dioxide in the apparatus (never more than 3 per cent). The energy cost of grazing was calculated[4] from the mean increments of carbon dioxide production and of oxygen consumption between the 'resting' and grazing periods; methane production and nitrogen catabolism, which together contribute less than 2 per cent to the calculation of heat production, were ignored.

The energy expenditure of the sheep always increased during grazing and fell again during the subsequent rest period, but there was no significant change when the pre-cut grass was given to the sheep. The grazing increment did not vary significantly from sward to sward, and had a mean value of $0{\cdot}62 \pm 0{\cdot}04$ kcal/h/kg body-weight for a 29-kg Merino ewe and of $0{\cdot}84 \pm 0{\cdot}12$ for a 53-kg Merino wether. When considering the daily expenditure of a sheep at pasture these values must be reduced to allow for the fact that only one-third of the day is spent in grazing[5]. They then amount to 12 and 18 per cent of the heat produced by the small and large animal, respectively, when hand fed.

These experiments are being continued with other sheep and pastures, but it may be concluded tentatively that the energy expended by a sheep in walking and grazing is not likely to be more than one-quarter of its heat production when stall-fed. This expenditure would not wholly account for the apparent additional energy requirements of grazing sheep[1] mentioned here.

Laboratory experiments[6] have shown that the metabolism of sheep can be increased two-fold when they are placed in an environment to which they are not accustomed. It remains to be determined whether climatic factors or the social environment can stimulate the metabolism of grazing sheep similarly and so increase their energy requirements substantially.

I thank Messrs. J. Taylor and R. Raabe for their assistance.

Effect of Mucus on the Swimming-Rate of Sperms

It has been shown that bull sperm swim more slowly in mucus from the cow's uterine cervix than they do in saline[1]. This slowing-down might be an effect of hydroxyl ions, since the pH of mucus is rather high[2], and it has been claimed that media above pH 8·3 are very harmful to sperm[3]. Alternatively, it might be due to the presence of inhibitory substances in solution, or to the visco-elasticity imparted to the secretion by very large flexible molecules.

Our present experiments indicate that probably it is the last of these factors which is the most important.

We have carried out experiments on the effects of varying the pH of simple saline/phosphate mixtures on the swimming-rate and survival of bull sperm. In the majority of individual experiments, and in the mean for all experiments pooled, it appeared that initially both the swimming-rate and percentage of motile sperm were higher at pH 8·5 than at 7·5 and 6·5 or in unbuffered saline. Although this advantage was transitory, its existence precludes explanation of the slowing down of sperm by mucus as a simple effect of pH.

Œstrous mucus may be readily separated into a gel and a supernatant by centrifugation at 44,000g for $1\frac{1}{2}$ h; the viscous supernatant yields a further precipitate after 4 h, at 103,000g [4]. The final supernatant is essentially non-viscous, but contains the soluble material, mainly protein and low molecular weight substances, present in the native secretion[4]. The behaviour of spermatozoa in this supernatant was examined.

The pH, after addition of a suitable amount of semen, was in the range 7·4–7·7. Supernatants from two separate samples of mucus were tested. The first of these was used as diluent for three samples of semen, and the sperm in each case were found to swim at about four-fifths the saline rate at the same cell concentration, as compared with about two-fifths the saline rate in the whole mucus. In the second experiment two samples of semen from different bulls were made up each at two dilutions, 20,000 and 5,000 sperm per µl., in saline and mucus supernate. Rates were measured at the beginning and also at the end of 1 h, and at the end of 3 h. At the beginning of the experiment the rate was considerably higher in mucus supernate than in saline at both dilutions, about 20 per cent higher at 20,000 and 30–60 per cent higher at 5,000. This difference persisted at the end of an hour, but at the end of 3 h the rates in mucus supernate were similar to those in saline.

Finally the supernatant from a large pool of a number of separate samples of mucus was tested. The rates of sperm from five samples of semen from five different bulls were higher in this material than in saline, in one case nearly twice as high. Although the difference diminished at the end of an hour the rates in mucus supernate were all still higher than those in saline.

It appears, therefore, that neither the high pH nor the presence of soluble-inhibiting substances can be considered as an explanation of the slowing down of sperm by mucus. The gel which may be spun out of the native mucus contains, after repeated washing with saline, very little of the soluble substances in the original secretion, but after appropriate dilution with saline retains the rheological properties of the mucus. It appears to be a complex of sialomucopolysaccharide and protein[5]. In this material the spermatozoa behave as they do in native mucus, both as regards their velocity[1] and their orientation along strain lines[6].

Abnormal Crystals in *Amoeba lescherae*

For the elucidation of a problem that I was investigating, it was necessary for me to have the developmental stages of *Amoeba lescherae*. A quick method of obtaining these is to use material from a culture grown under natural conditions[1] containing a large supply of mature amoebæ. It will be remembered that in such a culture, or in a catch procured from a natural source in summer, there will be found[1]: (1) mature and ageing adults; (2) encysted developmental stages of every variety; (3) spores; (4) possibly actively moving developmental stages. In the mature individuals there will be spores and differentiating spores. A sudden change in the pH (ref. 2) brought about by any agent not detrimental to the culture will kill off all the adults and so release any spores present in those adults. A study of the phenomenon is best made in Petri dishes (4 in. × 1 in.). After the lapse of a varying period of time (a week, more or less) subsequent to the changing of the pH, a search with the No. 7 objective water immersion lens will reveal large numbers of hatching spores, and creeping amoebulæ of various ages. But all these have a tendency to encyst, after a feed, especially at night, so the best time to search the Petri dish for active specimens is towards noon and early afternoon.

I chose for my source of material a set of three amoeba cultures grown in shallow Petri dishes (7 in. × 1 in.) which, with a hand lens, were seen to be luxurious. Because of what I found when I examined the adults under higher magnification, it will be necessary to state the history of these Petri dish cultures. The top culture was started on February 12, 1961, in the usual way by putting adult amoebæ plus culture fluid into Glasgow tap water containing boiled wheat grains. Food was renewed on June 12, 1961. On September 1, 1961, the culture was passed through a butter muslin net sieve to remove old grains and matted mould growth. The filtrate was so luxurious in adults that it was divided into three sub-cultures.

In January 1962 the phenomena to be described were discovered. I began by pipetting material from the top dish of the three stacked cultures for examination under a Greenough binocular. There was luxuriant growth, but the amoebæ had a yellowish tinge unlike the usual bluish one. Many looked very young; therefore, very transparent. Seen in a rectangular glass block with a dish-like bottom under No. 3 objective by transmitted light they presented a startling appearance. Some of the transparent ones had a mottled look, others were heavily packed with cytoplasmic inclusions. The most conspicuous cytoplasmic inclusions of adult *A. lescherae* are crystals and nutritive spheres (= excretory spherules = refractive spheres), the size of each being proportional to the age of the amoebæ, large nutritive spheres betokening adults. These specimens, however, contained abundant and abnormally large crystals, many times the size of those normally present; the largest, cube-shaped crystal measured 11μ in diameter, and apparently no nutritive spheres. They moved rapidly, quickly attaching themselves to the substratum, and fed readily.

So the questions arise: Has the nucleus stopped functioning? Is the absence of nutritive spheres due to a failure of the nucleus to emit chromidia for the production of spores (in the *proteus* group of *Amoebæ* spores are formed by the utilization of nutritive spheres by chromidia)? A detailed examination of many nuclei showed them to be perfectly healthy. *Amoebæ* were found with two nuclei, even with four; chromidia were present in some, as were blocks of chromatin around the contractile vacuole: all perfectly normal and healthy.

Fortunately crystals are easily dissolved in alcohol, and acetic alcohol is especially effective in clearing the cytoplasm of crystals. Therefore it was easy to find out if the nutritive spheres were hidden by the excessive masses of crystals. After all the crystals had been dissolved out, the cytoplasm looked ghostly —there were no nutritive spheres, the nucleus stained well in aceto-carmine.

The amoebæ of this culture were then excreting plentifully by their large and numerous crystals, but were failing to make any provision for their spore formation cycle. The fission cycle, so far as I have been able to observe, seems unimpaired. Further observations are being made to find out if this can go on indefinitely. So far, sub-culturing of the culture has been successful.

Of the remaining two Petri dishes the second down in the stack of three contained a few normal individuals possessed of ordinary crystals and nutritive spheres. These normal ones can easily be picked out under No. 10 magnification.

The lowest culture in the stack contained many more normal individuals which could be induced to produce hatching spores, etc., by the alteration of the *p*H.

The abnormal conditions obtaining in these three cultures are evidently of cytoplasmic and not nuclear origin. The anabolic products are being used to maintain this abnormality instead of to form nutritive spheres, a prerequisite for spore formation, and the excretory products of this are going to the formation of these large crystals.

Microscopical Examination of Living Cells

MICROSCOPICAL examination of living cells such as small marine eggs, amœba and isolated cells from larger organisms frequently involves the construction of suitable chambers. After years of struggle with fragments of coverslip, paraffin wax, 'Plasticine' and polythene film, a very simple and versatile design of microscope slide chamber has been developed. The method is to cut paraffin wax sections on a microtome at the required thickness and then to mount the sections of wax on a microscope slide from warm water. The paraffin blank can be cast with a cylindrical hole to give a non-perfusing chamber, as in Fig. 1, or otherwise shaped to give perfusion chambers as in Fig. 2. The mounted sections should be dried at room temperature in a desiccator and then warmed slightly to consolidate the section to the slide. A selection of chambers from 2μ to 35μ can be easily prepared and stored. I have found chambers with enough wax to support a 1½ in. × ⅞ in. coverslip satisfactory. The skill necessary to fill a chamber 10μ deep without bubbles or wastage is easily acquired. Fragments of coverslip, overlapping the ends of the coverslip and the slide, provide reservoirs for perfusion.

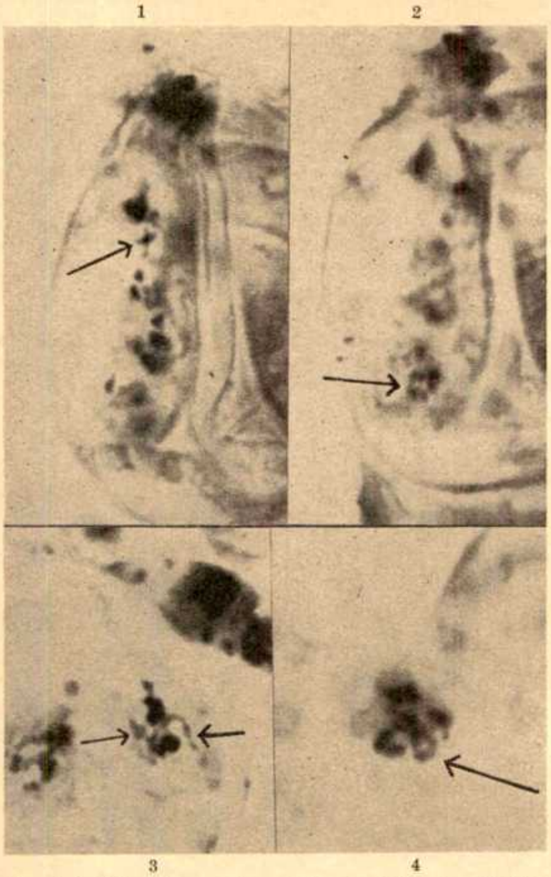
Use of Camphor-induced Polyploidy to determine the Place of Meiosis in Fungi

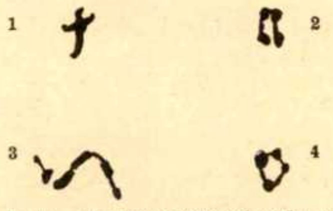
NUCLEAR divisions in the oogonia and antheridia of oomycetes have previously been reported to be mitotic[1]. Since the chromosomes are very small, it is not easy to determine whether they are meiotic bivalents or highly condensed mitotic chromosomes. It appears that it has not yet been possible to count the chromosomes in vegetative divisions because the chromosomes do not normally condense in these divisions.

In *Pythium debaryanum*[2], a ring of four chromosomes was observed in a late metaphase in the oogonium. This was taken to be conclusive evidence that the nuclear divisions in the oogonium are meiotic.

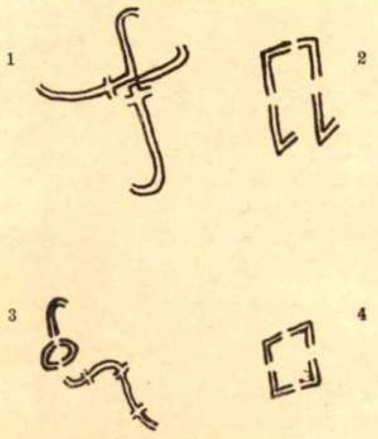
Observations on *Phytophthora cactorum* showed metaphases in the oogonium and antheridium with approximately ten chromosomes. In order to obtain evidence as to whether these divisions were mitotic



Figs. 1–3, *Phytophthora cactorum*; Fig. 4, *Achlya* sp., all after camphor treatment. Figs. 1 and 2, part of a tetraploid oogonium at two different foci showing quadrivalents (arrowed) (× *c.* 2,400). Fig. 3. Nucleus from tetraploid oogonium showing two multivalents (arrowed) (× *c.* 2,400). Fig. 4. Tetraploid nucleus from antheridial branch showing ring of four chromosomes (arrowed) (× *c.* 3,800)



Figs. 1*a*–4*a*. Drawings of arrowed configurations



Figs. 1*b*–4*b*. Possible interpretations

or meiotic, cultures of *Phytophthora cactorum* were treated with natural camphor. Cytological preparations were made using the aceto-orcein squash technique. Some of the oogonia and antheridia obtained after treatment with camphor had larger nuclei than untreated oogonia and, under favourable conditions, configurations of more than two chromosomes could be recognized (Figs. 1, 1*a*, 1*b*, 2, 2*a*, 2*b*, 3, 3*a*, 3*b*).

In *Phytophthora cactorum*, therefore, meiosis occurs in the oogonia and antheridia as in *Pythium debaryanum*.

The same method of inducing or selecting polyploid nuclei by camphor treatment was applied to a species of *Achlya* isolated from a local pond. Again, multiple associations were obtained in the oogonia and antheridia (Fig. 4, 4*a*, 4*b*), thus providing evidence that these divisions are meiotic.

Conclusive evidence has thus been obtained of meiosis in the oogonium and antheridium in two species belonging to the Peronosporales and one species belonging to the Saprolegniales. It seems probable, therefore, that this is the regular condition in the members of these orders, which must therefore be diploid in the vegetative phase. Similar evidence regarding the nature of these divisions might also be obtained by inducing structural changes by chemical or irradiation treatments.

Genetical observations on the Oomycetes are scanty, but such as they are, they are in accordance with the present cytological observations. Of particular relevance is the work of Buddenhagen[3] on induced mutations in *Phytophthora cactorum*. He obtained a number of mutants after ultra-violet irradiation, some of which were unstable when single zoospores were planted out, segregating into more extreme mutant types and also types approaching to the standard type. Such results could be explained if his original mutants were heterozygous for partially dominant genes. Somatic segregation by chromosome non-disjunction or somatic crossing-over could lead to the segregation of wild-types and the homozygous mutant types.

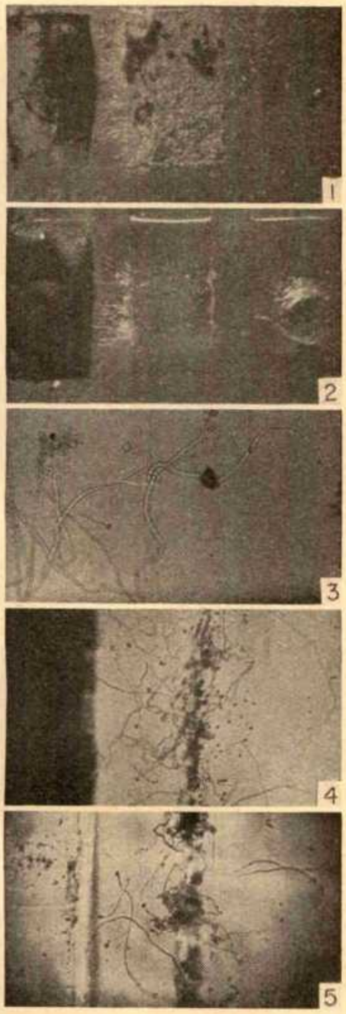
Chemotropic Response of *Antirrhinum majus* Pollen to Calcium

A RECENT review[1] on pollen tube chemotropism tentatively suggests that the chemotropic factor may be the same chemical entity in many plants. Figs. 1–5 are the evidence that the pollen tubes of *Antirrhinum majus* grow tropically towards a source of calcium. A stainless-steel mould was used to make sets of three depressions in nutrient agar[2] with each depression separated from the other by an agar wall 1 mm thick. The depressions are 3 mm wide, 5 mm long, and 3 ml. deep, with a 2-ml. thick layer of agar, underneath the depression. In Fig. 1 dry pollen was placed in the centre or pollen depression, nothing was added to the right or control depression, while solid calcium carbonate (used because of its low solubility) was placed in the left or test depression.



Figs. 1–5. Chemotropic response of pollen tubes of *Antirrhinum* to calcium. The calcium carbonate is in the left depression in Figs. 1, 2 and 4 and below the pollen tubes in Fig. 3. No calcium carbonate is present in Fig. 5

Pollen tubes grew well into the test wall, while few grew into the control wall. This procedure is referred to in the rest of this communication as the bioassay. In Fig. 2 single rows of pollen were placed in the pollen chamber adjacent to the test and control walls. Virtually all the pollen tubes on the test side of the pollen chamber grew into the test wall, whereas those on the control side remained within the pollen depression. In Fig. 3 pollen was placed on the surface of the nutrient agar in a line 1 mm from the outer wall of one of the depressions. Solid calcium carbonate was placed in the depression against the outer wall (out of view below picture). Once again, almost all the pollen tubes grew towards the calcium carbonate while very few grew in the opposite direction. Figs. 4 and 5 are essentially the same as Fig. 3, except that the pollen was placed in a slit made in the agar. With calcium carbonate against the outer wall of the depression (left side of picture), the pollen tubes grew towards the source of calcium (Fig. 4), whereas in Fig. 5 with nothing in the depression the pollen tubes grew in both directions. These demonstrations of a chemotropic response to calcium require careful timing of pollen tube germination and growth in relation to the establishment of the concentration gradients of calcium.

Using the bioassay, it was found that calcium carbonate can be replaced by the nitrate, sulphate, chloride, gluconate, malate and caseinate. On the other hand, no response was obtained to the chlorides of magnesium, barium, strontium, sodium or potassium, or as reported earlier[2] to a large number of organic compounds, such as sugars, amino-acids, organic acids, plant growth hormones, and so forth. The response to calcium appears to be specific.

Calcium functions here as a chemotropic agent even though it also enhances the growth of pollen tubes as observed by Kwack and Brewbaker[3] and by us. The effect of calcium, however, is not simply an enhancement of the growth of those tubes which happen to start their growth in the direction of the source of calcium. In addition to the evidence presented in Figs. 1–5, it can be observed microscopically that pollen tubes which protrude from the pollen grain in the opposite direction to the source of calcium change their direction of growth until they are growing towards the calcium. Further, neither sucrose nor yeast extract, both of which enhance the growth of pollen tubes, induces a chemotropic response when sub-optimal concentrations are provided in the nutrient medium and additional amounts in the test chamber of the bioassay.

The gynœcium of *Antirrhinum* contains the following amounts of calcium, expressed as a percentage of the dry weight: upper one-third of the style, 0·51; middle one-third of the style, 0·50; bottom one-third of the style, 1·23; ovary wall, 1·3; and ovules plus placenta, 2·17. All these tissues, as reported elsewhere[2], elicit a strong chemotropic response in the bioassay described here. On the other hand, petals and stamens do not effect a chemotropic response; neither do they contain calcium in the amounts found in the gynœcial tissue. Thus, as a percentage of the dry weight, the amount of calcium in petals is 0·18 and in stamens 0·36. These figures, showing a relatively high level of calcium in the ovules, lend support to the conclusion that calcium is the chemotropic factor in this plant.

The pollen of the following species has also been found to respond chemotropically to calcium when tested in the bioassay: *Narcissus pseudonarcissus* and *Clivia miniata*. Although the evidence is not available, it seems possible that calcium is the chemotropic factor generally in flowering plants. This would explain the lack of specificity referred to in the introduction. The chemotropic response of pollen to calcium could also explain the unconfirmed reports[1] of the growth of pollen towards such substances as sodium malate, compressed yeast, diastase, and egg albumin on the basis that these preparations may have contained concentrations of calcium sufficient to induce a chemotropic response.

MICROBIOLOGY

Relationship of Fibrin Formation to Serum Bactericidin

In a previous communication[1] a clotting factor present in aqueous fibrin extracts was described. It was antigenically related to *C* reactive protein, which is found in the sera of patients suffering from acute infectious diseases. No antibacterial effect could be demonstrated with *C* reactive protein or aqueous fibrin extract. The bactericidal activity of serum has recently been reported to be localized in its β-lipoprotein fraction[2], and since in serum clotting factor becomes associated with β-lipoprotein[1], an attempt was made to relate this factor to serum bactericidin.

Pooled normal human serum was used. Dilutions were carried out with 0·9 per cent sodium chloride. Bacteria were grown in heart infusion broth at 37° C. One loopful of a 24-h culture was placed in 1 ml. of saline, and one loopful of the dilute suspension was used for inoculating 0·2 ml. of serum or dilutions thereof. Tubes were kept at room temperature (25–28° C). Aliquot amounts were streaked on heart infusion agar plates after 2 and 4 h. The plates were incubated at 37° C for 24 h. The bactericidal titre of a serum was established as the reciprocal of the dilution, killing 95–100 per cent of the bacteria after 4-h incubation.

It was found that Gram-positive bacteria, such as *Bacillus* and *Staphylococcus*, were more resistant than Gram-negative organisms of the genera *Aerobacter*, *Alcaligenes*, *Escherichia*, *Proteus*, *Salmonella*, and *Shigella*. Most sensitive proved to be a strain of *Escherichia coli*, which was afterwards used in all experiments. The inoculum of the dilute suspension contained $1{\cdot}5 \times 10^4$ *E. coli*. The bactericidal titre for this number of organisms of several sera used was 20–40. A saline control was included in each series of experiments.

Bactericidal activity was removed from serum by passing it through a Seitz filter pad, by heating it at 56° C for 30 min, and by incubating equal volumes of serum and of heparin or lytic factor[1] for 24 h at 5° C. Fifty units of heparin were used for 0·1 ml. of serum. The measure of potency of the lytic factor preparation was the ability of 0·1 ml. to prevent the clotting of an equal amount of oxalated plasma on the addition of one drop of 0·1 M calcium chloride. Lytic factor inactivated by heating at 70° C for 10 min was ineffective.

Potent clotting factor preparations elevated the bactericidal titre of some sera slightly, of others not at all, and were unable to restore the bactericidal property to heat-inactivated or Seitz-filtered sera. This may be explained by assuming that the amount of active material formed is contingent on some factor of limited availability, such as hæmolytic complement, which would be removed by filtration or heating.

As the result of combination of clotting factor with β-lipoprotein certain changes may be expected to arise. Thus, serum bactericidin is more heat-labile than clotting factor. Also, in the formation of the complex, clotting factor appears to be bound in such a way that it can no longer react with *C* reactive protein antibody. Serum freshly obtained from the recalcification of oxalated plasma produced a visible aggregate with this antibody, but the same serum, on standing for 2 h at room temperature, failed to react. The counteracting effect of heparin and lytic factor would seem to present the most convincing evidence for visualizing clotting factor as part o serum bactericidin.

Hæmolytic complement is apparently not required for bactericidal activity. Sera kept at 5° C for 3– weeks remained unchanged in bactericidin wherea only traces of complement were retained. No complement was left in serum on incubation at 37° C for 24 h, yet its bactericidal titre was lowered only from 20 to 10.

A relationship of fibrin clot production to bactericidal action has long been recognized. Gengou[3] found that uncoagulated cell-free plasma, obtained without the aid of anticoagulants, was not bactericida whereas the serum from the same blood was active Under normal physiological conditions there would be no need for such a substance, but when an injury is sustained and fibrin is laid down to wall off the area involved, the simultaneous release of a bactericide would certainly represent a device of great usefulness for the defence of the body.

This investigation was supported in part by a grant from the Kansas Heart Association.

Prophylaxis of 'Wet-Tail' in Hamsters

THOUGH the Syrian hamster (*Mesocricetus auratus*) is generally free from spontaneous disease[1] many laboratory workers have observed in their colonies outbreaks of fatal diarrhœa colloquially known as 'wet-tail'. This disease has been prevalent in the Wellcome Laboratories of Tropical Medicine, particularly in hamsters subjected to spleen biopsy during the course of screening compounds for leishmanicidal activity[2]. Indeed in some tests more than half the animals succumbed, most of them dying on the third, fourth and fifth post-operative days. In the early stages of the disease the animals are fractious and anorexic. Diarrhœa soon begins and causes the moist caudal area from which the disease gets its name. Death usually occurs within 48 h.

Autopsies performed on hamsters dying of 'wet-tail' revealed that in each animal the ileum, jejunum, colon, and rectum contained merely a little yellow semi-fluid material and some gas. Many animals had inflammatory lesions of the terminal ileum, often associated with similar lesions in the cæcum. In a few cases the cæcal mucosa was found to be ulcerated. No other lesions were consistently found. In healthy animals the small intestine was always filled with partly digested food, the cæcal contents were much thicker, and the colon was loaded.

Examination of the intestinal contents of both sick and healthy hamsters revealed comparable infestations with dwarf tapeworm (*Hymenolepis nana*) and with one or more of several species of protozoa (*Trichomonas muris*, *Giardia muris* and *Balantidium coli*)[3]. Dark-ground microscopy showed vast numbers of bacteria in gut contents removed from all parts of the alimentary canal. Large non-motile bacilli and spirochætes predominated. When agar, blood agar, and McConkey plates were seeded with gut contents from affected hamsters, heavy growths of *Escherichia coli* were invariably obtained. In contradistinction, similar cultures made from healthy animals grew only occasional colonies of *E. coli*, *Staphylococcus* and *Bacillus* spp. Tube agglutination tests were made on boiled suspensions of 11 of the *E. coli* isolates, using the commercially available polyvalent *E. coli* antiserum: 026, 55, 11, 119, 125, 126, 127 and 128. None of the strains was agglutinated.

Table 1. EFFECT OF NEOMYCIN SULPHATE ON THE MORTALITY OF HAMSTERS AFTER SPLEEN BIOPSY

	Treated		Untreated	
	No.	Per cent	No.	Per cent
Wet-tail	4	5·7	29	41·4
Drug toxicity	3	4·3	2	2 9
Other deaths	8	11 4	10	14 3
Survivors	55	78·6	29	41·4
Total	70	100 0	70	100 0

Supporting experiments showed that the growth of the *E. coli* strains isolated from hamsters dying of 'wet-tail' was inhibited *in vitro* by concentrations of neomycin sulphate greater than 8 μg per ml. Furthermore, it was found that hamsters of 40 g weight were able to tolerate daily doses of this drug as great as 50 mg, and that its administration had no effect on the leishmania infection. Starting on the day of spleen biopsy, therefore, half the hamsters used during a period of five weeks were given a daily intragastric dose of 10 mg of neomycin sulphate dissolved in 0·25 ml. of water. Those animals not given the drug received only water. The results of this test are shown in Table 1. The 78·6 per cent survival-rate in treated animals compares favourably with the 41·4 per cent in the untreated group.

Since April 1960, all hamsters used in the leishmanicide screen have been dosed daily with 10 mg of neomycin sulphate. The first dose is administered intragastrically in 0·25 ml. of water, immediately prior to spleen biopsy; the subsequent doses are given in the form of cheese pellets. These pellets are prepared in bulk, and each contains 10 mg of neomycin sulphate in 0·5 g of cheddar cheese. One pellet is dropped into each cage each day. A total of 2,724 hamsters has been used, and of these 2,353 (86·3 per cent) have survived. Only 29 (1·4 per cent) of the deaths observed were due to 'wet-tail' and these frequently occurred in hamsters which refused cheese. The remaining deaths were due to drug toxicity (7·7 per cent) and various other causes (4·6 per cent).

The results obtained in this work show that 'wet-tail' in hamsters resembles in many respects infantile diarrhœa, scouring in piglets and chickens, white scours in calves[4], and the recently described mucoid enteritis of rabbits[5]. The many similarities between 'wet-tail' in hamsters and similar conditions in other animals make it reasonable to suppose that in hamsters, too, *E. coli* can be the cause of fatal diarrhœa. This view is strongly supported by the effectiveness of neomycin sulphate in the prophylaxis of 'wet-tail'.

Alterations in the Carotenogenesis in *Staphylococcus aureus* after Adaptation to Pyrithiamine

IT has been reported recently[1] that *Staphylococcus aureus*, when cultured successively in media (glucose, 3·0 g; hydrolysed vitamin-free casein, 4·0 g; dipotassium hydrogen phosphate, 5·0 g; cysteine hydrochloride, 0·02 g; nicotinic acid, 0·02 g; thiamine hydrochloride, 10 μg; dist. water, 1 l.; pH 7·0) containing increasingly higher doses of pyrithiamine, acquires resistance to this antivitamin. After this adaptation, the bacteria can grow well in the presence of pyrithiamine (1 μg/ml.) even in the absence of thiamine with some changes in the metabolic pattern. Of the major biochemical alterations as a result of adaptation, severe depression in glucose utilization with the concomitent stimulation in the utilization of acetate has been noticed. By measuring the rate of formation of carbon dioxide labelled with carbon-14 from glucose-1-^{14}C and glucose-6-^{14}C, it has been observed that the percentage reduction in $^{14}CO_2$, formation from glucose-1-^{14}C by the adapted organism is much more than that obtained from glucose-6-^{14}C, causing thereby a lowering in the glucose-1-^{14}C/glucose-6-^{14}C metabolic ratio after adaptation. Relative to the normal strain the adapted strain utilizes acetate-^{14}C at a much faster rate both in the formation of $^{14}CO_2$ and also in the incorporation of carbon-14 into the protein and lipid fractions of the bacterial cells. It has further been noted that as a result of adaptation to pyrithiamine the colour of the pigment of the organism is changed from orange-yellow to lemon-yellow.

Previous studies show that there is either complete suppression of carotenogenesis by *S. aureus* as in the case of adaptation to tetracyclines[2], or an alteration in the nature of the pigments as in the case of adaptation

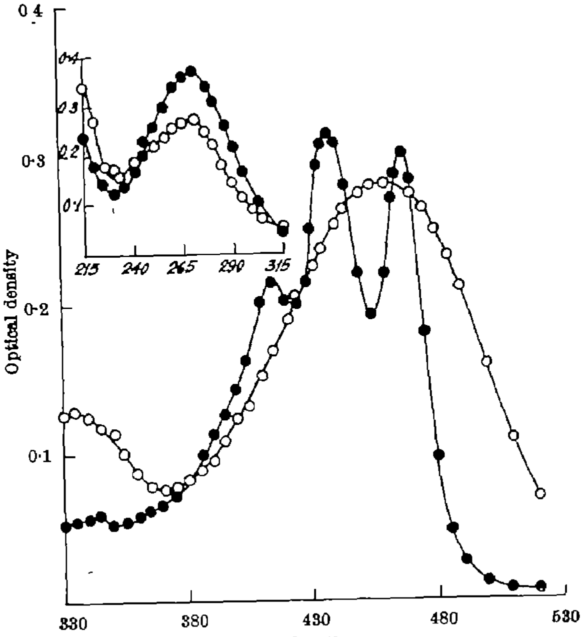

Fig. 1. Absorption spectra of the pigments extracted from normal and pyrithiamine-adapted *S. aureus*. ○, Normal; ●, pyrithiamine adapted. 50 ml. of methanol were used for the extraction of 1 g cell (wet wt., 24 h growth at 37° C), diluted twice for visible spectrum and five times for ultra-violet spectrum studies

to sulphathiazoles[3] or fluoropyrimidines[4]. The absorption spectrum studies of the methanol extracts of both the normal as well as of the pyrithiamine-adapted *S. aureus* have been made in a Beckman spectrophotometer model *DU*. Maximum optical densities of the methanolic solutions of pigments have been observed at 337 mμ and at 460 mμ for the normal organism and at 414 mμ, 437 mμ and at 468 mμ for the adapted organism. In the ultra-violet region, the absorption maxima for either of the strains were at 267 mμ (Fig. 1). The changes in the nature of the pigment as reported here is due to some alteration in the biosynthetic pathways leading to the formation of carotenoids, besides some significant changes as observed with respect to the utilization of carbohydrates by *S. aureus* after adaptation to pyrithiamine.

We thank Prof. B. C. Guha for his interest in this investigation.

Isolation of Antigenic Fractions from *Bordetella pertussis* by means of Lysozyme

A considerable number of Gram-negative bacteria have been broken up in recent years by means of lysozyme[1–4]. The results of lysozyme treatment of *Bordetella pertussis* and the analysis of the resulting antigenic fractions form the subject of this communication. Suspensions (phase I), obtained from 24-h-old liquid shaken cultures, were used. After washing them with distilled water, we adjusted their germ count to 4 to 6 × 10^{10}/ml. with reference to the International Standard for Opacity. We determined the conditions under which lysis would least impair antigenicity and found that our purpose would be best served by using a combined treatment with crystalline lysozyme (100 μg/ml.) and versene (200 μg/ml.) in a 0·03 M *tris* buffer of *p*H 8·0 under continuous stirring in a water bath of 37° C for 2–3 h.

Fig. 1 shows the effect of the *p*H and the buffer on lysis as measured by the diminution of opacity. A one-cell photometer was used for the determination of opacity, and its decrease was expressed as a percentage of turbidity. Unpublished experiments showed that a rise of temperature (especially one within the range between room temperature and 37° C) promoted the decrease in opacity. Still higher temperatures, for example, 45 and 56° C, promoted lysis to a considerably lesser extent. We therefore performed our experiments at 37° C, and this the more so because treatment at 45° or 56° C had been found definitely harmful to the antigens.

A very cautious acidification of the viscous substance obtained by treatment with lysozyme yields a precipitate between *p*H 6·7 and 7·05; this precipita contains the undissolved bacterial components. I centrifuging we obtained a pellucid, and but ve slightly viscous, supernate (fraction 1). If fraction 1 further acidified, a floccular precipitate is prompt obtained which is readily soluble in a phospha buffer of *p*H 7·2 (fraction 2). Table 1 shows, in cor parison with the initial suspension, the immunogenic properties of fraction 2 obtained at *p*H 4·1 and adju ted to the volume of the original substance. W treated the control suspension with 'Thiomersa (0·02 per cent) and kept it in a water bath at 37° C f 3 h. Fraction 2 contained 0·01 per cent of 'Thiomersal'. Table 1 indicates mouse protective potenc (ED_{50}), histamine-sensitizing activity (HSD_{50}), aggl tinin-producing ability in mice (AgD_{50}), leth (LD_{50}), and dermonecrotic toxicity (DNT). A ascertained by the micro-Kjeldahl method, the tot nitrogen contained in the initial suspension amounte to 0·28 mg nitrogen/ml., against 0·04 mg nitrogen/m in fraction 2. Figures in Table 1 express the antigen value of the substance per 1 mg nitrogen. It evident that the purified fraction 2 contained the mo important antigens of *B. pertussis*.

Table 1. Antigenic Properties of *Bordetella pertussis* Fractions

Material	ED_{50}*	HSD_{50}*	AgD_{50}*	LD_{50}*	*DNT*
Control	1,052	48·5	153·8	11·7	nil†
Fraction 2	1,786	490 0	147·0	847·4	16 × 16 *N*‡

* ED_{50}, HSD_{50}, AdD_{50}, LD_{50}/mg nitrogen.
† Diluted 1 to 50.
‡ In mm; *N*, necrosis; diluted 1 to 100.

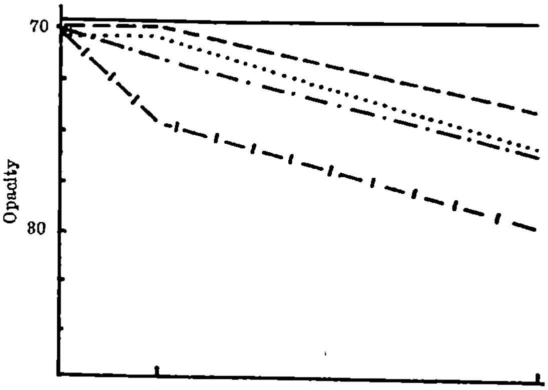

Fig. 1. ——, Control; – – –, phosphate buffer *p*H 7·2; . . . phosphate buffer *p*H 8·0; —·—, *tris* buffer *p*H 7·2; —ı—, *tri* buffer 8·0

The concentration of the protective antigen ro slightly, that of the histamine-sensitizing factor (HSF rose about ten-fold, and the amount of agglutinoge remained unchanged in the course of purification. Th behaviour of both the lethal and the dermonecroti toxins was noteworthy. The LD_{50}/mg nitrogen c fraction 2 was 77 times that of the initial suspensio This must have been due to the treatment wit lysozyme facilitating the passage of a great mass c toxins from the bacterial protoplasm into the solutio while the liberation of toxins from intact bacteri cells is a slow process.

The lethal toxic action of fraction 2 can be stoppe in 30 min at 56° C and in 3 h at 37° C. Its DNT-effec does not diminish within 3 h at 37° C. It should b noted that the HSF-content of fraction 2 disappear in 30 min at 56° C, while that of the whole suspensio is not affected[5,6]. The total nitrogen-content of th purified substance becomes 6–8 times less in th course of fractionations. As ascertained by th method of Ogur-Rosen, the level of nucleic acid (referred to as protein nitrogen) was about twice a much in fraction 2 as in the initial suspension.

By varying the *p*H values, applied for the produc tion of fraction 2, between 6·0 and 3·5, we obtaine fractions which contained the antigenic properties i fferent proportions. Experiments are now in ogress with the view of isolating the different tigens of *B. pertussis* in a possibly pure form by eans of the method described here, and also with e aid of other biochemical methods.

VIROLOGY

Erythrocyte Receptors for Type A_2 Influenza Viruses

The close similarity in chemical structure between -type inhibitors of influenza virus hæmagglutination nd erythrocyte receptors for myxoviruses is now well known[1,2]. The affinity of some A_2 influenza viruses for a new type of serum hæmagglutination nhibitor with distinctive properties[3-5] therefore uggested the possibility of a new type of cell receptor or these viruses. Evidence for this has, in fact, been btained by some authors[6,7], who have shown that rythrocytes treated with neuraminidase remain gglutinable by inhibitor sensitive A_2 strains but not y insensitive ones or by type *B* virus.

Treatment of erythrocytes with graded doses of euraminidase destroys sequentially their capacity to e agglutinated by various strains of influenza virus[8,9]. On this basis viruses can be arranged in a sequence called the receptor gradient. The possibility that agglutination of neuraminidase-treated erythrocytes by inhibitor-sensitive A_2 strains is a manifestation of this phenomenon was, therefore, considered and the experiments reported here support the suggestion.

The effect of neuraminidase treatment on the agglutinability of human, fowl and guinea pig erythrocytes by two influenza virus strains Lee, Type *B*, and an inhibitor-sensitive variant of *A*/Singapore/1/57, Type A_2, was first investigated. A 5 per cent suspension of erythrocytes was incubated at 37° C with neuraminidase suitably diluted in calcium acetate saline *p*H 6·2. Aliquots were removed at intervals, centrifuged, washed and resuspended in physiological saline to a concentration of 1 per cent. Erythrocytes suspended in calcium acetate saline without neuraminidase were treated similarly and served as controls. Hæmagglutination of treated and control cells by the two prototype strains was then assessed by the standard pattern method of titration. The results summarized in Table 1 show that receptors for the inhibitor-sensitive *A*/Singapore variant on cells from the three species tested were destroyed by neuraminidase. It is noteworthy that receptors for the Lee strain were destroyed more rapidly than those for *A*/Singapore and that receptors for the latter strain on guinea pig erythrocytes were the most resistant to destruction by neuraminidase; indeed, in one experiment there was incomplete destruction even after 7 hours treatment.

These results do not support the conclusions of other authors that inhibitor-sensitive A_2 viruses attach to specific cell receptors qualitatively different from those utilized by other myxoviruses[6,7]. Rather, they imply that these viruses attach to the same receptors but occupy a position in the receptor gradient which allows them to agglutinate enzyme-treated cells which are inagglutinable by other strains.

In order to determine if there is a direct relationship between the inhibitor sensitivity of A_2 strains and their position on the receptor gradient a number of sensitive and insensitive variants were investigated. In these experiments 2·5 per cent suspensions of human erythrocytes in serial two-fold dilutions of neuraminidase were held at 37° C for 3 h, centrifuged, washed and resuspended in physiological saline to a concentration of 1 per cent. Each suspension was now tested for hæmagglutination by the addition of 0·25 ml. to an equal volume of a number of test viruses, containing 4 agglutinating doses. The results of three replicate experiments are summarized in Table 2, where the highest dilution of neuraminidase sufficient to prevent hæmagglutination reflects the ease with which the receptors for each test virus are destroyed. No precise correlation between this and inhibitor sensitivity is apparent. Nevertheless, the

results obtained with our inhibitor-sensitive strains do indicate that the difficulty of removing their erythrocyte receptors with neuraminidase is due to their position in the receptor gradient. If so, the rate at which they are destroyed by neuraminidase will depend on the concentration of the enzyme as well as the duration of treatment. Variations in either of these factors would explain the discrepancy between our results and those of other authors.

Latent Ectromelia

Ectromelia, a highly infectious disease of mice, is caused by a pox virus closely related to the causal agents of variola and vaccinia. The disease is frequently found in laboratory mice, and its existence poses a difficult problem for those responsible for the supply of laboratory animals. It therefore seems worth while to record certain preliminary observations which may bear on the epidemiology of the disease.

Fenner[1] showed that a large amount of virus was excreted from the skin of mice which developed a rash, and he believed the chief mode of infection was contact of virus with abraded skin[2]. Virus ceased to be excreted 3 weeks after the onset of the rash, and recovered mice were immune to re-infection. The epidemic behaviour and antibody response resembled the pattern associated with smallpox and seemed incompatible with persistent infectiousness of recovered mice. However, the carriage of ectromelia virus in colonies of apparently healthy mice has long been suspected, and accounts have been published of the appearance of acute ectromelia following the inoculation of mice with various biological substances[3-5]. The authors interpreted their observations in terms of the hypothesis that the virus may be carried in latent form in apparently normal mice.

In the hope of resolving these differences, attempts were made to isolate the virus from mice which had survived infection with small doses inoculated intraperitoneally. Although the virus was not isolated from cultured spleens later than 37 days after inoculation and most recovered mice appeared healthy, a few developed regressive lesions on the tails quite insignificant compared with those produced by the inoculation of the virus into the tails of normal mice. This observation and the observation of Dr. Janet Niven that apparently healthy mice may manifest microscopic lesions characteristic of ectromelia in the intestine led me to look for virus in the tail skin and fæces of recovered mice. Virus was isolated both from the intestinal contents and tail skin of each of six mice 84 days after infection and from the tail skin of 2 of 5 mice 99 days after infection[6]. Th results indicated that virus is excreted into intestine and from the tail skin of recovered m long after the development of immunity and clini recovery. Such mice could presumably infect t next generation of mice and infection of each succ sive generation might follow.

Experiments are being undertaken to investig whether ectromelia can be transmitted from gene tion to generation in this way, and some facts interest have come to light, although these expe ments are still incomplete. It appears that mice c be regularly infected *per os* with large doses of vir (10^6 LD_{50} or more, as measured by intraperitone inoculation of mice) and that even with much small doses of virus *per os* ($<10^2$ LD_{50}) about 1 : 5 m are infected. Oral infections, unlike infections follo ing intraperitoneal and footpad inoculation, are oft inapparent with large doses of virus and practical always so with small doses. Such inapparent infectio may be recognized by the development within 3 weeks of immunity to withstand intraperitone inoculation of 10^6 LD_{50} of virus and by isolation virus from the tails and intestinal contents. Thu two mice died of 120 (2 per cent) infected *per os* wi doses ranging from 10 to 10^4 LD_{50}, while 20/88 (23 p cent) of these became immune. Twenty-seven mi died of 59 (46 per cent) after 10^6 or more LD_{50} of vir *per os* and 27/31 (87 per cent) of the survivors we immune. Virus was isolated in mice from the ta skin and fæces of one mouse of seven given *per* 10^2 LD_{50} of virus 81 days before. Virus was similar isolated from the tail skin and/or fæces of mi infected *per os* with large doses (10^6 LD_{50} or mor as shown in Table 1.

Table 1

Days after oral infection	Ratio $\frac{\text{Mice which yielded virus}}{\text{Mice examined for virus}}$
32–35	2/9
69	3/8
81	2/4
116	1/4
	8/25 (32%)

These results show that ectromelia can be an in apparent infection and that mice may harbour th virus in the intestinal tract and tail skin for a lon time. The possibility of a similar situation with othe diseases of the pox group deserves consideratio Virus was isolated more frequently from the tail ski than the fæces. Nevertheless, it seems likely tha fæces are the principal source of virus and that th tail skin becomes infected by fæcal contamination The presence of antibody in the fæces would explai the fewer virus isolations from this source. Isolation of virus have been attempted only from individua mice, but experiments are now being undertaken t determine whether virus can be isolated from tail ski or fæcal suspensions of groups of mice. This migh provide a simple screening test for ectromelia i colonies of mice, to supplement the usual test fo hæmagglutination-inhibiting antibodies.

araday Society (in the Chemistry Lecture Theatre, The Univer-, Nottingham), at 5 p.m.—Dr J. H. van der Waals (Amsterdam). udy of the Phosphorescent State of Organic Molecules by Electron sonance" (Bourke Lecture).*

nstitution of Electrical Engineers, Science and General vision (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. Denis ylor: "Radioactivity and Process Measurements" (Chairman's dress).

niversity of London (at the London School of Hygiene and opical Medicine, Keppel Street, Gower Street, London, W.C.1), at 0 p.m.—Dr. H. A. Sissons: "Bone Structure and Metabolic Bone sease".* (Third of eighteen lectures on "The Scientific Basis of dicine" organized by the British Postgraduate Medical Federation.)

nstitution of Mechanical Engineers, Industrial Administran and Engineering Production Group (at 1 Birdcage Walk, estminster, London, S.W.1), at 6 p.m.—Discussion on "Planned intenance".

ociety of Chemical Industry, Plastics and Polymer Group 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. C. H. mford: "Solid State Polymerization".

Wednesday, October 24

nstitute of Fuel (at the Institution of Civil Engineers, Great orge Street, London, S.W.1), at 5.30 p.m.—Dr. R. S. Silver and e Hon. W. K. J. Weir: "Fuel, Heat and Energy Aspects of Seater Distillation".*

University of London (at the Warburg Institute, Woburn Square, ndon, W.C.1), at 5.30 p.m.—Prof. H. Bondi, F.R.S.: "Time and smology".*

British Institution of Radio Engineers (at the London School Hygiene and Tropical Medicine, Keppel Street, Gower Street, ndon, W.C.1), at 6 p.m.—Annual General Meeting of Corporate embers. 7 p.m.—Dr. A. Von Engel: "An Introduction to Plasma ysics".

nstitution of Mechanical Engineers (at 1 Birdcage Walk, estminster, London, S.W.1), at 6 p.m.—Mr. J. H. Pitchford esidential Address.

Society of Chemical Industry, Food Group—Nutrition Panel 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Miss D. F. llingsworth: "Changes in the Nation's Food Habits".

Society for Analytical Chemistry, Microchemistry Group "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—scussion Meeting on "Difference Between Continental and British actice in the Determination of Elements in Organic Compounds" troduced by Dr. W. Schoniger.

Royal Institute of Chemistry, Manchester and District ction (in the Manchester Town Hall), at 7 p.m.—Sir Lawrence agg, F.R.S.: "Living Molecules" (Twelfth Dalton Lecture).

Wednesday, October 24—Friday, October 26

Institution of Electrical Engineers, Electronics Division Savoy Place, London, W.C.2)—Second Symposium on "Electronics uipment Reliability".

Thursday, October 25

University of London (in the Anatomy Theatre, University llege Gower Street, London, W C.1), at 1.15 p.m.—Prof. Sir William olford: "The Life and Death of the Big City".*

Chemical Society (in the Main Lecture Theatre, Chemistry Dertment, University College, Gower Street, London, W.C.1), at 45 p.m.—Symposium on "The Chemistry of the Early Transition ements".

University of London (in the Physiology Theatre, University llege, Gower Street, London, W.C.1), at 5 p.m.—Prof. H. L Kornrg: "The Metabolism of Two-Carbon Compounds in Microganisms".* (Further lectures on November 1 and 8.)

University of London (at Westfield College, Kidderpore Avenue, ndon, N.W.3), at 5.15 p m.—Prof. J. E. Webb: "Tropical Zoology" naugural Lecture).*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. B. E. C. Nordin: "Calcium and Phosphorus Metabolism".* (Fourth of eighteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Thursday, October 25—Friday, October 26

Royal Geographical Society (jointly with the Medical Research Council, and the three Services, at the Royal Army Medical College, Millbank, London, S.W.1)—Symposium on "Exploration Medicine".

Friday, October 26

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. P. J. Lawther: "The Clinical Consequences of Air Pollution".*

Faraday Society (in the Main Lecture Theatre, Chemistry Department, The University, Sheffield), 4.30 p.m.—Dr. J. D. van der Waals (Amsterdam): "Study of the Phosphorescent State of Organic Molecules by Electron Resonance" (Bourke Lecture).*

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. W. T. Williams: "Computers as Botanists".

Saturday, October 27

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Felix Mann: "Origin and History of Chinese Acupuncture".*

Monday, October 29

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. C. E. Everard, Mr. R. J. Chorley and Mr. B. T. Bunting: "Slope Profiles".

British Institution of Radio Engineers, Electro-Acoustics Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Prof. E. J. Richards: "Noise Control".

Institution of Electrical Engineers, Electronics Division (joint meeting with the British Institution of Radio Engineers Medical Electronics Group, at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Data Processing in Medicine".

Institution of Mechanical Engineers, Process Engineering, Refrigeration, Ventilation and Vacuum Plant Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Reducing the Cost of Maintenance".

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. B. F. Skinner (Harvard): "The Future of Teaching Machines".*

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. G. Sykes: "Horizons in Disinfection and Antisepsis" (Jubilee Memorial Lecture).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (well qualified in physics with suitable teaching, research or industrial experience) in Physics—The Principal, Brunel College. Woodlands Avenue, Acton, London, W.3 (October 27).

Scientific Officer (with a first- or second-class honours degree in chemistry, with or without postgraduate experience) in the Chemistry Section, Forensic Science Laboratory (Home Office), which deals mainly with toxicological problems—The Director, N.R. Forensic Science Laboratory, 32 Rutland Drive, Harrogate (October 27).

Scientific Officer (Unestablished) (with a first- or second-class honours degree in a scientific or engineering subject), to help to undertake, or promote investigations into selected aspects of scientific and technical communication which will assist in guiding the future information policy of the Department—The Secretary, Department of Scientific and Industrial Research, H.Q. Information Division, State House, High Holborn, London, W.C.1, quoting Ref. E/AH/040 (October 29).

Assistant Lecturer (with medical qualifications registrable in this country) in Anatomy—The Registrar, The University, Manchester 13 (October 30).

Research Fellows in Metallurgy, Chemistry and Physics, and Research Assistants in Metallurgy and Physics—The Staff Officer, College of Advanced Technology, Gosta Green, Birmingham 4, quoting Ref. N/17D (October 30).

Lecturer (with special interest in reactor physics or reactor kinetics and control), and a Lecturer (with special interest in reactor design) in the Nuclear Power Group—Dr. P. J. Grant, Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7 (October 31).

Senior Scientific Officer (with a first- or second-class honours degree in mechanical engineering and at least three years postgraduate experience), to join a group concerned largely with research in ergonomics—The Director, Warren Spring Laboratory, D.S.I.R., Stevenage, Herts, quoting Ref. WSL 24 W (October 31).

Lecturer or Assistant Lecturer (man or woman with a degree in physiology, and preferably with experience in teaching histology) in the Department of Physiology—The Assistant Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (November 5).

Reader (with considerable research experience in the chemistry (including biochemistry) of proteins, particularly of enzyme proteins) in Protein Chemistry in the Department of Agricultural Chemistry at the Waite Agricultural Research Institute—The Registrar, University of Adelaide, or the Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, November 15).

Senior Lecturer or Lecturer in Electrical Engineering at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, November 15).

Lecturer in Organic Chemistry—The Secretary of University Court, The University, Glasgow (November 17).

Professor of Archæology in the Department of History—The Registrar, The University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C 1 (November 18).

Professor of Geography at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W C.1 (November 18).

Associate Professor in Educational Psychology or in Educational Sociology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 19)

Graduate Entomologist (preferably with a knowledge of genetics), to work in the resistance of insects to insecticides—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (November 23).

Chair of Applied Mathematics in the University of Melbourne—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W 1 (Australia and London, December 1).

Junior Technician or Technician (male) in the Department of Physiology—The Assistant Secretary, Royal Veterinary College, Royal College Street, London, N.W.1

Medical Laboratory Technician (A.I.M L.T. or equivalent)—The Administrative Officer, North London Blood Transfusion Centre, Deansbrook Road, Edgware, Middlesex.

Microbiologist (with a good honours degree, and preferably previous experience of relevant subjects), for work on the microbiology of irradiated food—The Secretary, Low Temperature Research Station, Downing Street, Cambridge.

Physicist (with experience in dosimetric techniques)—The Director, Experimental Radiopathology Research Unit, M.R.C., Hammersmith Hospital, Ducane Road, London, W.12.

Reader (highly qualified in physics with suitable academic and/or industrial experience) in Physics—The Academic Registrar, Brunel College, Woodlands Avenue, Acton, London, W.3.

Reader (with evidence of research ability in the academic and industrial fields, and preferably experience in the food industry) in Food Science—The Principal, National College of Food Technology, St. George's Avenue, Weybridge, Surrey.

Research Assistant in the Department of Physics, to carry out work on the propagation of ultrasonic vibrations in semiconductors under the direction of the Head of the Department—The Academic Registrar, Brunel College, Woodlands Avenue, London, W.3.

Research Assistant (organic chemist or biochemist), to undertake work on polysaccharides of invertebral disks and connective tissues—The Secretary, The Royal Infirmary, Bradford 9, and The Registrar, Bradford Institute of Technology, Bradford 7.

Senior Research Assistant (preferably with experience in the field of high pressure research), to join a team doing research in high pressure chemistry, with some applications to geochemistry—Dr R. S. Bradley, Department of Inorganic and Structural Chemistry, The University, Leeds 2.

Statistician or Ecologist, to develop statistical techniques in ecological studies of plankton and herring, in hydrography and in the analysis of sampling methods (fifteen years data and computer facilities available)—The Officer-in-Charge, Oceanography Laboratory, Scottish Marine Biological Association, 78 Craighall Road, Edinburgh 6.

SCIENCE AND THE NATURE OF POLITICS

IN moving the second reading of the Finance Bill in the House of Lords on July 30, Lord Hailsham made an appeal for unity and realism which expresses an attitude frequently found among scientists. Continuing the plea he had made in reference to broadcasting policy on July 18, he urged that at this juncture what was needed was integrity and resolution, common sense and clarity of thought—Britain was tired of obsolete and unrealistic political theories and looked for leadership and originality on both sides. It was not simply the Government which was on trial, but the whole nation—Parliament, Britain's belief in freedom, her experiment in democracy, her religions, her philosophies, her civilization, and all that went to make up her way of life. He did not believe there was anything radically wrong with the British society, but it was important to eliminate the hypercritical attack so fashionable on things and people who had succeeded. Further, although the element of chance entered into almost every human enterprise, it was essential to reduce this element so far as possible by conscious and methodical forethought and realistic appraisal of the facts.

There were, Lord Hailsham suggested, three great issues before the world. First, there was the fact that its political and social institutions, whether in the Communist or the Free World, no longer matched the requirements of the human race or the technical facts of life. This was true both of internal and external relations. Secondly, there was the moral crisis: the West had failed to live up to its moral ideas, and the East, rejecting those moral ideas, now found it could not live without them. Thirdly, there was the inability of the West to generate sufficient economic power to support the volume of activity which would enable it to win the 'cold war'. This was an international problem which could only be solved at international level, but Lord Hailsham pointed out that there were moral and social realities which were not altered by shifts in technology or the balance of power. What was required was an absolute determination that Britain's distinctive national society should thrive and prosper in the changed conditions of the twentieth century—but for this purpose it was essential that Britain should be radical and flexible in much else. Relations between the State and the individual, between the State and the trading organization, between the State and the voluntary associations needed to be radically recast, and many noted concepts which had served her forefathers required constant re-examination if Britain were to pursue realistic courses in the changing currents of a revolutionary world. This placed an immense strain on the flexibility of mind and consistency of purpose of public men.

Britain was, Lord Hailsham continued, suffering from rigidity and a degree of inefficiency, and was trying to operate a system of essentially nineteenth-century customs and technologies. Inefficiency of management and restrictive practices must be eliminated and bring Britain's traditional and inadequate system of apprenticeship into line with economic and educational reality. Old and obsolescent craft industries needed a new scientific basis, and reluctance to adopt modern methods of machining in the engineering industry, slowness to apply scientific ideas in shipping operation and shipbuilding, the clinging to batch rather than continuous methods of processing, the condition of the docks—all these, as well as comparative neglect of social studies, required consideration in Britain to-day, and this was much more than a task for the Government: it was a task for the whole people and called for the rejection of the national hypocrisy which refused to face realities in Government expenditure and taxation.

While there is much truth in what Lord Hailsham said, his plea for unity needs to be considered in the light of some such analysis of the nature of politics as Prof. J. D. B. Miller gives us in his recent book*. Moreover, special considerations are required of his insistence that politics is both a rational and a non-rational activity, that it consists essentially of conflict, in varying degrees, over the use of Government, engendered by many forms of diversity of condition, status and opportunity, and that there are serious limitations to what politics can accomplish. These limitations, he had pointed out, were built into the fabric of any society, including those imposed by natural resources, by the lack of omnipotence of Governments, and by the plain fact of incompatibility in its widest sense, to which indeed Lord Hailsham referred. With a penetrating discussion of the existence of varying interests in any developed society and of the assumption that there is a general interest in society, Prof. Miller provides the basis for a realistic approach to the problem of Government and science which should correct a good deal of loose thinking on such themes. Furthermore, it should stimulate a practical approach to some of the most pressing problems of Government to which Lord Hailsham and Sir Charles Snow, to mention only two, have recently directed attention.

Prof. Miller, in fact, devotes some attention to what Sir Charles Snow described as "closed" politics and on which Sir Charles has since written a *Postscript*†, reiterating the importance of the decisions which are taken in this way, and of the implications if they are taken by men who have no first-hand knowledge of what the cardinal choices available depend on or of what their results may be, and, in particular, urging the danger of ever depending on a single scientific judgment. Prof. Miller is, of course, concerned with the more general issue, and points out, indeed, that the closed politics described by Sir Charles, and which he himself discusses in terms of Government bureaucracy, are equally characteristic of the politics of institutions like a university, a cathedral chapter or a club. Nevertheless, his more detailed analysis, following Sir Charles Snow's distinguishing of the three categories of committee politics, hierarchical politics and court politics, is one that deserves the careful attention of any scientist who is concerned with the way in which effective and wise action can be secured on matters in which scientific or technical factors can be of decisive importance. Incidentally, he notes, though without discussion, the increasing importance in the modern state of tension between scientific and non-scientific departments.

* *The Nature of Politics.* By Prof. J. D. B. Miller. Pp ix+296. (London: Gerald Duckworth and Co., Ltd., 1962.) 30*s*.

† *A Postscript to Science and Government.* By Sir Charles Snow. Pp. ii+87. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1962.) 3*s*. 6*d*. net.

Prof. Miller makes two points which are frequently ignored in discussions of the relations between science and Government—for example, in J. S. Dupré and S. A. Lakoff's study *Science and the Nation: Policy and Politics*‡, and in D. K. Price's article *The Scientific Establishment*§—though they have a decisive influence on the means that are adopted for resolving differences. General interests, he maintains, are found only occasionally and do not last long. Secondly, conflict lies at the heart of politics, which is a matter of the expression, advocacy, settlement and modification of disagreements. It also involves agreement, though not necessarily more permanent than the disagreements.

As this view is worked out by Prof. Miller it bears striking resemblance to the scientific method, with its emphasis on diversity, its opposition to regimentation, its denial that all wisdom resides in a few people whose right to rule must not be questioned, its recognition of individual and human interests, and its search for voluntary, not compulsory, agreement for what—though Prof. Miller does not use the term—might be described as something akin to the idea of 'the sense of the meeting'. It is this changing, dynamic conception of the recognition of changing and diverse interests and their reconciliation and adjustment under the rules regulating interests and individuals made by the appropriate body which also provides the opportunities for position, privilege, security and advantage out of which the interests arise, that the scientist will recognize as having affinity to the way in which he works. It should provide both the safeguard which Sir Charles is seeking against the dominance of a single judgment and the flexibility which Sir Bernard Lovell desiderated in a comment on Sir Charles's *Postscript*.

If scarcely as profound as Sir Ernest Barker's *Reflections on Government*, Prof. Miller's book should appeal to the scientist for its pragmatic approach to the practical tasks of Government and its restraint in discussing political theory and systems, which are given their due weight but no more. He has comments on the education of the politician which have implications for education for management and dispose just as effectively of excessive claims or loose thinking. He has no use for narrowly professional education, but dogma is kept firmly in its place as a servant or instrument of thought and denied all claim to be guide let alone master.

In suggesting that existence of a general interest is exceptional and transient rather than normal, Prof. Miller judges that a multiplicity of interests is the normal and healthy condition and that political movements, whether in the nation or society as a whole or in groups or institutions (which are enemies of such plurality), should be viewed with suspicion. "There cannot be any discussion, or any system of government by discussion," wrote Sir Ernest Barker in 1942, "except upon the assumption that truth dwells in more than one habitation, and that its elements have to be collected, and not only collected but reconciled, before it can be enthroned." He saw the real issue as one between two different tempers of mind—the spirit and temper of accommodation and the spirit and temper of intransigence. The soundness of that view is thoroughly attested by post-war experience, and Prof. Miller's concern with the element of conflict and continuous adjustment seems to lead him to a very similar position.

This is apparent in the scope he sees for the individual in the interplay of interests which constitute the essence of politics, although the changes which individuals can effect cannot run completely counter to the general social inclinations of the community. The alleged dichotomy between administration and policy Prof. Miller rejects as false, and he stresses the existence between these two extremes of a vast no-man's-land where the departmental view, the advice of the expert, the considerations of the Cabinet, the personal view of the Minister, and the convictions of the political party may function according to the circumstances. Here, pragmatism, regard to what is possible in practice, rather than what is theoretically desirable, is the decisive factor, and while Prof. Miller never quotes the first Earl of Lytton, much in this book recalls the latter's insistence that expediency alone is the basis of all Government, that circumstances are the only things with which Government has to deal and that political action is good or bad, right or wrong according to its consistency, not with theory, but with circumstance, in all its human, fluctuating variety.

This is particularly noteworthy when Prof. Miller deals with the sovereign state at the international level. Here he deals soberly with the assumption that a vague generalized interest in peace is likely to lead to a voluntary agreed creation of a world Government. The sovereign State must still be recognized as the prime fact of political life, and his comments in this connexion are as pertinent in reference to Britain's proposed entry into the Common Market as they are in relation to the functions of the United Nations. The limits of national action in the field of foreign policy are set by the lines of force prevailing in the world at large, and even more than domestic policy, foreign policy is the slave of possibility.

---

‡ *Science and the Nation: Policy and Politics*. By J. S. Dupré and S. A. Lakoff. Pp. x+181. (Prentice Hall, Englewood Cliff, New Jersey, 1962.) 16s. or 1.95 dollars net.

§ *Proceedings of the American Philosophical Society*, No. 3, 106 235 (1962).

This welcome note of sanity does not, of course, dispose of the awkward, disturbing issues either in internal or external politics which are set by technical or scientific advance. Nevertheless, the field within which the expert may seek to function is clearly delineated, and also the points where critical and constructive thought is required about the whole apparatus of advice and its limitations. In this connexion there is much wisdom in what Prof. Miller writes about ideas in politics and their effect. Each country, he suggests, develops its own ideas in accordance with its own practice, and, while ideas assist in the creation of a climate of opinion in which selfish and altruistic interests can blend, the existence of climates of opinion is usually a national phenomenon.

This is not to deny that movements such as the Pugwash Conferences are entirely without effect, but rather to suggest that the tempo is slow and their limits of influence strictly circumscribed. It is for discussion how the process could be accelerated, but the discussion must be realistic and guided by the nature of politics. Here, perhaps especially, Prof. Miller's reason for studying politics—that it is better to know the truth than not to know it—applies. He makes no large claims for the value of political study, but he sets out soberly some potentialities of utility that the scientist who is concerned with the relations of Government and science could examine with profit. His book should at least help scientists to avoid the over-simplifications which are a major weakness of Dupré and Lakoff's study of the changes in institutional relations between science and the Federal Government during the past thirty years, in which science has become the major Establishment in the American political system: the only set of institutions, as D. K. Price observes, for which Federal funds are appropriated almost on faith, and under concordats which protect the autonomy, if not the cloistered calm, of the laboratory.

Dean Price's analysis is worth considering in the British context, for he claims that the major difference between the two systems is the persistent dominance in Britain of the Administrative Class of the Civil Service, staffed by men mainly without a scientific or technical education, whereas in the United States scientists move freely into the highest administrative positions and in and out of Government. This system, he admits, maintains a continuous interchange of men and ideas between the Government and universities, but it also makes it impossible to maintain an institutional distinction between ends and means, between policy decisions on one hand and on the other scientific research or administration. Party responsibility in the parliamentary sense becomes impossible and the task of co-ordinating either policy or administration is greatly complicated.

The value of this continuous interchange is undeniable though it should not be limited to the universities, and the Zuckerman Committee fully recognized that it was something to be encouraged, though Britain need not copy the American system to do so. The blurring of the distinction between ends and means is, however, questionable, even if Dean Price is right in suggesting it is part of the scientific approach. On the other hand, though universities and private foundations in the United States have a hand in the initiation of new public policies to an exceptional extent, policy decisions remain the responsibility of Government and cannot be delegated. This, however, is merely a change in the character of the interests and of their conflicts rather than a new system. For all that, the development and its political and administrative patterns may have been stimulated by a demand that the organization and procedures of Government, as well as its policies, should be open to scientific inquiry and independent criticism, and may to some extent reflect the way scientists themselves behave.

Unlike Sir Charles Snow, Dean Price, however, sees little reason to fear that major Government decisions affecting science will be secret but rather fears that they will be popular. In either way could lie disaster, for neither is consistent with the existence of well-informed discussion. As G. M. Young pointed out*, the compactness of party organization necessitated by the vast size of a modern electorate and the technical intricacies of modern administration are gradually contracting the area of such discussions. He suggested that to re-engage the interest of those best qualified, by education or experience, to occupy it, restoring the weight they should carry in a well-balanced constitution, was a task to which Britain's more enlightened statesmanship might well lend itself. The emphasis placed on free and informed discussion by the American writers, no less than by Sir Ernest Barker, Sir Charles Snow, Prof. Miller, or again by Prof. K. C. Wheare, who has examined the whole system of *Government by Committee* in his book under that title, is notable. It should be a first objective in any modification of the organization by which the participation of scientists in the task of Government is promoted; this being so, the dangers which Sir Charles Snow and Sir Bernard Lovell fear should largely be avoided.

With this, however, must go the other things. First, a wide understanding of the nature of politics such as Prof. Miller seeks to encourage. Secondly, a fuller public understanding of what science is about, of its limitations as well as its potentialities. Thirdly, educational programmes and institutions which will ensure the provision of scientists and of administrators capable of understanding the problems of each other and the significance of the factors they are called on to assess in political decisions. It is largely in the measure in which these problems of communication are handled satisfactorily that the conflicts and tensions between the diverse, changing interests of society will occur under conditions and in ways that permit decisions to be made which do not involve technical disaster or catastrophe.

* Introduction to *Last Essays*. By G. M. Young. Pp. 288. (London: Harper Davis, 1950.)

ROTHSCHILD COLLECTION OF FLEAS

An Illustrated Catalogue of the Rothschild Collection of Fleas (Siphonaptera) in the British Museum (Natural History)

By G. H. E. Hopkins and Miriam Rothschild. Vol. 3: Hystrichopsyllidae (Acedestiinae, Anomiopsyllinae, Hystrichopsyllinae, Neopsyllinae, Rhadinopsyllinae, Stenoponiinae). Pp. viii+560+10 plates. (London: British Museum (Natural History), 1962.) 168*s*.

LIKE its predecessors, this volume is essentially monographic in nature, since the authors have made every effort to include all relevant information which could be obtained about six of the subfamilies of Hystrichopsyllidae in order amply to meet the stated criterion of facilitating the rapid identification of fleas. Inasmuch as the Rothschild Collection contains 1,478 of the known 1,740 species and sub-species of fleas, and includes type-specimens of 826 forms, even strict adherence to the title of the volume would have been of inestimable value to scientists in this field. However, in Volume 3 alone, Hopkins and Rothschild discuss and illustrate 42 forms not represented in the collection, largely species little known heretofore to scientists of the Western World.

There are approximately 350 names of species or sub-species discussed (of which 73 are cited as synonyms or misidentifications), accompanied by 1,049 figures, of which 308 were especially prepared by Arthur Smith and F. G. A. M. Smit for this volume. There are 34 particularly useful illustrations depicting the skeletal anatomy of fleas, not restricted to the Hystrichopsyllidae, and these include details of the male and female genitalia which have been inadequately used in the past studies on Siphonaptera. There are ten plates of photographs of representative genera and species, illustrating the general configurations of these fleas. The glossary supplements the terms used in Volumes 1 and 3, and will do much to standardize the terminology used by siphonapterologists, an end that will be furthered by the table which synonymizes and compares the terms used by Hopkins and Rothschild with those recently proposed by Peus. The family, sub-family and tribal names and references for the fleas considered in Volumes 1 and 2 are presented in this book now that the question of priority for family group names for insects has been settled.

There are terse, dichotomous keys to all the superfamilies and families of fleas, and similar but illustrated keys to the sub-families, genera, sub-genera, species and sub-species of fleas. Under each name there is a citation of all pertinent references of a taxonomic nature. The text consists of diagnoses and short descriptions designed to include characters sufficient to categorize the species or sub-species and pared of extraneous details. The discussions of the various species are followed by detailed data on material represented in the Rothschild Collection, including careful acknowledgment of the source of specimens donated to the Collection.

The figures are all clear, and well illustrate the pertinent morphological features used in modern systematics. The keys are simple, accurate and easy to use, especially since so many of the critical characters are illustrated. The diagnoses and descriptions are lucid, and deal with well-chosen anatomical structures. The list of records contribute much data of value regarding distribution and even affinities of both the fleas and their hosts.

The system of classification used, based on that of Karl Jordan, but modified, especially concerning taxa and little-known forms, is fully accepted by modern siphonapterologists. The logic and soundness of this scheme of systematics are demonstrated by the relative ease by which unidentified fleas can be determined when using any of the volumes in this series. This facility in accurate identification, and in correctly and promptly learning the affinities of specimens, is also an indication of the scientific and intrinsic value of the book, as well as a tribute to the authors' ability to transfer a thorough knowledge of their subject to the printed page in assimilable form.

Despite the complexity of the subject, the technicality of the terms and multiplicity of references and citations, no errors have been noted by me. The high standards of preparation and editing utilized throughout are illustrated by the fact that the corrigenda for the previous volumes, although based on comments from critical specialists, consist mainly of errors in geographical names due to misspelled labels, clarification about the names used for localities and hosts, and changes in status.

The series of volumes by Hopkins and Rothschild constitute the definitive works on Siphonaptera, and Volume 3 is a fit companion to its predecessors in being completely authoritative and indispensable to anyone whose duties or interests in preventive medicine, mammalogy or entomology entail the identification of fleas or information about their affinities, host-range and geographical distribution.

Publication of the next volume in the series is awaited with keen anticipation. ROBERT TRAUB

ORGANIC CHEMICAL METHODS

Methoden der Organischen Chemie

Von J. Houben und Th. Weyl. Vierte, völlig neu gestaltete auflage. Herausgegeben von Eugen Müller. Unter besonderer mitwirkung von O. Bayer, H. Meerwein und K. Ziegler. Band 14, Teil 1: Makromolekulare Stoffe. Pp. lxiv+1360. (Stuttgart: Georg Thieme Verlag, 1961.) 287 D.M.

ORGANIC chemists sometimes tend to regard synthetic macromolecules as dull, structurally indefinite species, and essentially the concern of their physico-chemical or industrial colleagues. The editors of the fourth edition of the Houben–Weyl encyclopædia of organic chemical methods have challenged this view in deciding to devote two massive Volumes to the subject. Part 1 deals with the polyzation of vinyl and divinyl compounds, while its companion, when available, will provide a similar treatment of polycondensation and of polymerizations resulting from ring-opening in heterocyclic molecules, such as epoxides.

Librarians of teaching and research institutes who have purchased other, indispensable volumes of the Houben–Weyl series should have no hesitation in adding this one to their shelves. It appears opportunely, when four decades of development of the science and art of polymerization can be surveyed, when naturally occurring polymers have a central place in biochemical thought, and when chemists in general find themselves increasingly concerned with macromolecular structures. The book will have most direct interest, however, to those engaged in polymerization research, and such prospective purchasers will wish to know what principles have guided editors and authors in their selection of topics. The vast extent of the available literature is indicated by the 19 pages which are devoted in this volume to lists of monographs, and by the 158 pages required for the author- and subject-index.

It is the general practice, in compiling Houben–Weyl volumes, to classify chemical reactions primarily as methods of preparation, and to give subordinate space to the chemical properties of products. This treatment suits an account of synthetic macromolecules, since variation in preparative techniques, in accordance with the nature of the monomer, with properties desired in the polymer, and with the economics of manufacture, is the dominant theme in polymerization literature.

The volume inevitably required multiple authorship, and has been divided nearly equally into general and specialized parts. This arrangement leads to some duplication of subject-matter. The general section begins with a short discussion of terminology, followed by 108 pages devoted to polymerization in bulk and in solution (from Prof. W. Kern and Dr. R. C. Schulz, of the University of Mainz), and then by an account, nearly four times as long, of polymerizations in emulsion and in other heterogeneous systems (from Dr. H. Logemann of the Farbenfabriken Bayer *A.G.*, and other industrial chemists). Kern and Schulz's section is an excellent concise survey, with several hundred references; it includes tabulated data on polymerizable compounds, initiators, copolymerization parameters, and solvents for polymers; it describes apparatus and other practical matters; and it deals briefly with some large themes, such as polymer characterization, branched and block polymers, and (in a sub-section by Dr. B. Braun) stereochemical features of polymerization.

The section on emulsion methods blends chemistry with some technology, and comes from veteran and expert practitioners of the art. All practical aspects are thoroughly considered, with abundant references, and discussion of properties of polymer latices is included. There are many tables; those dealing with peroxides and other initiators, and with components of redox catalyst systems are particularly welcome.

The specialized part of the book is effectively a series of monographs on individual monomers. Kern, Schulz and Logemann are again the authors, supplemented by several other chemists, including Dr. E. Trommsdorf and his colleagues of the Rohm and Haas Company. This latter group deals with acrylic and methacrylic polymers in a little more than 100 pages, and similar space is given by other authors to butadiene and isoprene. About 90 pages are devoted to styrene, about 50 each to ethylene and to vinyl ethers, and smaller sections (10–30 pages each) to other olefines, 2-chlorobutadiene, vinyl halides, vinyl esters, olefinic aldehydes and ketones, vinylsulphonic acid, *N*-vinyl compounds, allyl compounds, and copolymers containing carbon monoxide or sulphur dioxide. Discussions of methods of preparing stereoregular polymers appear in various places. The following topics, discussed in the case of acrylonitrile, exemplify the contents of a typical section: the monomer; its polymerization in bulk, in solution, in emulsion, with ionic catalysts, and with redox catalysts; its use in copolymerizations, summarized in 12 pages of tabulated data.

The book is rich in experimental details of laboratory preparative methods and in references to the patent literature of the polymer-producing industries, but the treatment of physico-chemical aspects of polymerization and of polymer properties was not the intention of its authors. Some readers might prefer less discussion of particular topics and more of others. A book dealing with so large a subject is bound to encounter minor criticisms, but its undoubted achievement is to present, in a most authoritative way, and between the same covers, a vast amount of information that is either scattered through many smaller books or is unobtainable except by laborious searches through chemical abstracts. R. G. R. BACON

CHEMISTRY OF LITHIUM AND SODIUM

Supplement to Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry

Prepared under the direction of an Editorial Board. Vol. 2, Supplement 2: The Alkali Metals, Part 1. Pp. xxxix + 1458. (London: Longmans, Green and Co., Ltd., 1961.) 360*s*. net.

THE original second volume of Mellor's *Treatise* dealt with both the alkali metals and the halogens in 894 pages. The supplementary volume on the halogens, published in 1956, contained 1,152 pages and the present one, dealing only with lithium and sodium, has 1,458 pages. Some idea of the growth of knowledge since 1922 is conveyed by these figures. The older volume was the work of one author: the supplements of editorial boards. A good proportion of Mellor's work was done with original sources; the supplements are stated to be based on abstract literature, but the originals must have been used in many cases to provide the numerical information given. Reliance on abstract literature, which seems to have been the origin of most of the work, has its drawbacks, since information on particular topics may be contained in papers of which the titles give no clue to this. As an example, it may be mentioned that no method for the preparation of pure lithium iodide is to be found either in the original volume or the supplement, since it is contained in a paper on electromotive forces. The statement that lithium hydride has no large-scale uses is surely misleading for the deuteride. Such omissions are inevitable when work is divided among many persons, each responsible only for a small field and relying on abstract titles.

The arrangement of literature references at the end of each sub-section is a great improvement on that of the original volumes. The meaning of the figures in brackets after each reference should have been repeated from the first supplement. The collection of literature abbreviations shows what a very wide field of publications, including Russian, has been covered.

The book is not intended for elementary students but for practising chemists and works managers, who in designing plant costing many thousands of pounds require factual information. The surface tension of lithium, we are told, has been calculated by wave mechanics as 400, 639, and 890 dynes cm^{-1}, and empirical estimates are 430 and 473. If the value had not recently been determined experimentally it would have been economical to make such a determination. In chemical industry, again, processes and plants described in students' text-books as 'obsolete' may be of considerable importance.

Every student is taught that the Deacon chlorine process is obsolete, and his teacher has probably never heard of an older and even more obsolete Dunlop process, yet both these are to-day of considerable technical interest. In the case of sodium production, it is by no means improbable that the old thermoreduction with carbon may assume importance, and something is rightly said in the present volume of such processes.

Disquisitions of purely theoretical interest are not very prominent, but enough is said to indicate where further information can be found. In some cases they could with advantage have been further reduced, as in the discussion of alloys in the section on lithium alloys. There is really a good deal of theory in the book, and the treatment is commendably well balanced. The numerical information is very detailed and there are many clear graphs and phase diagrams, and some illustrations of technical apparatus. The type was set up on a 'Varitype' machine and the work reproduced and printed by offset lithography. The result is clear and free from flaws, although some may prefer conventional typography. The price is reasonable in view of the enormous amount of factual information provided, much of it available only in large libraries and there to be acquired only by expenditure of costly time and effort. The book is one which every practical chemist must have available, and all concerned in its production deserve congratulation for the result of their careful and skilful work.

J. R. PARTINGTON

SCIENTIFIC METHOD

The Development of Scientific Method

By W. S. Fowler. (The Commonwealth and International Library of Science, Technology and Engineering. History of Science and Technology Division, Vol. 1.) Pp. xiii + 116. (London and New York: Pergamon Press, 1962.) 10*s*. net.; 1.75 dollars.

SOME fifty volumes of the Commonwealth and International Library of Science, Technology and Engineering are planned for this year, and by 1967 it is hoped that the total will reach one thousand (see *Nature* of May 19, p. 631). The vision behind such an enterprise in scientific literature is matched by the experience and standing of those associated with it. Sir Robert Robinson is chairman of the Honorary Editorial Advisory Board and Prof. W. H. G. Armytage is general editor of the History of Science and Technology Division.

The table of contents of the book under review covers five pages and may well act as an index: it has the advantage of presenting a summary of the material contained in each of the eight chapters. As the title suggests, emphasis is on the method of the sciences, though this is not divorced from the history of science on one hand, or from contemporary philosophy on the other. The book should therefore appeal to a wide circle of general readers as well as to the man of science; it is specially to be recommended for its numerous quotations from sources.

Chapter 1, aptly headed "The Heroic Age of Science", covers the Greek period from Thales to Plato. The importance of Aristotle in relation to method is discussed in Chapter 2. The unusual title, in a book on science, "Theology the Queen of the Sciences", is justified as Mr. Fowler unfolds the influence which Neoplatonism had on scientific method. After reference to the practical aspect of Islamic science, the author returns to the main theme as illustrated by the Schoolmen. This naturally leads to a survey of the Copernican revolution and its results. Another chapter is devoted to "Method and Metaphysics", beginning with Descartes and extending to Kant. Chapter 6, "Revolution and Experiment", surveys the practical approach, in physics, chemistry and biology, of the eighteenth and nineteenth centuries. In a chapter devoted to the exploration of Nature, Mr. Fowler takes the reader into the heart of twentieth-century theory, whether of the atom or of the universe. The book closes with a stimulating approach to the "Nature of Method".

The thoughtful reader cannot fail to be impressed by the way the author presents a comprehensive survey within the confines of a relatively small book. To assist those members of the public who would like to read further, Mr. Fowler has added a book-list arranged under the three headings: "History of Science", "Method of Science", "Philosophy and Science". This bibliography has the merit of comparative brevity. There is, in addition, a valuable "Glossary of Principal Names". The book is illustrated and well produced.

H. D. ANTHONY

SPELÆOLOGY IN BRITAIN

British Caving

An Introduction to Speleology. Edited by C. H. D. Cullingford. Second edition (revised). Pp. ix + 592 + 48 plates. (London: Routledge and Kegan Paul, Ltd., 1962.) 75*s*. net.

THE publishing of *British Caving* in 1953 marked a great advance in the development of scientific spelæology in Britain. This much-enlarged second edition of the book, compiled by members of the Cave-Research Group, shows the amount of work which has taken place in the past nine years. The revision is somewhat uneven. Two chapters, Chapter 4 ("Cave Formations and Deposits"), and Chapter 9 ("Cave Fauna and Flora"), have been both rewritten and enlarged. All the other chapters have been simply reprinted, but many of the more important ones are followed by extensive new supplements and bibliographies indicating the scope of the work that has taken place since 1953. Thus more than 30 pages are added to the chapter on the caving regions of the British Isles and the length of accompanying bibliography is increased by 13 pages. A similar long supplement occurs at the end of the section on archæology and palæontology. Many of the other chapters have short supplements but one or two are completely unchanged. This method of revision means that the new material is not well integrated into the text, but it was probably adopted to keep down the price of this second edition.

The value of the book has been increased by more extensive reference to present-day European and American developments. This is indicated in the comprehensive bibliographical collections, but I still maintain, as I did in 1954, that the value of these would be even greater if brief notes were added. The good format of the book and the high standard of the plates and diagrams have been maintained. The index has been thoroughly revised; but the lists of "Caves, Mines and Resurgences" and of British caving organizations given in Appendix *B* have not been revised.

M. M. SWEETING

NUCLEAR EXPLOSIONS IN SPACE

By Prof. S. F. SINGER
University of Maryland, College Park, Maryland

CONCERN has been voiced[1] about the effects of nuclear explosions in space. The present article deals with these matters. The discussion will be first on a relatively simple level suitable for a non-specialist, followed by a more detailed quantitative treatment. I shall discuss in turn: (1) the injection of electrons from the β-decay of fission fragments; (2) injection of electrons from the β-decay of slow neutrons, from nuclear reactors as well as from bombs; (3) injection of ~ 10 MeV protons from fusion neutrons; (4) removal of naturally trapped particles by 'space sweeping' and by hydromagnetic waves.

Fundamental Problems and Inputs

From a scientific point of view, the major questions raised are whether such explosions can tell us more about the origin of the natural radiation belts around the Earth; from other points of view one wishes to know whether such explosions can affect or possibly do away with the natural radiation belts; or whether they increase significantly the level of radiation in the space around the Earth. These questions lead naturally to the possibility that there may be other methods, apart from nuclear explosions, for affecting the natural radiation belts or for producing an artificial one.

As we shall see, practically all these questions can be answered in a direct way. The only prerequisite is an understanding of the properties of the Earth's magnetic field and atmosphere at high altitudes, and the interactions of the products of a nuclear explosion with the field and the atmosphere.

Most of the relevant facts and theories have already appeared in the open scientific literature. For example, a theory for the trapping of charged particles in the Earth's magnetic field was put forth as long as six years ago[2]. It, in turn, was based on basic theories developed by the Swedish astrophysicist Alfvén[3]. Even earlier, Ross Gunn in the United States and a Norwegian astrophysicist, Störmer, made many fundamental mathematical investigations of the motion of particles in a magnetic field.

The only item not released is a description of the nature of particles and radiations coming from a nuclear explosion. Here, however, a basic knowledge of nuclear physics, and in particular of the fission process of uranium, can supply much of the needed information. Thus, a physicist can work out the consequences of atomic explosions in space. It may seem strange to the non-specialist that such assessment is possible without recourse to classified data or even actual experiments. It turns out, however, that order-of-magnitude calculations are in many cases able to give a clear-cut yes-or-no answer. In most practical cases, it is sufficient to know that an effect is either many times too large or many times too small.

Trapping in Earth's Field

Basic to all the discussion to follow is an understanding of the motion of charged particles in a magnetic field.

A proton or electron will simply spiral about a line of force. The spiral can be quite flat with pitch angle of 90° just as in a cyclotron. Or it can have a smaller pitch angle, in which case it will progress along the line of force and trace out a helix or screw thread. The pitch angle depends essentially on how the particle is started out in its motion in the magnetic field.

The situation becomes of great interest when the magnetic field changes in intensity from point to point, as it does in the case of the Earth. As the particle moves into a region where the magnetic field increases (as shown by the fact that the lines of force crowd together), the pitch angle steepens, the spiral becomes flat, and the particle is reflected at the point where the pitch angle reaches 90°. The Earth's magnetic field is constructed in such a way that its strength increases as one approaches the Earth's surface. Therefore, a particle released in space will spiral about a line of force until it reaches a point where the magnetic field is strong enough to reflect it. From then on it will bounce back and forth between the mirror points and be trapped (Fig. 1).

The two major problems now are: (1) How do particles get into the magnetic trap, how many, and where? (2) How long are particles stored in the magnetic trap, and what happens to them to remove them?

Most of the trapped particles, and practically all beyond a radial distance of 2 Earth radii (altitude of 4,000 miles), appear to derive their energy from the Sun by a process of local acceleration. A similar process seems to furnish the many low-energy particles necessary to produce the aurora borealis and australis.

The inner belt of trapped particles found by Van Allen[4] in 1958 and identified by Freden and White a year later[5] is probably not of solar origin. I believe that it is produced by high-energy neutrons

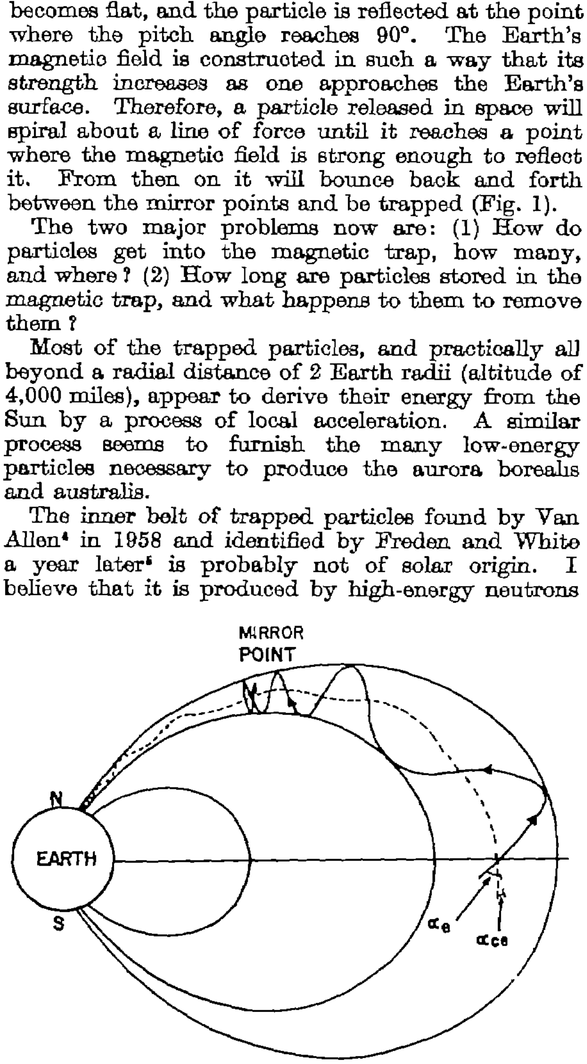

Fig. 1. Schematic diagram showing the helical paths of two particles in a dipole magnetic field. Solid line corresponds to a pitch angle greater than critical; the particle survives for many north-to-south orbits and is properly termed 'trapped'. Dashed line corresponds to critical pitch angle; the particle enters the 'loss cone' and disappears quickly into the dense atmosphere

arising from the impact of cosmic rays on the Earth's upper atmosphere. On the way out into space some of these neutrons decay radioactively into protons and electrons which are then trapped by the Earth's magnetic field. This theory predicts a maximum intensity for high-energy protons close to the Earth, and at low latitudes near the equator[6].

Particle Motion and Injection

In addition to bouncing back and forth between the mirror points, which are located on about the same magnetic meridian, it has been shown that the particles will also drift in longitude. Positive particles will drift to the west, and negative particles, such as electrons, will drift to the east.

It is of great practical importance in discussing the effects of high-altitude explosions to know the speed with which the particles transfer from the southern to northern hemisphere and the speed with which they drift around the Earth. Calculations made in connexion with the trapped particle theory of magnetic storms and auroræ are reproduced in Table 1.

Table 1. CHARACTERISTIC TIMES FOR TRAPPED PARTICLES IN THE GEOMAGNETIC FIELD (FROM REF. 18)

(1) Gyro period = $2\pi\, m/qB$ (sec; B in gauss)
Protons: $6·5 \times 10^{-4}/B$
Electrons: $3·55 \times 10^{-7}/B$

(2) Bounce period = $4\, s r_e/\beta c$
with $s = 1·38 - 0·32\,(\sin \alpha_e + \sin^{\frac{1}{2}} \alpha_e)$
For $\beta = 1$ (relativistic): $\sim 8·5 \times 10^{-2}\,(r_e/R)$ sec

(3) Azimuthal drift period $= 2\pi q B_e R^2\,[mc^2\gamma\beta^2\,(r_e/R)]^{-1}$
Non-relativistic—in equatorial plane.
$= 2·65 \times 10^9\,[E(r_e/R)]^{-1}$ in sec; E in eV
Relativistic—in equatorial plane:
$= 5·3 \times 10^9\,[mc^2\gamma\beta^2(r_e/R)]^{-1}$ sec, mc^2 in eV

For particles which move out of the equatorial plane (that is, for $\alpha_e \neq 90°$) the drift period is increased somewhat, namely, by a factor $1·5\,(1 + 0·5 \sin \alpha_e)^{-1}$.

Here R is the Earth's radius, $r_e = LR$ the distance to the crest of the line of force in the equatorial plane, with L the so-called magnetic shell parameter, s is the dimensionless length of the spiral path from equatorial plane to mirror point.

An important consideration in discussing high-altitude nuclear tests is to know what fraction of the particles released is immediately dumped into the atmosphere and what fraction is stored in the Earth's field. This result depends on the exact location at which the explosion is carried out.

If we release a particle 'above the equator' (that is, in the plane of the magnetic equator) with a certain initial (directed) velocity and therefore a certain initial pitch angle, then as it proceeds along the line of force it will either be reflected before it hits the atmosphere, or it will hit the atmosphere first, in which case it is absorbed and therefore removed from storage. We can define a critical pitch angle α_{ce} at the equator: particles that have a smaller angle hit the atmosphere, while those that have a larger angle are reflected and stored (see Fig. 1). Table 2 gives this information for a number of lines of force. (A line of force is defined by the latitude at which it intersects the Earth's surface. It then sweeps out to a very high altitude LR above the equator and re-enters the Earth in the other hemisphere at approximately the same magnetic latitude.)

If we assume an isotropic burst above the equator, then the last column in Table 2 gives the fraction of particles stores. However, if we move the burst point along the same line of force off the equator, the fraction stored becomes less and less.

Finally, if the explosion takes place just above the atmosphere, practically all the particles will be released into the atmosphere and only a few will be stored. This fact can be clearly seen from Fig. 1. Only particles which start out with a pitch angle of nearly 90° will again be reflected above the atmosphere at the other hemisphere, but as we shall see later, their lifetime will not be very long.

Table 2. FRACTION OF PARTICLES WHICH REMAIN TRAPPED*

It is assumed that particles are released isotropically at a point near the plane of the magnetic equator. Particles having a pitch angle less than α_{ce} are immediately absorbed into the atmosphere. The rest remain trapped with a lifetime which increases with the particle's pitch angle α_e (always referred to when the particle crosses the equatorial plane). Particles with $\alpha_e = 90°$ stay in the equatorial plane and live longest

Line of force defined by L	λ	Critical pitch angle α_{ce}	Fraction trapped† (per cent)
1·1	17°	55°	57
1·5	35°	27°	89
3·0	54°	12°	97
5·0	63°	9°	99
7·0	68°	2°	99·9

* Ref. 6.

† This fraction is greatly reduced when the burst point is off the equatorial plane, and becomes very small when it is at the limit of the atmosphere.

The point of bomb burst therefore controls what happens. If one wants to dump the particles into the atmosphere in the opposite hemisphere, the burst altitude should be as low as possible. (For added effect, the burst should take place where the magnetic field is higher than usual[7]. Then the particles going to the opposite hemisphere will enter the atmosphere much deeper and produce more pronounced effects, such as artificial aurora.)

On the other hand, if one wants to lose as little of the radiation as possible into the atmosphere and store it in space for a long time, then the burst point should be high above the equator.

Particle Lifetime

A crucial problem is the lifetime of the particles trapped in the field. In the absence of any atmosphere and in a perfectly quiet magnetic field, the particles could stay trapped for ever (except where the field is too weak). But in fact there exists a very tenuous atmosphere around the Earth which becomes more and more rarefied the higher we go. As the trapped particles collide with atmospheric atoms or ions or atmospheric electrons, the particles are scattered, their kinetic energy decreases, and their pitch angle changes slightly. If, by chance, the pitch angle should drop below the critical value, then the trapped particle is released into the atmosphere and of course disappears.

It is almost immediately obvious that those particles which penetrate deepest into the atmosphere, where the density is highest, will lose energy fastest and will have the shortest lifetime, while the particles which stay close to the equator, and therefore at high altitudes, will be preserved much longer.

This calculation of the length of time for which a particle remains trapped in the Earth's magnetic field is a complex theoretical problem.

The lifetime T depends on the nature, energy and trajectory of the particle, on the density of neutral atoms and of ions in the outer atmosphere, and on the degree of 'noisiness' of the magnetic field which in turn is related to 'activity' on the Sun and therefore quite variable.

A very detailed treatment has recently been given of lifetime for electrons[8] and for protons[9], with the following results:

(1) Up to about 2 Earth radii, the atmosphere determines the lifetime of trapped particles except for very high energy protons ($\gtrsim$ 100 MeV).

(2) In any event, the atmosphere sets an upper limit; magnetic field fluctuations would decrease this lifetime.

(3) For protons generally, and for relativistic ($> 0{\cdot}5$ MeV) electrons, energy-loss sets the lifetime, and pitch angle scattering can be neglected.

(4) For non-relativistic electrons, scattering must be considered, but this will not concern us here since we will count the electron as 'dead' when its final energy E_f drops below 0·5 MeV (a typical detector threshold).

(5) A useful approximate formula for relativistic electron lifetime is[10] (in sec):

$$T = 3{\cdot}33 \times 10^{13} (\bar{\rho}\, mc^2 \ln\Lambda)^{-1} (E_0 - E_f) \qquad (1)$$

where $\bar{\rho}$ is the averaged atmospheric density in 'effective' electrons per cm^3 (ref. 8), mc^2 is the electron rest energy in MeV, $\ln\Lambda \sim 23$; E_0 and E_f are measured in MeV.

For electrons (with $E_0 = 2$ MeV and $E_f = 0{\cdot}5$ MeV) which do not travel too far from the plane of the magnetic equator, we derive approximate lifetimes (Table 3). These values are substantially less for lower-energy electrons and for particles the trajectories of which extend far along the line of force into the denser atmosphere.

Table 3. LIFETIME FOR A 2-MeV ELECTRON TO SLOW TO 0·5 MeV

Altitude (km)	500	1,000	2,000
Air density (gm cm^{-3})	$4{\cdot}5 \times 10^{-15}$*	3×10^{-17}*	8×10^{-20}†
$\bar{\rho}_E$ electrons cm^{-3})	6×10^{8}	4×10^{6}	1×10^{4}
Lifetime	2 hours	2 weeks	14 years

* Predominantly oxygen (ref. 18).
† Predominantly hydrogen (ref. 9).

Thus, it is shown that the lifetime increases as we deal with radiation released at higher altitudes or higher latitudes, that is, along a line of force which sweeps out to a greater altitude above the equator. Beyond 3 Earth radii, the atmosphere is probably no longer the determining factor for lifetime. Instead, it is believed that the 'noisiness' of the rather weak magnetic field causes scattering of the particles and eventually removes them from the trapped condition.

Artificial Radiation Belt

Now, in fact, a direct measurement of particle lifetime is of fundamental importance for studying the origin of the natural radiation belts, for studying interactions of magnetic waves with trapped particles, and for studying the density of the outer atmosphere; many other applications could be mentioned.

The best way to measure lifetime is to inject more trapped particles suddenly and look at their decay. For scientific purposes, an atomic explosion is a very crude injection device. So, for that matter, is the natural injection which takes place, for example, after solar flares. A much more refined measurement is possible if one uses an electron accelerator for injection, an experiment suggested independently by N. C. Christofilos[11] and by me[12]. Then the energy of the electrons can be precisely controlled, the direction of injection can be controlled if desired, and the number of electrons released is definitely known. Also, it can be turned on or turned off at will.

The Uranium Fission Process

We now summarize some of the properties of the fission process[13]. A uranium nucleus which has absorbed a neutron will undergo fission and break up into two smaller fragments. Most frequently the fragments are krypton of atomic weight 93 and barium-143. The velocity of the fragments is of the order of 10^8 cm/sec corresponding to a total kinetic energy of more than 160 MeV (million electron volts).

In the fission also an average of 2·5 neutrons are released having a most probable energy of 0·8 MeV and a mean energy of 2 MeV; this multiplication of neutrons makes a chain reaction possible. A small fraction of neutrons, about 1 per cent, are delayed and released after about 0·01 sec (this fact makes the operation of a controlled nuclear reactor possible). Prompt γ-rays are released having an energy of about 5 MeV.

The two fission fragments are of particular interest. They are highly unstable and will undergo several radioactive decays before they reach a stable nucleus condition. In each decay they emit an electron. The energy of the β-rays can be calculated from nuclear theory and averages about 2 MeV.

Now let us take as our reference a fission bomb of 1 megaton TNT (equivalent) yield. A simple calculation tells us that this release of energy corresponds to $4{\cdot}2 \times 10^{22}$ ergs or $2{\cdot}5 \times 10^{28}$ MeV. If we make use of the fact that each fission releases about 200 MeV then we derive the total number of fissions as $1{\cdot}3 \times 10^{26}$. (The weight of the fissioned atoms is only 10 lb., but the amount of fissionable material in the bomb is of course much greater.)

Knowing the number of fissions, we can calculate the output of neutrons, γ-rays, and β-rays (electrons). The latter are emitted with a wide range of energies, but it seems reasonable to assume about one high-energy electron (about 2 MeV) per fission with the rest at much lower energies where their effects are of little importance because of their much smaller lifetime.

Only the highest energy electrons emitted from the fission fragments are of any significance for trapped radiation. The fission fragments themselves are unimportant, the γ-rays escape from the Earth's field since they are uncharged, and most of the neutrons will escape. In any event, the decay of a low-energy neutron only gives a low-energy proton and an electron of about 0·5 MeV; both have very short lifetimes.

Limits to Trapped Particle Flux

It would seem that effects of successive bomb explosions could be superimposed indefinitely to build up extremely large trapped particle fluxes. This, however, is not the case. There is a theoretical limit to what can be trapped in the Earth's magnetic field; it can store only a certain maximum concentration of particles set by their reaction on the magnetic field itself. The particle energy density can be at most a fraction, about 50 per cent, of the magnetic field energy density. Since the latter varies as the inverse cube of distance, the energy density, which is $B^2/8\pi$, varies as $1/r^6$ (Table 4).

Electron Injection in the Pacific Test

Case I: Injection of electrons from fission fragments. We are now ready to consider the injection of fission electrons from the forthcoming test shots in the Pacific. According to the *New York Times*, a nominal 1 megaton bomb will be exploded 500 miles over Johnston Island (longitude 191° E., latitude 17° N.). Two sub-cases will be considered: (*a*) injection at the point of explosion; (*b*) injection along the line of force.

Case I (a): What will happen to electrons which are released at the point of explosion with an isotropic

Table 4. UPPER LIMIT TO PARTICLE FLUX WHICH CAN BE TRAPPED

Distance from centre of Earth (in Earth radii)	1 2	1·5	3·0	5 0
Maximum particle concentration cm^{-3} (2-MeV electrons)	400	110	1·7	$7·8 \times 10^{-2}$
Maximum particle flux cm^{-2} sec^{-1}	$1·2 \times 10^{13}$	$3·3 \times 10^{12}$	5×10^{10}	$2·3 \times 10^{9}$

These limits are based on the principle that the energy density of the trapped particles may not exceed 50 per cent of the energy density $B^2/8\pi$ of the unperturbed magnetic field.

distribution in the directions and with an assumed unique energy of 2 MeV ? (This case would be realistic only if the fission fragments had a β-decay half-life very much shorter than the bounce period.) In order to solve this problem we have to examine first of all the properties of the magnetic line of force which passes through this point. From published tables[14], it is seen that at the 'crest' of the line of force the magnetic intensity will be 0·20 gauss; the altitude will be 1,200 km.

It would seem, from Table 3, that these particles could survive for many bounce periods above 800 km. But now we must consider the peculiar construction of the geomagnetic field. To a reasonable approximation the field can be represented by a dipole which is placed eccentrically about 436 km from the centre of the Earth. (Therefore particles trapped in the magnetic equatorial plane do not maintain a constant altitude as a function of longitude but describe an eccentric orbit which is displaced with respect to the Earth's centre.) Adding to this the effects of local anomalies as determined by the actual magnetic field causes the particles to dip down very deeply in the South Atlantic (Fig. 2). In fact, all the particles which are released at the explosion point 800 km above Johnston Island, even those with 90° pitch angle, will be removed on their first trip around the Earth.

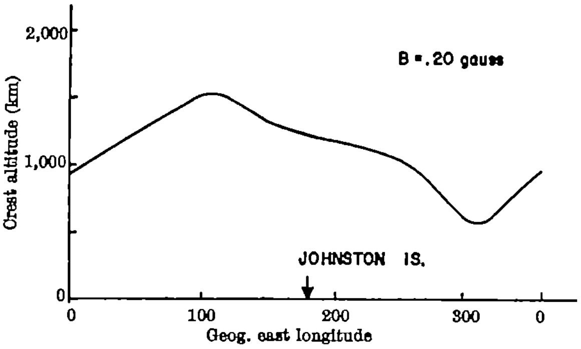

Fig. 2. Altitude of the crest of a magnetic shell of the actual terrestrial field corresponding to a particular value of B. The dip corresponding to the South Atlantic anomaly shows up clearly at 310° longitude east. This curve was obtained from the Tables of ref. 15 and from ref. 14

The calculation is carried out in the following way. We note first of all that the magnetic moment μ, the so-called first adiabatic invariant, is given by:

$$\mu = E_{\perp}/B = \text{const.}; \therefore \sin^2\alpha/B = 1/B_m \qquad (2)$$

where $E_{\perp}$ is the kinetic energy perpendicular to the magnetic field, B the local value of magnetic field and B_m the value at the mirror point.

There exists also a second adiabatic invariant, the so-called longitudinal invariant, given by:

$$I = mv \oint (1 - B/B_m)^{\frac{1}{2}}\, dz = \text{constant} \qquad (3)$$

Together, conservation of the two invariants determines the orbit of the particle completely and locates the magnetic shell in which it travels. Tables of the second invariant have been computed[15] on the basis of Vestine's spherical harmonic expansion of the actual magnetic field.

We obtain first the minimum mirror altitude corresponding to complete energy-loss of a particle, as it passes the South American anomaly.

For orbits which go to a low enough altitude where the scale height is small compared with R, the Earth's radius, the average density $\bar{\rho}$ over the orbit is related to the density at the mirror point ρ_m by[16]:

$$\bar{\rho} \sim \rho_m \frac{1}{s}\left[\frac{\pi}{6}\,\frac{H}{r_e}\,\frac{x_m \quad (4 - 3x_m)^2}{(8 - 5x_m)\,(1 - x_m)}\right]^{\frac{1}{2}} \qquad (4)$$

where $x_m = r_m/LR$; r_m is the geocentric distance to the mirror point, LR is the distance to the line of force in the equatorial plane for an equivalent dipole field; s is the dimensionless length of the spiral path from equatorial plane to mirror point.

The thickness of atmosphere traversed from equatorial plane to mirror point is (for low mirror points $r_m \sim R$):

$$d = \bar{\rho}sLR \sim \rho_m\left[\frac{\pi\ HR\ (4 - 3L^{-1})}{6(8-5L^{-1})(1 - L^{-1})}\right]^{\frac{1}{2}}\ \text{g/cm}^2 \qquad (5)$$

Now L is defined as (sea-level field/crest field)$^{\frac{1}{3}}$; here $L \sim (0·31/0·20)^{\frac{1}{3}} \sim 1·20$; hence:

$$d \sim 2·8 \times 10^4 H^{\frac{1}{2}}\rho_m \qquad (6)$$

The South Atlantic anomaly is ~ 30° wide. Calculating a drift time of 30 min and a bounce time 0·1 sec, a particle makes 30 × 60 (30/360)/0·1 = 1,500 reflexions in the anomaly.

In each penetration it passes through d g cm^{-2}. Now a 2-MeV electron has a range ~ 1 g cm^{-2}. Therefore, if we set:

$$d = 2·8 \times 10^4 H^{\frac{1}{2}}\rho_m = (1{,}500)^{-1}\ \text{g cm}^{-2} \qquad (7)$$

we find the maximum permissible value of $H^{\frac{1}{2}}\rho_m$ to be $\sim 2·38 \times 10^{-8}$ g cm^{-3} $cm^{\frac{1}{2}}$. Taking $H \sim 10$ km (near 100 km altitude) we have $\rho_m \sim 2·4 \times 10^{-11}$ g cm^{-3}. This density occurs near 110 km; and this is the minimum mirror altitude for just one pass.

On the other hand, Tables in ref. 15 give an estimate of the mirror altitudes from 35 to 110 km for Case (*a*). Therefore, it is quite likely that most electrons will not survive the first passage of the anomaly.

Case I (*b*): We now consider a more realistic case in which the electrons are not released at the explosion point but all along the line of force which passes through this explosion point. It may be assumed that the fission fragments after being created will stay tied to the line of force, bouncing back and forth but moving very slowly in longitude. Therefore, some β-decay of fission fragments, and release of electrons, will take place near the peak of trajectory, that is, in the immediate vicinity of the equatorial plane. These electrons have the best chance for survival.

Let us consider an extreme case of an electron which is released with a 90° pitch angle in the equatorial plane; its lifetime gives an upper limit to the decay of the trapped electrons. The procedure is to determine again the magnetic shell in which it moves, integrate the density within the equatorial plane (that is, along the 'crest' of the shell), and compare with the range of the electron.

A plot of the crest line (Fig. 2) (obtained from the Tables in ref. 15 for $B = 0·20$) gives a curve which has an altitude of 1,200 km at longitude 191° E. (Johnston Island); a maximum altitude of 1,540 km at 106° E., and a minimum of 560 km at 310° E.

The width of the minimum is 30°, measured at an altitude one scale height ($H \sim 100$ km) above 560 km. The average density therefore is $2 \times 10^{-16} \times (30/360)$ g/cm³ and the lifetime, for a range of 0·9 g/cm², is:

$$0{\cdot}9 \left(\frac{360}{30}\right) \frac{1}{2 \times 10^{-16}} \; \frac{1}{3 \times 10^{10}} = 2 \times 10^{6}$$

or about one month.

As a very rough approximation, a change of the firing altitude by $\pm$ H km will change this maximum lifetime by $\pm$ a factor e.

We next must calculate the fraction of fission electrons which may survive for this maximum length of time. This number is obtained in three steps:

(i) We assume that at the explosion point the fission fragments are emitted isotropically. We then have an immediate loss of all fission fragments except those which are emitted in a small solid angle around a local pitch angle of 90°. This solid angle is calculated by finding the pitch angle α_e at the emission point which leads to a mirror point at an altitude which is lower by 1 scale height.

Denoting the emission point by:

$$r_1 = x_1 r_e \tag{8}$$

and the lower mirror point by:

$$r_2 = x_2 r_e = r_1 - H = (x_1 - h) r_e \tag{9}$$

and using the relation (2) as well as:

$$B(x) = B_e \frac{(4 - 3x)^{\frac{1}{2}}}{x^3} \tag{10}$$

we have:

$$\sin^2\alpha_e = B_1/B_2 = (x_2/x_1)^3[(4 - 3x_1)/(4 - x_2)]^{\frac{1}{2}} \tag{11}$$

For $H \ll R$, or $h \equiv H/R \ll 1$

$$\cos \alpha_e \sim h^{\frac{1}{2}} \, [(3/x) + 3/(8 - 6x)]^{\frac{1}{2}} \tag{12}$$

A typical value for $\cos \alpha_e$ is 0·24; it corresponds to an emission point at 800 km altitude, and to $H \sim 100$ km. (Actually the remaining 76 per cent of the fission fragments are not really all lost; a good fraction, however, is slowed down so appreciably that the chances of decaying near the crest line are negligible.)

(ii) Only a fraction of the fission fragments will actually decay near the peak of trajectory—this fraction must be estimated by looking at the particular magnetic line of force, and calculating the fraction of time which the particle spends near the crest.

The time taken to spiral from the crest (in the equatorial plane) to the mirror point is:

$$sRL/v \tag{13}$$

where $s \sim 1{\cdot}0$ for a wide range of equatorial pitch angles and v is the particle's speed.

The neighbourhood of the crest is defined by letting the particle descend one scale height along the line of force to a latitude λ. Then $\cos^2\lambda = 1 - h$, and for small values of h, one finds $\lambda \sim h^{\frac{1}{2}}$. Therefore, the time spent near the crest is $\sim RLh^{\frac{1}{2}}/v$ (assuming a small equatorial pitch angle), and the fractional time becomes $h^{\frac{1}{2}}$.

(iii) Finally, in the β-decay the electron is also emitted isotropically, and again only those survive which are emitted in a small solid angle around 90°. This fraction is given by an expression like (12).

If we now multiply these three fractions together, we see that of the initial fission fragments only about $4h^{3/2}$ will give electrons which have the right orbit to survive for the maximum length of time.

For our particular example, this time was ~ one month, and the fraction turns out to be $\sim 5 \times 10^{-3}$ for a scale height of 90 km. It should be noted, however, that because of the non-dipole character of the magnetic field, the altitude of the trapped particle, and the relevant scale height, will vary with longitude. Just as in the foregoing lifetime calculations where the peak density encountered had a significant effect, so it is necessary to use the smallest scale height encountered to calculate the fraction having this lifetime. Since H can be as low as ~ 8 km in the E-layer, the fraction may be as small as 10^{-4}.

Numerical Estimates

In the foregoing discussion, the assumption was made that the β-decay lifetime of a fission fragment is long compared with the bounce time; this leads to an upper limit for the fraction of $\sim 10^{-3}$–10^{-4}.

Also it was assumed implicitly that all the explosive power is due to uranium fission. In fact, an unspecified fraction, depending on the cleanness of the bomb, will be due to hydrogen fusion, which leads to a great reduction in the number of fission fragments. However, to get upper limits, we will ascribe all the explosion to fission.

The number of 2-MeV electrons injected is therefore $\sim 10^{23}$. The volume into which they diffuse after a few drift periods around the Earth is $\sim 2 \times 10^{24}$ cm³; here the thickness of the shell is adopted as ~ 40 km, similar to that of the *Argus* experiment. The concentration of electrons thus becomes 5×10^{-2} per cm³, and the flux $\sim 1{\cdot}5 \times 10^{9}$ per cm² sec. It should be emphasized again very strongly that this flux is an upper limit for the various reasons already mentioned. In addition, a greater shell thickness, as might be expected from the larger explosion, increases the volume in proportion, and thus decreases the flux further.

Adverse effects produced by such large radiation fluxes on unshielded components in satellites are not in the least surprising. Semiconductors, for example, solar cells, transistors, etc., are most sensitive to large radiation doses; a value of $\sim 10^{6}$ r. can result in a deterioration in performance, or produce failure. Now a dose of 10^{6} r. corresponds to 6×10^{13} MeV of energy deposited in 1 gm of tissue. Using a minimum energy loss rate of 1·6 MeV per gm-cm⁻², the flux of $1{\cdot}5 \times 10^{9}$ per cm²-sec gives the damage dose in about 1 h. This time may be more like 100 h, considering that this flux is an extreme upper limit, and that the solar cells spend only a fraction of each orbital period in the artificial radiation belt.

Case II. Injection of electrons from the β-decay of Fission Neutrons. As described earlier, neutrons of (most probable) energy 0·8 MeV are emitted in the fission process. In a bomb explosion a certain fraction, partly moderated, will escape. Their effects in producing trapped particles are quite inconsequential (compared, for example, with the fission electrons just discussed); hence, order-of-magnitude estimates will suffice. The maximum energy of electrons from neutron decay is 780 keV, with a mean near 300 keV. Hence the lifetime, and the intensities, are greatly reduced compared with 2-MeV electrons (by more than a factor 10).

The β-decay of slow neutrons from natural cosmic ray albedo contributes a portion of the trapped electrons in the Earth's radiation belts[8]. At the present time we do not know just what this fraction is; but in any event it is likely to be small in number as compared with the electrons which are produced by other natural sources. Particularly, farther out in the radiation belt, at lines of force connecting to high latitudes, the production by a process of local acceleration must be quite important since electrons are often precipitated into the atmosphere at a very heavy rate.

It will be useful to compare the neutrons emitted in a fission explosion directly with the cosmic ray neutron albedo; taking the latter to have an intensity of about 1 per cm^2 per sec, we arrive at a figure of $1 \cdot 6 \times 10^{26}$ emitted over the whole Earth each year. This is just about the number of fissions of a 1 megaton bomb, and if we assume that the number of escaping fission neutrons equals the number of fissions we can then state that an explosion will contribute about one year's worth of neutrons.

In addition, with a velocity of $\sim 1 \cdot 5 \times 10^9$ cm per sec, and a decay half-life of $\sim 10^3$ sec, only a small fraction ($\sim 10^{-3}$), of the neutrons actually decay within 2 or 3 Earth radii. We have therefore $\sim 10^{23}$ electrons diffused in a volume of $\sim \frac{4}{3}\pi\,(1 \cdot 5 \times 10^9)^3 \sim 10^{28}$ cm^3, leading to a flux of $\sim 10^5$ per cm^2 sec. (A more accurate estimate could be made; see, for example, Case III.)

It is interesting to consider a case of continuous injection, for example, the artificial radiation belt produced by operating a nuclear reactor, for example, in a communication satellite[7]. If the reactor's power-level is 100 kW, and its orbit 1,000 miles above the equator, then the following estimates apply: number of uranium fissions about 6×10^{15} per sec, which also gives roughly the number of escaping neutrons.

Assuming these to be of thermal energy, they travel an average distance of 200 miles before decaying radioactively into an electron and proton. The electrons are released with an energy of about 0·5 MeV into a volume around the Earth of about 6×10^{25} cm^3. Taking a lifetime of a few months, their concentration build up to 10^{-3} per cm^3; but their flux will be something like 10^7 per cm^2 per sec.

Fortunately, it is easy to shield against 0·5-MeV electrons, which have a range of $1 \cdot 7 \times 10^{-1}$ g/cm^2 of aluminium; the reactor therefore produces no hazard. However, the phenomenon of trapped radiation can be used to detect the existence of an orbiting nuclear reactor.

Case III. Injection of protons from fast neutrons. In the case of explosion of a fusion bomb, in which isotopes of hydrogen are involved, the reactions between deuterons and tritons give rise to 14-MeV neutrons. Let us assume as an extreme upper limit that everyone of these neutrons escapes. (Obviously this cannot happen unless the bomb has essentially no mass, but this assumption does give an extreme upper limit for the resulting trapped protons.) For 1 megaton, their extreme maximum number N is 2×10^{27}.

These neutrons may lose some energy in traversing the bomb material; therefore, we shall assume a mean energy of 10 MeV. These neutrons will travel with a speed of 4×10^9 cm per sec and will therefore move ahead of the bomb debris, fission fragments, etc. While travelling through the Earth's magnetic field, a certain fraction of them will decay and the resulting protons will carry forward the kinetic energy.

In a sense this calculation is very similar to that already performed[9] for neutrons which are produced by solar 'cosmic rays' impacting on the Earth's polar regions, but with two important differences: (i) the solar cosmic rays produce many neutrons with energies higher than 10 MeV which lead to highly penetrating protons; in the present case, the neutron energy is 10 MeV which means that we arrive at a proton that cannot penetrate more than $1 \cdot 7 \times 10^{-1}$ g/cm^2 of aluminium. (A thickness of $\sim$ 0·6 mm.) (ii) But on the other hand, solar cosmic rays have a very small injection efficiency for trapped protons, $\sim 10^{-3}$ on intermediate lines of force, zero on low latitude lines of force[9]; for a fusion bomb explosion near the equator the injection efficiency is near unity.

From a scientific point of view, it is worth while to do a detailed calculation on the distribution of the injected protons, and on their lifetimes. This is not the case for the electrons (cf. Case II). The reasons are as follows:

(i) Protons are essentially unscattered in atmospheric collisions; their magnetic moment is conserved. This makes the lifetime analysis much simpler.

(ii) There seem to be other sources for $\sim$ 0·5 MeV electrons, unaccountable quantitatively on an *a priori* basis. For protons the only other source appears to be cosmic-ray neutron albedo which can be described quantitatively[8]. Therefore, the fate of the newly injected protons can be traced with little ambiguity.

(iii) Protons can be easily detected, down to about 1 MeV. Very low energy electrons ($\lesssim$ 50 keV) are difficult to measure precisely.

It is first necessary to calculate the decay density, that is, the number of decays per cm^3 as a function of distance from the explosion. The flux of neutrons will vary according to the inverse square law, with the neutrons streaming out radially from the explosion point.

The number of decays is quite small; it is given as a probability per cm by the expression:

$$\lambda = \Lambda(\beta\gamma c)^{-1} \tag{14}$$

where Λ is the decay constant, 9×10^{-4} per sec, βc the velocity, and γ the relativistic dilation factor $(1 - \beta^2)^{-\frac{1}{2}}$.

This decay probability turns out to be 2×10^{-13} per cm, which indicates that within the Earth's magnetic field the neutrons will be scarcely attenuated by decay; therefore, the assumption of the inverse square law is well justified.

For purposes of rough estimates, we will assume that only about 10 per cent of the decays, those within an angle of 30° of zenith, are significant. The reason is that neutrons coming off at larger angles release protons in a fairly dense atmosphere; these therefore have a relatively shorter lifetime.

Consider now the number of neutron decays Q within a volume which is determined by the intersection of a solid angle cone Ω and a spherical shell of radius h (approximately the altitude above sea-level if the explosion is at not too high an altitude) and thickness d. Because Ω is small this portion of a spherical shell can be considered as a portion of a shell of magnetic lines of force, and therefore the protons injected are spread around in longitude into a much larger volume V.

$$Q = N(\Omega/4\pi)\lambda\, d \tag{15}$$

$$V = 2\pi(R + h)(\sim h)\, d \tag{16}$$

The resulting concentration of trapped protons is then:

$$n = Q/V = N(\Omega/4\pi)\lambda\left(\frac{1}{2\pi}\right)(Rh + h^2)^{-1} \text{ per cm}^3 \tag{17}$$

Numerically

$$n = 2 \times 10^{27}\ (0{\cdot}05)(2 \times 10^{-13})\left(\frac{1}{2\pi}\right)(Rh + h^2)^{-1}$$
$$\sim 4 \times 10^{12}\ (Rh + h^2)^{-1}$$

Table 5 gives the initial flux nv as a function of altitude for an assumed burst at 530 km over the equator; in equation (17) $R = 6{,}370 + 530$ km; h = altitude − 530 km.

Table 5. 10 MeV Proton Fluxes and Lifetimes

Altitude (km)	730	1,030	1,530	2,530
Flux (cm² sec)$^{-1}$	$1{\cdot}1 \times 10^6$	$4{\cdot}3 \times 10^5$	2×10^5	9×10^4
Lifetime (sec)	4×10^3	2×10^4	2×10^6	4×10^9

The lifetime is given quite accurately as (range/atmospheric density). Some caution must be exercised in obtaining the relevant density $\bar{\rho}$. Because of the non-dipole structure of the geomagnetic field, the value of $\bar{\rho}$ depends on altitude as well as on longitude; an average must be obtained over the crest of the magnetic shell (cf. the analogous treatment for the fission electrons, Case I). For a Johnston Island firing (longitude 191° E.) $\bar{\rho}$ corresponds to ρ at longitude 290° E. and 330° E. where the crest altitude is ~470 km less than at 191° E. Applying the same correction at all altitudes we obtain the lifetimes of Table 5.

Case IV. Removal of naturally trapped radiation. One of the most intriguing aspects of a nuclear explosion is to determine whether it will dump some of the naturally trapped protons. The opinion has been expressed that some dumping will take place in a restricted region[17]. In the explosion, the material of a bomb is ionized and expands, its pressure being sufficient to move magnetic lines of force. The expansion of this bubble gives rise also to a hydromagnetic wave which may scatter a fraction of the trapped radiation into the loss cone.

I am of the opinion that the effect on the naturally trapped protons will be even smaller than that surmised by Kellogg and Ney, if the explosion occurs away from the magnetic equator. First, as the bubble expands it excludes a magnetic field within it. The resulting compression of the lines of force will tend to produce mirror points ahead of the bubble so that protons will be reflected before they approach the bubble and are scattered by it. Next, the bubble expansion velocity, even assuming all the energy is kinetic, cannot exceed 10^8 cm per sec, and may be as low as 10^7 cm per sec. Therefore, Fermi effects from a single collision off the moving mirror point are negligible. Further, the bubble effect is likely to be adiabatic: the time to traverse a proton gyroradius is ~ few seconds while the proton gyro period is in the millisecond range (Table 1).

To some extent this fits in well with what is observed for natural disturbances of the field. The most careful analyses seem to show that in spite of the existence of strong hydromagnetic waves produced by natural events, the trapped protons are scarcely affected—at least up to about 4,000 miles[9,18]. The observations can so far be explained in terms of removal of protons chiefly by the atmosphere, plus an effect whereby the dipole field eventually loses its trapping ability when the radius of curvature of protons becomes comparable with the scale of the magnetic field.

It is puzzling indeed to realize that the naturally trapped protons have such long lifetimes (up to 100 years) in spite of the existence of large amplitude hydromagnetic waves above the ionosphere. It is therefore quite important to establish whether a man-made hydromagnetic wave of large amplitude can displace any of the trapped protons. The effect, if it exists, is likely to be small but its actual magnitude appears to be an open question.

Particle 'Sweeping'

On the other hand, high-energy protons are constantly being removed by other human activities in near space. The operation of artificial Earth satellites results in the absorption of protons which hit them. An idea of the effectiveness of this process may be gained by analysing the operation of a 'space sweeper' satellite[12]. This scheme may work, because the injection-rate for the hard protons is so small. It requires, however, satellites of very large area (and therefore mass) distributed throughout the radiation belt.

The effective removal-rate of the particles is given by the cross-sectional area of the satellite; that is, the number of particles removed depends on the product of satellite area, A_s, and operating time, T_D. The fractional reduction in intensity, $\delta J/J$, is given very roughly by the number of particles absorbed divided by the total number of particles in the volume affected. The former is simply $JA_sT_D = nvA_sT_D$, and the latter is $n(2\pi rA_c)$. The cross-sectional area A_c is determined by the radius of curvature, a, of the protons in the Earth's magnetic field, B, and is therefore quite large. At a distance r from the Earth's centre we find[12]:

$$A_c = (r\,.\,\Delta\lambda)a = r\,\frac{H}{2r}\;\frac{Mc^2\beta}{300B} \qquad (18)$$

where $\Delta\lambda$ (the effective latitude interval over which the concentration is $\sim n$) is proportional to the scale height, H; and $Mc^2\beta$ is the proton momentum in electron volts (Mc^2 = 931 MeV).

Hence:

$$\frac{\delta J}{J} = \frac{v}{2\pi rA_c}\,A_sT_D \qquad (19)$$

In our specific example, assuming an intensity reduction of 50 per cent, the product A_sT_D turns out to be about 10^{15} cm²-sec. Thus the operating time would be about one year if the sweeper satellite had a radius of about 30 m, or about one month if twelve such sweeper satellites were used.

It is an interesting consequence of this theory that the sweeping time is independent of the proton energy to a first approximation, but that the satellite in a given time sweeps up a larger volume of the higher energy particles, which is, of course, very desirable.

Conclusions

Nuclear explosions in space produce negligible effects on the Earth, for example, a distinctly decreased intensity of fall-out; they produce more significant perturbations of the upper atmosphere, but these are very temporary (measured in hours). It is in near-space itself where very noticeable effects can be produced which can last for many months because of the presence of the Earth's magnetic field.

It is evident that weapons tests in space can have important scientific by-products. The most interesting are the creation of a thin shell of 2-MeV fission electrons the decay and diffusion of which can be studied, as well as the creation of a thick belt of low-energy protons from fusion neutrons. It will probably be desirable to monitor these artificial radiation belts with quite sophisticated energy-resolving detectors, to suppress the naturally trapped radiation, as well as the much larger changes (of factors of 10–100 and even higher) produced by such natural events as solar flares and magnetic storms.

I thank Mr. A. M. Lenchek for assistance in the calculations.

Note added in proof. The present paper was originally prepared in mimeographed form (May 28, 1962) while I was at Jet Propulsion Laboratory of the California Institute of Technology, and was given private distribution. The paragraph concerning the effects of the radiation on solar cells was added at the time of submission when it was learned that solar cells on some satellites had been adversely affected. It would appear, however, that in cases where the solar power supply had an adequate power margin, as, for example, in the case of the weather satellite *Tiros V*, no effect on overall performance occurred.

SUBSTITUTION OF STONE TOOLS FOR BONE TOOLS AT MAKAPANSGAT

By PROF. RAYMOND A. DART

University of the Witwatersrand, Johannesburg

TOWARDS the end of 1961 a block of the basal grey breccia from Makapansgat, while undergoing laboratory development, exhibited a structure roughly resembling a deciduous proboscidean molar. The opposite side of the block showed antelope bones (Fig. 1) and other curious forms. Some of these were large and rather amorphous, but others were smaller and rod-like (? tusk), and some of these round objects were pointed at one or both ends. Others again were plate-like but triangular or partially rounded.

The block was photographed and its constituents carefully isolated (see Fig. 2, which exhibits forty of its forty-one elements). The supposed 'molar tooth and tusk' proved on section and examination by Dr. H. B. S. Cooke, now assistant professor of geology in Dalhousie University, to be "only stalactite". Indeed, seventeen of the objects—most of which are seen in the upper three rows of our second illustration—are stalactitic, but they were used as a source of tools. The third article in the second row from the top on the left side (Fig. 2) is an actual artefact not of stalactite but in chert and has a rostrocarinate form.

On the right side of this chert tool (Fig. 2) is the broken end of a slender stalactite, the point of which fits neatly into the punctate depression found in the spirally broken shaft of the antelope humeral distal end, seen just below it (Fig. 2). These two objects lay right alongside one another in the centre of the compact block (Fig. 1). It is justifiable therefore to assume that this was the actual stalactite used to do the puncturing and cracking of this right humerus and its fellow left humerus (seemingly from the same animal) alongside it (Fig. 2), before their having been spirally broken by twisting. In any event, the lower three rows of the second illustration exhibit twenty-three objects, which are chiefly skeletal, some of which were definitely used as tools before their fossilization.

The essential purpose of this article, however, is to point out that the greatest proportion of this mixed assortment of brecciated material consists of debitage and artefacts which, apart from the chert rostrocarinate tool, are stalactitic in origin. Secondly, despite the deliberate damage these stalactites suffered prior to fossilization, their derivation, whether from long and slender or from thick and massive stalactites, is self-evident. The plate-like forms, whether triangular or rounded, show that they too were produced, like the rostrocarinate tool, by a deliberate process of splitting and trimming stalactites.

The most unexpected artefacts in this fantastic mixture of stalactitic and osteodontokeratic articles are the second object from the left and the second

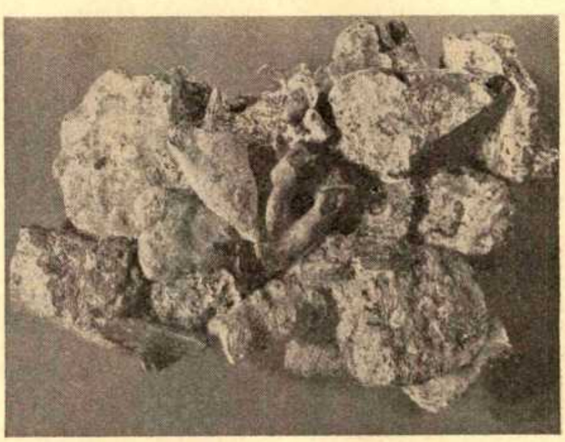

Fig. 1. Block of grey breccia *M.G.B.7* from Makapansgat Limeworks containing many bone fragments and numerous cylindrical, rounded and plate-like, or even triangular, pieces of stalactite. Note the pointed stalactite alongside the distal end of the antelope humerus in the centre of the block, the rod-like stalactite below it and the rounded edge of the chert rostrocarinate tool in the bottom right-hand corner

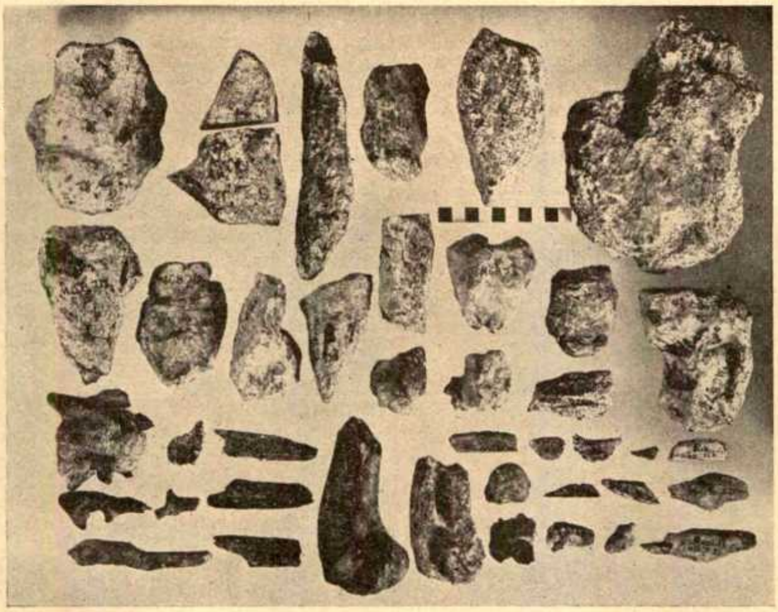

Fig. 2. Forty of the forty-one objects isolated from the compact grey breccia block *M.G.B.7*. The three upper rows are mainly stalactitic; the three lower rows are chiefly osteodontokeratic. Note the chert rostrocarinate (third from left in second row from top), the pointed stalactite on its right and the distal humeral end (with punctate depression) below the pointed stalactite, along with its fellow distal humeral end and other skeletal objects. The two stalactitic hand axes are in the top row; the second from the left (with its very blunted edge facing upwards) is the transected 'elephant molar'; the second from the right has its sharp edge facing downwards

from the right respectively, in the top row of Fig. 2. The second from the left has a spur of colophonite attached to it and is actually the supposed 'molar tooth' after its transection to display its own stalactitic origin. Its counterpart, the second from the right, is also part of a similar thick stalactite and has been oriented to show the implemental purpose of both of them. They are the simplest possible sort of stalactitic hand-axes imaginable (Figs. 2 and 3).

The more lacunar centre and the obviously concentric lamination of their artificially sectioned surfaces show that the stalactites, from which these two hand-axes came, were originally about five inches thick. The contrast between their rounded external surfaces and their flat planes of cleavage display with diagrammatic clarity the three direct, consecutive steps of the unsophisticated, yet ingenious and deliberate, technique involved in their manufacture.

Short cylindrical blocks about 4 in. high were first detached from suitably thick stalactites. This could only have been done by powerful lateral blows with a block of dolomite or some other weighty stone furnished with a sharp enough edge, probably in the same way as Australian Aborigines still use natural eoliths to chop through trees and to fashion wooden implements[1].

The resultant short cylindrical stalactite blocks were then placed on the dripstone floor or some other suitable anvil and each split into two half-cylinders by a vertical blow down through the middle of the block with a shoulder blade or some other blade-like tool. Thereby each half-cylinder automatically acquired two sharp borders or chopping edges.

The third step was to select the edge which would make the keener blade and to provide this chosen cutting edge with a suitable blunt back. This was done by merely removing the blunter edge with another blow. With the half-cylinder's vertical cleavage face flat on the floor or anvil the detaching blow was delivered about the middle of the half-cylinder alongside the edge to be removed. Judging from the two specimens available, the same three steps were adopted for making both hand-axes. They could both have come from the same thick stalactite.

The concurrence of chert, stalactitic and osteodontokeratic tools in one and the self-same block shows that it formed part of a living floor that was also a factory site. The intimate association of the chert artefact with these two hand-axes made from split stalactites is a clear proof that the many other stalactitic and chert, as well as the few foreign quartzitic and shale objects encountered in other blocks of the grey breccia, were not, as previously imagined, accidental occurrences. They provide authentic, objective evidence of the natural manner in which inorganic substances were becoming involved in the manufacture of implements by bone-tool-making australopithecines.

It was in *Nature*[2] that the late Prof. C. van Riet Lowe first announced the original discovery by Dr. C. K. Brain of the earliest stone implements recognized at the Makapansgat Limeworks site. They came from the upper, or pink breccia, and were then believed to be post-australopithecine; but later, in the same year, I reported[3] the discovery by Mr. Alun R. Hughes of an australopithecine maxillary fragment from the same

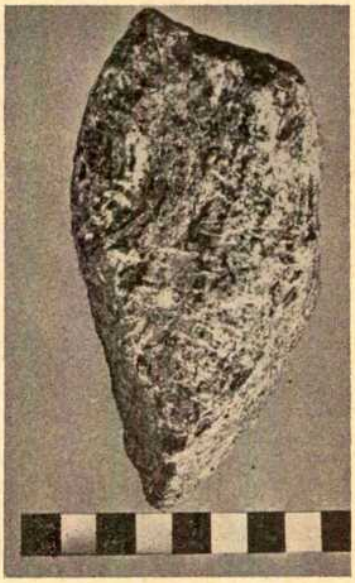

Fig. 3. An enlarged view of the stalactitic hand-axe (seen in Fig. 2, second from the right in the top row) to show: its right rounded peripheral stalactitic surface; its left plane of cleavage, that passed through the more lacunar structure of the centre of the stalactite; and how a flat back or hand grip was provided by removing the less preferable cutting edge of the split stalactitic half-cylinder

locality. Since that time the conjunction of stone implements with australopithecine remains has been demonstrated both at Sterkfontein[4] and at Olduvai[5].

The importance of the present discovery lies first in its corroborating Prof. C. van Riet Lowe's prescience in recognizing that at Makapansgat men used the local dolomite cavern materials such as dolomite and chert for toolmaking by extending his observations to other unexpected, but patently serviceable, dolomitic stony materials such as stalactites. Secondly, it demonstrates that, despite the preponderance of their osteodontokeratic tools and utensils, the earliest Makapansgat australopithecines were intelligent enough to substitute stalactites for teeth as penetrant tools, and for bones as pounding utensils from the beginning of their occupation of the Limeworks Cavern.

Thirdly, and most importantly, this block has furnished an essential and dramatic illustration of the manner in which cave home-life in general, and perhaps dolomitic cavern home-life in particular, provided from the outset natural multi-millenial environmental settings for evolving mankind such as rendered the ultimate substitution of stone tools for some of the piercing, chopping and cutting as well as pounding and crushing operations, previously discharged by osteodontokeratic artefacts, virtually automatic or inevitable among our small-brained but intelligent tool-manufacturing ancestors.

FIFTIETH ANNIVERSARY OF THE STRANGEWAYS RESEARCH LABORATORY, CAMBRIDGE

1912–62

By Dr. HONOR B. FELL, F.R.S.
Director of the Laboratory

THIS year is an important one for the Strangeways Research Laboratory, because it marks the fiftieth anniversary of the opening of the original building on the present site. To celebrate the occasion the Trustees have published a short *History** of the Laboratory.

Our founder, Thomas Strangeways Pigg Strangeways, qualified at St. Bartholomew's Hospital. There he worked under Prof. Kanthack; when Kanthack moved to Cambridge to take the chair of pathology at the University, Strangeways went with him and later became Huddersfield lecturer in pathology under Sims Woodhead. In 1902 Dr. Strangeways married Dorothy Beck, eldest daughter of Dr. Beck, Master of Trinity Hall. To her he imparted an idea that he had had in mind for some years, of making "a systematic investigation of some more important diseases the pathology and treatment of which are as yet undetermined". She received what became known to them as the 'Scheme' with enthusiasm, and throughout his life gave it all the help and encouragement in her power. We are greatly indebted to Mrs. Strangeways for writing the first chapter in the *History* covering the period 1905–26, in which she vividly describes their adventures in bringing the 'Scheme' to life.

To carry out Strangeways's idea, "it would be necessary to have the patient in a small hospital under a qualified nurse. The patients would be told that they would be there for observation and research". The disease selected for study was rheumatoid arthritis and allied disorders. Money was raised from various sources, including Dr. Strangeways himself. Mrs. Strangeways writes: "to launch the Scheme we were spending one-third of our income of £150 per annum upon it, and we had two children". A fund was established of which the Trustees were Sir W. Selby Church, Sir Thomas Clifford Allbutt, Prof. Sims Woodhead and Dr. Strangeways. In 1905 a small house in Hartington Grove, Cambridge, was taken and converted into a six-bed hospital, the coal-shed being turned into a laboratory. A matron and nurse (both unpaid) looked after the patients who came in relays for clinical study. In addition, Strangeways visited the London infirmaries, where he was allowed to examine patients and from which he received much pathological material.

In 1907 the annual cost of the whole project was about £500, including £256 for the upkeep of the hospital. Small though this sum was, in 1908 funds were exhausted and the little hospital had to be closed; however, it was reopened the following year. At about this time, a friend persuaded Strangeways that he must build a larger hospital if the work was to continue. So a public appeal was launched with considerable success. A freehold site was found and bought with a gift of £300; later, through the generosity of the late Dr. G. P. Bidder, another acre of ground was purchased. A building was erected at a cost of £1,600 and opened, free of debt, on May 24, 1912. Visitors to the Laboratory often suppose, from its appearance, that this original block was a converted house, but this is not so. In the report for 1910 the plan of the future building is described, and the architect (who, incidentally, gave his services without fee) is congratulated "on the skilful manner in which he has carried out the difficult task of designing a building which can be used either as a private residence, a hospital or a hospital and laboratory combined".

During the First World War the building was used as an officers' hospital under the War Office, but was still directed by Dr. Strangeways. Throughout this period all the running expenses were paid by the late Sir Otto Beit, who had been a generous supporter of the hospital from its foundation. In 1917 the last officers left, and the study of rheumatoid arthritis was resumed.

---

* *History of the Strangeways Research Laboratory (formerly Cambridge Research Hospital)*, 1912–1962. Pp. 38+5 plates. (Cambridge: Strangeways Research Laboratory, 1962.) See also p. 320 of this issue of *Nature*.

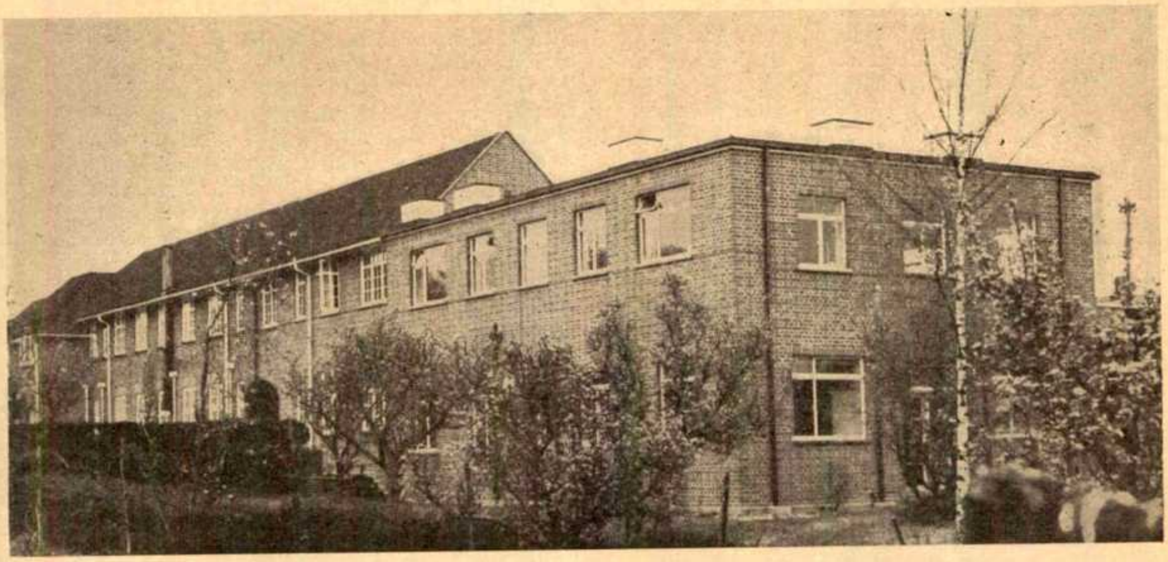

Fig. 1. The Strangeways Research Laboratory, Cambridge: new wing

Strangeways made many valuable contributions to our knowledge of rheumatic diseases, as a result of his investigations at the Research Hospital, but he came to the conclusion that research on rheumatoid arthritis was being seriously hampered by ignorance of the physiology of the cells of the joints. For this and other reasons, in 1923 he decided to close the wards, transfer the clinical work to St. Bartholomew's Hospital, and to devote himself mainly to the study of living cells by means of tissue culture *in vitro* and *in vivo*, a field in which he was one of the chief pioneers. In 1923 I joined him as his assistant in this work. So in this rather curious way, cell biology first became established in the Research Hospital, and it is interesting that investigations now in progress in the Laboratory "show signs of illuminating some of the obscurities of arthritic disease" (to quote from Sir Rudolph Peters's foreword to the *History*).

Strangeways died on December 23, 1926, on the eve of his sixtieth birthday. Owing to severe deafness, he never liked to have more than a few people working with him, so that with his death the Research Hospital faced sudden extinction. At a crucial meeting in January 1927 two of the three surviving Trustees at first favoured closing the hospital, but the third (Dr. Malcolm Donaldson) fought stubbornly for its continued existence. The situation was saved for the time being, when the Medical Research Council, under the chairmanship of the late Sir Walter Fletcher, agreed to continue and even to increase the annual grant that they had made to the establishment during Strangeways's lifetime.

Dr. Andrews, a retired doctor from Scotland, was put in charge (without salary) and the hospital was kept going on a temporary basis throughout 1927. The following year Dr. Andrews resigned, and I was appointed in his place. In the task that lay ahead, I had the close and invaluable co-operation of my colleague, Dr. F. G. Spear, whose unfailing help, advice and moral support in times of crisis I acknowledge with the deepest gratitude. Dr. Spear, who had joined the Laboratory in 1924, was later given the title of deputy director, an office that he held until 1958, when he retired after a distinguished career in radiobiological research. His devoted service to the Laboratory will never be forgotten.

Since the 'hospital' no longer contained patients, the Trustees decided to rename it, and it was called "The Strangeways Research Laboratory" in honour of its founder. But whether our hopes of making it a permanent memorial would be realized seemed doubtful at that time. For some years we lived a hand-to-mouth existence, never knowing whether our efforts would be in vain and the Laboratory closed. Nevertheless, progress was made. Our financial position was materially improved by the receipt of a legacy, and in 1929 the Medical Research Council provided a capital grant of £800 to erect a suitable building to house an X-ray set that had been given to us by the late Dr. Meyrick Jones. A condition of the grant was that the new laboratory should be so designed that it could be converted into a garage should the main building ever be sold as a private residence. There was even talk of incorporating a steel girder in one wall to hold the garage doors in days to come, but, to my lasting regret (it would have been a pleasing historical relic to show to visitors), the girder was omitted on the grounds of expense.

From now on our fortunes began to rise. More people came to work in the Laboratory; in 1931 a bequest of £5,000 from Sir Otto Beit enabled another storey to be built on the X-ray laboratory and talk of selling the place gradually faded away. The first major extension was completed in 1938, thanks to a generous grant from the Rockefeller Foundation.

During the Second World War, the population of the Laboratory naturally dwindled and further development was arrested; the remaining research staff turned their attention mainly to problems of wound-healing and the biological action of chemical warfare agents. As soon as life returned to normal, however, our research revived and began once more to expand. The year 1949 was marked by the receipt of a grant of £12,000 from the Nuffield Foundation, spread over a five-year period, to enable us to develop our work on cell physiology. Other support was forthcoming. The Medical Research Council continued its grants on an ever-increasing scale, as also did the British Empire Cancer Campaign, which for many years has borne most of the cost of our cancer research programme. In 1951 the Royal Society gave the Laboratory a grant of £3,500, which was particularly welcome because, being unrestricted, it could be used at the Trustees' discretion.

During the past decade, the biological interests of the Laboratory have shifted more and more from purely morphogenetic to physiological problems; in consequence the lack of an adequate biochemical section became a severe handicap. The Wellcome Trust, however, came to our rescue with a magnificent grant of £60,000 with which to build and equip a new wing (Fig. 1). This extension not only provided modern biochemical laboratories but also suitable accommodation for the Siemens electronmicroscope, presented to us in 1954 by the Rockefeller Foundation, and for the new X-ray set supplied for our use by the British Empire Cancer Campaign from money collected by members of the Inner Wheel. The new wing was opened by Sir Henry Dale in 1959, and has extended the scope of our research to a remarkable degree. Recently, in honour of our fiftieth anniversary, the Fleming Memorial Trust has made a splendid gift of £10,000 to buy equipment for fundamental research on cell physiology.

Legally, the Strangeways Research Laboratory remains what it was in its research hospital days, namely, an independent charitable institution controlled by a board of Trustees. The present Trustees are: Sir Rudolph Peters (chairman), Dr. Malcolm Donaldson, Lord Adrian, Sir Henry Dale and Dr. P. B. Medawar. At the present time it usually accommodates 25–30 research workers. The staff includes a varied assortment of biologists, two pathologists, four biochemists, three physicists and a biophysicist; in addition, there are always a number of guest workers from other institutions in the United Kingdom and abroad, and usually two research students working for the Cambridge Ph.D. degree.

An unusual feature of the organization is the fact that no member of the research or technical staff is paid out of the Laboratory's own funds. Three members of the research staff hold Sir Halley Stewart fellowships which were generously established by the Sir Halley Stewart Trustees to enable us to provide some permanent key appointments. Other members of the Laboratory belong to the Medical Research Council's external staff, others are supported by the British Empire Cancer Campaign, and I myself hold a Foulerton Research Fellowship under the Royal Society. No account of the Laboratory's history would be complete without a tribute to the loyal service of the technical staff, some of whom have been with us for 25–50 years. The wide variety of scientific disciplines represented by the research staff is a great advantage, because it enables us to approach a given problem from several different directions; in addition, we collaborate with a number of specialists in other departments. The methods in general use include animal experiments, organ culture, cell culture, microchemical and cytochemical procedures, and electronmicroscopy.

Among the purely biological problems now being investigated are: the action of vitamins and hormones on the structure and metabolism of tissues and cells *in vivo* and *in vitro*, and isolated cell organelles; the properties of the cell surface; intercellular relationships; the formation of keratin; and the synthesis of intercellular materials. Radiobiological research dates back to 1921, to the pioneer experiments on tissue cultures by Strangeways and Oakeley; radiation work was continued under the supervision first of Dr. F. G. Spear and then of the present deputy director, Dr. A. Glucksmann, who has extended it to the clinico-pathological analysis of irradiated human tumours supplied by collaborating hospitals. Other cancer research comprises studies on human and animal leukæmia, and experiments on chemical carcinogenesis *in vivo* and in culture. In microbiology, work is being done on bacterial metabolism and fine structure, and on the host : parasite relationship between cells and pathogenic mycobacteria.

Looking back over our Laboratory's long and eventful career, I realize how extraordinarily fortunate the place has been in its friends. I think gratefully of that long line of disinterested people who have worked for it, given it money, and—on occasion—strenuously fought for it during the past fifty years. It seemed fitting to dedicate the *History* to our first benefactor, E. Dorothy Strangeways, without whose courage and unselfishness the little Research Hospital of 1912 would not have lived to grow into the Strangeways Research Laboratory of 1962.

OBITUARIES

Dr. Harry Wexler

THE news of the sudden death of Dr. Harry Wexler, director of meteorological research in the U.S. Weather Bureau, at the early age of fifty-one came as a blow to his many friends in the world of international meteorology. He graduated in mathematics at Harvard University in 1932, followed by postgraduate work at the Massachusetts Institute of Technology which gained him the degree of Sc.D. in 1939. From 1940 until 1941 he was assistant professor of meteorology at the University of Chicago, but most of his scientific life was spent in the U.S. Weather Bureau, in which he built up an impressive research division.

Wexler wrote profusely on atmospheric science, contributing nearly eighty papers dealing with such varied topics as the radiative cooling of the air, polar anticyclones, atmospheric turbidity, the structure of hurricanes and the study of the high atmosphere. He also published papers on glaciology and oceanography. Much of his work dealt with possible large-scale climatic effects of terrestrial and extra-terrestrial events, such as the production of dust by volcanic eruptions and variations in the solar output, but recently he became absorbed in two major topics. One was the study of antarctic meteorology, especially as regards the consequences for global meteorology of the existence near the hub of atmospheric circulation in the Southern Hemisphere of "the world's most efficient cold air factory". During the International Geophysical Year he did much to organize meteorological observations at the South Pole, which he visited several times by aircraft. Afterwards, he turned his attention to the potentialities of weather satellites, in which he had an almost fanatical belief. His enthusiasm for this matter resulted in a long stay in Geneva earlier this year, where, with Prof. Bugaev of the U.S.S.R., he conducted an intensive and far-reaching survey, culminating in the publication by the World Meteorological Organization of a lengthy report on the advancement of atmospheric sciences and their application in the light of developments in outer space. The essence of this report is a comprehensive scheme for a 'world weather watch' which, if constituted, might well revolutionize meteorology. Wexler was undoubtedly the driving force behind these ambitious proposals.

The lasting impression left by Wexler is that of an enthusiast whose cheerfulness, colourful speech and general friendliness remain as a cherished memory for his friends. In his own country his achievements were widely recognized. In 1945 he received the Robert M. Losey Award of the Institute of Aeronautical Sciences, in 1956 the U.S. Air Force Award for Exceptional Services, and his work for the International Geophysical Year and antarctic meteorology gained him the Department of Commerce Exceptional Service Medal and the U.S. Navy Public Service Award. He leaves a widow and two daughters.

GRAHAM SUTTON

Dr. F. R. Irvine

DR. FREDERICK ROBERT IRVINE, who died suddenly on August 20 in Ghana, at the age of sixty-four, was well known in West African agricultural and botanical circles. His long association, from 1924, with Achimota College in the Gold Coast and later with the University, at Legon, Ghana, earned him many African friends. He taught botany and agriculture at Achimota for sixteen years and his *West African Botany* (1931) met a great need as it was the first text-book on the subject.

Irvine was an assiduous collector and compiler of information on plants, especially as to their uses and vernacular names. His agricultural training at the then Armstrong College, the Newcastle Division of the University of Durham, naturally gave him a bias towards crops and food plants. His *Plants of the Gold Coast* (1930) dealt principally with their uses, and in 1934 he published *West African Agriculture* which he was revising at the time of his death. However, he regretted that he was no taxonomist and this lack of a background in plant systematics was something of a handicap to him, especially during the compilation of his recent volume on the *Woody Plants of Ghana* (1961). He had recently accepted a research fellowship in Ghana to complete the companion volume on the herbs, but this remains unfinished. A further work, his *Vocabularies of Plant Names in the Nigerian Languages*, also remains unpublished.

His tall, slim, rather stooping figure was a familiar sight in the Kew Herbarium, where he would seek some obscure publication on food plants or ask advice on the taxonomy of the group in which he was then interested. Any further information was usually added to an already copiously annotated manuscript or inserted in a black pocket-book with the comment that he would now have to change half a dozen indexes. His interest in food plants ranged far and wide, especially those of the more primitive peoples such as the Australian Aborigines and the North American Indians. Besides his botanical activities, he also collected zoological information. Thus, he collaborated with J. R. Norman in *The Fishes and Fisheries of the Gold Coast* (1947).

He was keenly interested in the welfare of overseas students in the United Kingdom, and his work with the Society of Friends, notably as warden of their International Centre at Tavistock Square after the Second World War, brought him into contact with a large number of them.

While staying for a year in the United States, in 1959, under Quaker auspices, he became seriously ill, but he made a remarkable recovery on his return to Britain, though he quickly aged and did not enjoy good health thereafter. He is survived by his wife, a son and two daughters.

NEWS and VIEWS

Nobel Laureates in Medicine: Drs. F. H. C. Crick, F.R.S., M. H. F. Wilkins, F.R.S., and Prof. W. Watson

READERS of *Nature* will be pleased to learn of the award jointly of the Nobel Prize for Medicine to Dr. F. H. C. Crick, research worker for the Medical Research Council in the Council's Laboratory for Molecular Biology, Cambridge; Dr. M. H. F. Wilkins, deputy director of the Medical Research Council Biophysics Research Unit, Department of Biophysics, King's College, University of London; and Prof. James Watson, professor of biology in Harvard University, especially since the work of these three scientists has become well known through the columns of *Nature* and elsewhere. The official announcement cites the recipients for their achievement of a "most fundamental biological problem", the discovery of the molecular structure of deoxyribonucleic acid. The establishment of the 'biological code' especially for the formation of enzymes is now well known, and is exerting a profound influence on biochemical and biological research, especially in the fields of molecular biology and heredity. Recently, Dr. Crick was awarded the Gairdner Foundation Prize, and, among other awards, he was the first to receive the Charles-Léopold Mayer Prize of the Paris Academy of Sciences (*Nature*, 193, 223; 1962).

History of Science and Technology at Imperial College: Prof. A. R. and Mrs. Hall

SIMULTANEOUSLY with the announcement by the University of London of the appointment of Prof. A. Rupert Hall to the chair of the history of science and technology in the Imperial College of Science and Technology, the College announces the appointment of Prof. Marie Boas Hall, his wife, to a senior lectureship in the same Department. Prof. Hall and his wife are at present professors of history and logic of science in the University of Indiana. They take up their new duties in the summer of 1963. The study of the history of science and technology in its own right presents both a challenge and an opportunity. The new Department will be headed by distinguished scholars who, both individually and in collaboration, have made an important contribution in this field. *Unpublished Scientific Papers of Isaac Newton* appeared under their joint authorship as did various articles on the man himself. Prof. Rupert Hall's major publications are *Ballistics in the Seventeenth Century* and *The Scientific Revolution, 1500–1800*. He was one of the co-editors of *A History of Technology* published in five volumes during the 1950's. Among Prof. Marie Boas Hall's works are *Robert Boyle and Seventeenth Century Chemistry* and the recent *The Scientific Renaissance 1450–1630*, Vol. 2 of *The Rise of Modern Science*.

The new department will at first be chiefly concerned with research, and postgraduate education in research methods. Its primary objectives will be the training of future historians of science and technology, and the introduction of scientists and engineers to these studies. A generous contribution towards the cost of maintaining the new department has been made by Imperial Chemical Industries, Ltd., which recently supported the study of the history of technology by subsidizing some valuable publications, including the major *History of Technology* already mentioned.

Materials Science and Engineering at M.I.T. : Prof. R. A. Smith, C.B.E., F.R.S.

PROF. ROBERT ALLAN SMITH, known for his work on semiconductor and infra-red physics, has been appointed the first director of the new Center for Materials Science and Engineering at the Massachusetts Institute of Technology. Dr. Smith will also hold a simultaneous appointment as professor of physics in the Institute. He carried out pioneer radar research for the British Government during 1939–46, and from 1947 until 1961 was head of the Physics Department in the Royal Radar Establishment, Malvern. He spent the year 1961–62 as professor of physics in the University of Sheffield (see *Nature*, 190, 960; 1961).

Director-General of the Indian C.I.S.R. : Dr. Syed Husain Zaheer

DR. SYED HUSAIN ZAHEER, director, Regional Research Laboratory, Hyderabad, has been appointed director-general of the Council of Scientific and Industrial Research. He took charge of his office on September 1. Born on November 7, 1901, Dr. Zaheer was educated at Lucknow, Oxford and Heidelberg. From 1930 until 1946 he was reader in organic chemistry, Lucknow University, and two years later be became professor of organic chemistry. In 1948 he became director of the Central Laboratories for Scientific and Industrial Research, Hyderabad, which were later to become the Regional Research Laboratory, Hyderabad. During the fourteen years of his directorship he built up the Regional Research Laboratory as one of the foremost centres for pilot plant and developmental research in India. Dr. Zaheer has been responsible for many important industrial development projects in India, and also for the preparation of project reports and blueprints for starting many new industries in India. In 1954 he undertook a study of post-war German industry as a Senior United Nations Fellow and visited West Germany and Finland in 1955 to study plants and techniques for the utilization of low-grade coals at the invitation of the Government of the Federal Republic of Germany. Dr. Zaheer is a member or president of numerous learned societies.

CERN Research Directorate : Prof. G. Puppi

PROF. G. PUPPI recently joined CERN as a member of the directorate for research. Early next spring he will replace Prof. Gilberto Bernardini, who returns to his chair of physics at the University of Rome. Prof. Giampietre Puppi was born on November 20, 1917, in Bologna, Italy. He studied at the University of Padova under Bruno Rossi and Gian Carlo Wick. After the War, he was lecturer at the Universities of Bari, Bologna, Rome and Padova. In 1950 he was appointed to the chair of theoretical physics in the University of Naples. Since 1953, Prof. Puppi has been professor of higher physics and director of the Physics Institute in the University of Bologna. He will resume these responsibilities in October 1963. Prof. Puppi's research work has been mainly in the fields of cosmic rays and sub-nuclear particles.

The Strangeways Research Laboratory

THE Strangeways Research Laboratory, founded originally as a research hospital and now famous all over the world as a centre of tissue culture and cell biology, has recently celebrated its fiftieth anniversary by the publication of a short history of its development (*History of the Strangeways Research Laboratory (formerly Cambridge Research Hospital)*, 1912–1962. Pp. 38+5 plates. Cambridge: Strangeways Research Laboratory, 1962). The part of the history from 1905–26 has been written by Mrs. Strangeways, the widow of the founder and still a guiding spirit, well known to the workers in the Laboratory. It is a remarkable document and might be read with profit by all young doctors and research workers of to-day. The devotion and perseverance displayed by Dr. T. S. P. Strangeways and his wife in the pursuit of their goal of establishing a research hospital is almost incredible. Perhaps it is best illustrated by the following extract from the history. "Indeed, to launch the Scheme, we were spending one-third of our income of £150 per annum upon it, and we had two children. He [T. S. P. Strangeways] approached his Class and asked if they would back the project to the extent of £5 each; this they agreed to do, but I am thankful to say that they were never called upon." Needless to say, the scheme was launched, and how the institution has evolved and progressed is well told in the two other chapters of this slim but fascinating volume [see also p. 316 of this issue of *Nature*].

British Participation in the Indian Ocean Expedition

THE Royal Society and the British National Committee for Oceanic Research have announced proposals for United Kingdom participation in the International Indian Ocean Expedition which is supported by Unesco and the Intergovernmental Oceanographic Commission. Altogether, forty ships carrying scientists and specialized equipment from more than twenty countries are expected to take part. Most of the United Kingdom effort will be made in the Arabian Sea, between Africa, India and Ceylon, and will be based principally on two of H.M. Survey Vessels, H.M.S. *Owen* and H.M.S. *Dalrymple*, together with the National Institute of Oceanography's new research vessel R.R.S. *Discovery*. This extension of international co-operative research to oceanography will cover all aspects of marine science. The Indian Ocean is particularly suited to such an investigation on account of the nature of its current systems, and the information to be gained concerning the interaction between winds, climate and general circulation. The economic importance of its potential fishing grounds is already apparent, and chemical and biological measurements will increase basic knowledge of those factors influencing productivity and fertility of food fishes, and the general ecology of the region. Geophysical observations will include studies of bottom topography and sedimentology together with magnetic and seismic surveys. Physical measurements, in addition to the study of particular current systems, will include the operation of additional tide gauges, radiosonde/wind stations, and synoptic observations by all survey vessels and H.M. ships in the area (The Royal Society. British National Committee for Oceanic Research. *United Kingdom Scientific Programmes during the International Indian Ocean Expedition 1961–64.* Pp. 22. London: The Royal Society, 1962).

The Engineering Institutions Joint Council

BRITAIN's leading bodies of professional engineers, with a combined membership of more than 200,000, have set up the Engineering Institutions Joint Council under the chairmanship of Sir Kenneth Hague. The purpose of the Council is to enable representatives of the bodies concerned to meet together to consider and take action on matters of common interest relating to the advancement of engineering and the dissemination of knowledge in that field. It also aims at establishing a sound and useful channel of communication and understanding between the professional engineers, the Government, the public, and national and international bodies concerned with engineering. The bodies represented on the Council are: Royal Aeronautical Society, Institution of Chemical Engineers, Institution of Civil Engineers, Institution of Electrical Engineers, Institution of Gas Engineers, Institution of Marine Engineers, Institution of Mechanical Engineers, Institution of Mining Engineers, Institution of Mining and Metallurgy, Institution of Municipal Engineers, Institution of Production Engineers, British Institution of Radio Engineers, Institution of Structural Engineers. Mr. K. H. Platt has been appointed honorary secretary of the Council, the office of which is in the Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, S.W.1.

Automatic Weather Station

ON August 17, 1961, the world's first isotope-powered automatic weather station began transmitting weather observations to the U.S. Department of Commerce Weather Bureau from Axel Heiburg Island in Canada's Northwest Territories. Throughout its first year of operation, the unattended station has continued to report on the weather in this bleak, uninhabited region about 700 miles from the North Pole. The station was developed by the Martin Company for the United States Atomic Energy Commission and the Weather Bureau. Wind direction and speed, barometric pressure and temperature are continuously measured by the station's instruments. The measurements are fed into a data-processing system and transmitted every three hours to the Joint Canadian–United States Weather Station at Resolute, Canada. Ultimately, the Weather Bureau hopes that hundreds of these automatic stations will be placed in mountainous and polar regions, oceans and deserts, where it is impossible to establish permanent, manned weather stations.

Biorheology

AFTER a new name has been coined for a new division of science it does not take long for the appropriate specialist journal to appear. The name 'rheology' was first given to the science of the deformation and flow of matter in 1929. This has covered an extremely wide field, including such diverse subjects as metals, plastics, solutions and suspensions, building materials and biological substances, in which workers may have little in common except the need for rheological techniques. As biologists have increased their interest in rheological problems, the name 'biorheology' was first used in 1948, and now a journal appears to cater for this branch of science. The reputation of its editors-in-chief, Prof. A. L. Copley, of New York, and Dr. G. W. Scott Blair, of Reading, will guarantee the standing of the new journal. They are assisted by a Board of Editors from five other countries and by an Honorary Editorial Advisory Board even more widely distributed. The journal will only accept papers within the strict limits of its subject. Hydrodynamics or the classical theory of elasticity are excluded. Papers must deal with the rheology of "processes in the living organism (*in vivo*) and with material originating from the organism (extracorporeal)". The inter-relationship between rheological properties and structural aspects of the systems will be stressed. Papers will be in English, French and German. In addition to papers on original work (limited to 15 pages in general), there will be letters to the editor, book reviews, reports of meetings and news of interest to rheologists. The first number is well produced and clearly printed (1, No. 1; July 1962. Pp. 82. Annual subscription-rates: (*A*) For libraries, Government establishments, research laboratories, etc., £10 (30 dollars); (*B*) for individuals who place their orders directly with the publisher and certify that the journal is for their personal use, £5 (15 dollars). Oxford and New York: Pergamon Press, 1962). The new venture can be warmly welcomed and confidently expected to be successful in its purpose.

A Directory of British Scientists

ERNEST BENN, LTD., who are to publish the first edition of the *Directory of British Scientists* in April 1963, hope to include details of some 30,000 British science graduates engaged in scientific work at the present time. This has been made possible by the co-operation of the registrars of all the British universities. While the dispatch of questionnaires to all graduates has inevitably resulted in a number of duplications, there have also been a number of forms returned owing to changes of address, etc. Any scientists who consider themselves eligible for inclusion in the *Directory* (which does not cover dentistry, engineering, medicine or veterinary studies), and who have not yet received a form, are requested to write as soon as possible to: the Editorial Secretary, *Directory of British Scientists*, Orchard House, Caldecott Road, Abingdon, Berkshire.

A Bibliography of Plastics

A BIBLIOGRAPHY of plastics, compiled by E. R. Yescombe, with a preface by M. Kaufman, of the National College of Rubber Technology, has been issued by the Library Association as *Special Subject List* No. 38 (*Plastics*. Pp. 40. London: Library Association, 1962. 8*s*.; L.A. members, 6*s*.). Besides a select list of periodicals, it includes some 280 entries. These are arranged under guides to the literature; abstracts and indexes; surveys and reviews; introductory—elementary treatises; general—more advanced ; nomenclature ; trade names ; classification; high-polymer chemistry; high-polymer physics; properties, testing and quality control; materials; raw and ancillary materials; plant and processes; special applications. There is an author and title index and the pamphlet should prove a useful guide to librarians and others.

Lalor Grants and Awards for 1963

THE Lalor Foundation has announced the programme of awards for 1963, which it is offering for support of research on the fundamental biochemical and physiological mechanisms concerned with fertility and the early stages of reproduction in various forms of life. The objectives are to further the knowledge and understanding of the basic phenomena involved and to extend and develop the possibilities for effective regulation and control. The awards are open to all nationalities. The awards may range up to 8,000 dollars a year, depending on the scope and duration of the projects approved. Preference will be given to younger members of university and college faculties and staff with an upper age limit of forty-one years. The work may be carried on at the applicant's own institution or elsewhere. The Foundation will also grant post-doctorate summer or short-term research awards at the Marine Biological Laboratory at Woods Hole, Mass., or elsewhere, for appropriate projects in the fields specified. For these awards, the stipends will normally not exceed 1,000 dollars for a single man or woman, 1,200 dollars for a married man working at his home institution, and 1,350 dollars for a married man with principal programme at another institution. Applications and inquiries should be sent to the Lalor Foundation, 4400 Lancaster Pike, Wilmington 5, Delaware, and applications must be received by January 15, 1963.

The Perkin Centenary Trust: Awards

APPLICATIONS for the awards of the Perkin Centenary fellowship and scholarships are invited by the Trustees. *The Perkin Centenary Fellowship* is offered for one or two years for the purpose of higher study of any subject approved by the Trustees. Candidates will be required to show either that they have had experience in an industrial firm or other institution concerned in the manufacture or the application of colouring matters, or that their intended field of study has a direct bearing on these subjects. The value of the fellowship is £750 per annum with an additional grant of up to £100 per annum towards certain designated expenses. It is tenable, from October 1963, at any university, technical college or other institution approved by the Trustees. *The Perkin Centenary Scholarship:* two such awards are offered, each for one or two years, to enable candidates employed in an industrial firm or other institution concerned with the manufacture or the application of colouring matters to receive an education at a university or technical college. Each award will have a value of £350 per annum. This may be increased, at the discretion of the Trustees, to £400 per annum if the candidate appointed is required to live away from his normal place of residence. Applications and inquiries should be addressed to the Secretary, Perkin Centenary Trust, c/o Chemical Society, Burlington House, London, W.1. Applications must be made by May 1, 1963.

Research Assistantships and Fellowships in Forestry

THE College of Forestry of the State University of New York is offering twenty-six assistantships for the college year 1963–64, each worth between 1,800 and 2,400 dollars. Research fellowships, sponsored by industry, research foundations and government agencies, are also offered to qualified applicants for work on assigned research projects in several fields related to forestry. Each fellowship is worth from 2,100 dollars annually. Applications for assistantships or fellowships should be received by the College before March 1, 1963. Forms of applications and further information can be obtained from the Associate Dean for Graduate Studies, State University College of Forestry at Syracuse University, Syracuse 10, New York.

Announcements

PROF. DUDLEY STAMP has been awarded the honorary degree of Doctor of Natural Science by the University of Warsaw in recognition of his international work in applied geography.

PROF. E. B. CHAIN, professor of biochemistry in the Imperial College of Science and Technology, London, has returned from a lecture tour of Chile, Argentina, Uruguay and Brazil. He lectured in the universities of those countries on subjects of his research, including the new penicillins, the mode of action of insulin, and sugar–amino-acid relationships in brain. During his tour he was awarded honorary degrees from the Universities of Cordoba and La Plata (Argentina), Montevideo (Uruguay) and Brazil. In Argentina he was declared official guest of honour of the Republic of Argentina by special decree of the President.

THE fourteenth annual Ciba Foundation Lecture on "The Future of Man: Evolutionary Aspects" will be given by Sir Julian Huxley at the Royal Institute of British Architects on November 26. Further information can be obtained from the Conference Assistant, The Ciba Foundation, 41 Portland Place, London, W.1.

THE autumn meeting of the British Society for Immunology will be held at the Wellcome Building, London, during November 16–17. The programme will include a symposium on "Pharmacology of Allergic Reactions and Related Inflammatory States". Further information can be obtained from Dr. R. G. White, Bacteriology Department, London Hospital, London, E.1.

THE eleventh convention of the Scientific Instrument Manufacturers' Association of Great Britain Ltd. on "Looking Ahead—the Next Five Years" will be held in Eastbourne during November 7–9. The programme will include talks on: the economic outlook; future trends in engineering and production; instrumentation in space research; science in everyday life. Further information can be obtained from the Press Relations Officer, SIMA House, 20 Queen Anne Street, London, W.1.

A SYMPOSIUM on "Quality in Photographic Reproduction", arranged by the Royal Photographic Society of Great Britain, will be held at the Royal Society of Arts, London, during December 5–7. The topics under discussion will include: colour photography; aspects of tone reproduction in the fields of graphic arts, professional photography, photogrammetry and micro-reproduction; sharpness of photographic and electronic imaging systems; modulation transfer functions. Further information can be obtained from Dr. C. Roberts, Research Laboratory, Kodak Ltd., Middlesex.

SCIENTISTS IN THE PUBLIC SERVICE

PROMOTION OF INDIVIDUAL RESEARCH WORKERS

EACH year a special committee reviews the work of scientists carrying out research work in Government establishments and in similar establishments of other public bodies and recommends, under the provisions of the White Paper on the Scientific Civil Service (Cmd. 6679 of 1945), the promotion of individual research workers of exceptional merit. The promotions were effective from July 1 and include the following:

Deputy Chief Scientific Officers

Mr. G. K. Adams joined the then Armament Research Establishment in 1942 after graduating at the University of Bristol with first-class honours in chemistry. He moved to the Explosives Research and Development Establishment, now a part of the Ministry of Aviation, in 1946 and worked on the mechanism of combustion of liquid propellents. In 1955 he was awarded a special merit promotion to senior principal scientific officer and since then has had responsibility for combustion and sensitiveness research, ballistic assessment, and theoretical investigation of propellent burning and initiation of detonation of shock waves. Mr. Adams's best-known contribution is probably that to the theory of laminar flame propagation, where he has analysed the mechanism of the hydrazine decomposition flame and calculated the flame properties from isothermal kinetic data, a system more complex than any previously subjected to theoretical treatment. His calculations of the spatial distribution of radicals and the resulting hydrazine decomposition-rate as a function of flame temperature and pressure confirmed his theory of a chain reaction scheme. They led to the experimentally observed coefficient of flame speed and revealed a possible explanation of the anomalous pressure coefficient. An assessment of the explosive hazards of some of the higher energy propellent systems led Mr. Adams to study, in collaboration with Prof. D. C. Pack, the problem of the development of the shock waves in accelerating combustion and the initiation of detonation by shock waves.

Dr. O. Simpson first joined the scientific civil service in 1944 and served in the Admiralty Research Laboratory until 1946, when he returned as a research scholar to Trinity College, Cambridge. He was elected a Fellow of that College in 1949 and for the next three years he was assistant professor of physics in the University of Michigan. In 1953 he joined the Services Electronics Research Laboratory and gained a special merit promotion to senior principal scientific officer in 1957. Dr. Simpson initiated a new branch of solid-state physics by making the first comprehensive study of the fluorescence and conductivity of the crystalline aromatic hydrocarbons. In addition to his own research work, Dr. Simpson has since 1956 been head of the solid-state physics group at the Services Electronics Research Laboratory, which has acquired an international reputation for its contributions to research on super-conductivity in metals, compound semi-conductors and organic semi-conductors, and has pioneered in new applications of these solids. Dr. Simpson is active on various inter-service committees covering a wide range of electronic subjects.

Mr. J. H. Wilkinson joined the Scientific Civil Service in 1940 and was transferred from the Ministry of Supply to the National Physical Laboratory in 1946, where he worked in the Mathematics Division on the *ACE* electronic computer project under Dr. A. M. Turing. In 1948, when Dr. Turing left, he assumed charge of the *ACE* project. Mr. Wilkinson specializes in numerical methods and the exploitation of high-speed computers. The field that he has made particularly his own is that of linear algebra, a subject the importance of which has been enormously increased by the advent of the high-speed electronic computer. For some years he devoted himself to the development of new algorithms for the solution of matrix problems, and the testing and improvement of existing ones, with the view of developing as powerful and practical methods as possible. For many years, work had been seriously hampered by an inability to assess the accuracy of solutions of large-scale matrix problems, but in 1955 Mr. Wilkinson developed a new method of error analysis which proved to be applicable to a wide range of algebraic problems including the more difficult eigen-value problems; this also applied equally well to both fixed-point and floating-point calculations. His successful application of this method in the succeeding years led to a real understanding of the factors that govern the accuracy of solutions obtained by numerical methods. It has also led to the possibility of obtaining, for the error of the solutions, theoretical bounds that are close to those actually obtained in practice. Mr. Wilkinson, who was awarded a special merit promotion to senior principal scientific officer in 1954, is continuing to work in this field and hopes to extend his studies to cover non-linear problems.

Senior Principal Scientific Officers

Mr. R. L. Bickerdike, of the Royal Aircraft Establishment, is at present working on the development of new methods of preparing shaped pieces of graphite by impregnating loose or lightly bonded aggregates of particles with carbon deposited from the gas phase.

Dr. H. A. Gebbie, of the Basics Physics Division, National Physical Laboratory, has made outstanding contributions to the study of infra-red spectroscopy and has pioneered the use of interferometers in the far infra-red region and their application both in the laboratory and in astro-physics. He has led the team of the National Physical Laboratory which has been studying the transformation of non-metals under the highest obtainable pressures to the metallic state.

Dr. C. Hilsum, of the Services Electronics Research Laboratory, has been engaged since 1950 on various researches, some of which have eventually been developed for commercial use, among them being a new infra-red detector, the photo-electromagnetic cell and the Hall effect susceptibility meter. He is at present responsible for an intensive research programme on a compound semi-conductor, gallium arsenide, and is already well known for his work on this increasingly important material.

Dr. A. E. Johnson, of the National Engineering Laboratory, East Kilbride, is internationally known for his work on the creep properties of metallic alloys subjected to complex stress systems at elevated temperatures and the application of his results to the analysis of the stress/strain relations in engineering structures operating under such conditions.

Mr. N. B. Marshall, an ichthyologist at the British Museum (Natural History), has special interests in the taxonomy of fishes, the environmental effects of depths on the structure of the fish skeleton, and comparative and functional anatomy of the swim bladders in fishes.

Dr. R. J. Murgatroyd has for the past ten years been in charge of the Meteorological Research Flight of the Meteorological Office. He specializes in high-altitude meteorology, and has been relieved of administrative duties in order to undertake further research work.

Dr. R. A. Pattle, of the Microbiological Research Establishment, is in charge of a team carrying out research in the Munitions Research Division.

Dr. P. H. Thomas, of the Fire Research Station, is engaged in the study of the behaviour of fires in buildings, in particular the characteristics of fires in single compartments. He has also developed small-scale techniques which fully evaluate the venting of fires by openings in the roof and has produced a theoretical background to this work. His recent publications include new dimensionless correlations of the height of flames from natural fires and an extension of the theory of thermal explosion.

Similar promotions have been made by:

(1) United Kingdom Atomic Energy Authority: Senior Principal Scientific Officer

Mr. A. E. Glennie joined the Atomic Energy Authority in 1949 and worked with the Atomic Weapons Research Establishment, first at Fort Halstead and then at Aldermaston. Since 1957 he has been leader of an analysis group engaged in numerical solution of physical problems. This group was responsible for the systems programming for '*IBM* 704' and subsequent computers; it is at present concerned with the preparations for the installation of the new fast computer *STRETCH* to be installed at Aldermaston. Mr. Glennie is also interested in research work leading to the more effective use of fast computers, including an automatic programming language which could be used on large computers.

(2) Agricultural Research Council: Deputy Chief Scientific Officer

Dr. H. L. Penman joined the staff of Rothamsted Experimental Station in 1937 and became head of the Physics Department in 1954. He has worked on a wide range of agricultural and botanical problems and has made outstanding contributions to the knowledge of soil aeration, the availability to plants of water in soil, the role of stomata in controlling transpiration and the dependence of total transpiration on current weather. His investigations of the use of water by crops are the basis for modern irrigation practice. He has shown that routine weather records could be used to assess the likelihood that irrigation would increase yield, when crops needed irrigating, and how much water should be given. Dr. Penman has shown that irrigation often unexpectedly produces substantial increases in yield and has provided farmers with information that defines need for water objectively, so taking irrigation out of the realms of 'guess-work'. He has also studied the effects of microclimate on pests and diseases. Dr. Penman recently became an officer of the Order of the British Empire and is president of the Royal Meteorological Society. Earlier this year he was elected a Fellow of the Royal Society.

Senior Principal Scientific Officers

Dr. J. J. Bullen is the head of the Pathology Department, Rowett Research Institute, Bucksburn, Aberdeen. His research programme has been particularly concerned with host–parasite relationships in bacterial infections and he has made a number of notable contributions in this field.

Dr. A. T. Cowie, of the Physiology Department, National Institute for Research in Dairying, Reading, carries out all the major surgical procedures required by the Institute. He has made great contributions to endocrinological studies and has a special interest in the field of hormonal regulation of mammary growth and lactation.

Dr. G. A. Garton is a member of the Protein and Lipid Chemistry Section of the Rowett Research Institute and has done much original work on various aspects of lipid metabolism in animals, with particular reference to the pig, ox and sheep, in the course of which he has developed a number of new methods of isolating and analysing lipids.

Dr. J. S. Kennedy is a member of the Agricultural Research Council's Unit of Insect Physiology at Cambridge. His research work has had a great influence on present-day ideas about the behaviour of mosquitoes, the behaviour and nutrition of aphids and the behaviour and polymorphism of locusts.

(3) Development Commission: Senior Principal Scientific Officer

Dr. Mary Parke, senior algologist at the Plymouth Laboratory of the Marine Biological Association of the United Kingdom, is distinguished for her research work on the systematics and life-histories of marine unicellular algae.

SPECTROSCOPY IN THE METALLURGICAL INDUSTRY

THE trend towards more automatic methods for production control analysis was shown at a recent symposium held at Buxton, Derbyshire, arranged by the Spectroscopy Group of the Institute of Physics and the Physical Society in collaboration with the British Iron and Steel Research Association and the British Non-Ferrous Metals Research Association. An audience of about 130, including some overseas visitors, heard a range of eight papers in three half-day sessions (July 5–6) covering X-ray, optical and mass spectroscopic methods.

Analytical procedures depending on X-ray fluorescence are based on the simple and characteristic radiation emitted when X-rays fall on an element while those relying on optical spectroscopy involve the line spectra emitted when the element is excited by an electrical discharge. Mass spectroscopic methods involve measurement of the mass of the ion produced from similar discharges. All three methods have contributed to the knowledge of the electronic configuration of atoms, but it is only in the past decade that developments in instrumental techniques have allowed the extensive analytical application, particularly in the two former fields, where electronic detection can replace photographic methods. Commercially produced instruments are now available on which a sample can be spectroscopically analysed on a routine basis for some twenty to thirty elements.

The talk given by Mr. J. F. Duke (National Physical Laboratory, Teddington) on "Mass Spectroscopy" showed how a double focusing mass spectrometer fitted with a vacuum spark source could be used to detect impurities at, and below, the part-per-million level. The small sample size (μg) and the possibility of detecting upwards of seventy elements in a single analysis offset the high cost of equipment. Future possibilities of the method were discussed. In contrast to some of the more industrial developments for automated and repetitive analysis, Mr. J. S. Forbes (London Assay Office) gave an account of the application of emission spectroscopic methods to: (*a*) determine impurities in fine gold and silver (and incidentally show the changes in alloy and impurity elements in silver over the past few centuries); (*b*) aid in the examination of antique silver articles for detection of fakes; (*c*) develop possible methods to establish assay standards for platinum.

Mr. J. F. Gidley (Imperial Metal Industries (Kynoch) Ltd., Birmingham) showed how copper alloy production could be controlled at the casting stage by rapid X-ray fluorescence analysis for copper, the alloying constituents and impurities. After suitable preparation the cast sample was examined for fluorescent radiation characteristic of copper, chromium, maganese, iron, nickel, zinc, arsenic and tin. The interpretation of the alloying constituents was straightforward, but content determinations of copper required compensation for the interference effects. Comparison of chemical and routine X-ray results showed an accuracy of 0·20 per cent copper and the accuracy of the constituents was sufficient for control purposes. Results and recommendations for additions to the melt could be reported back in about 5 min. Further developments were required before miscellaneous samples can be adequately analysed. Mr. K. M. Bills (International Nickel Company (Mond), Ltd., Birmingham) described how this analysis technique could be applied to the work of an analytical section dealing with alloy development work involving various sample forms. Both in the talks and discussion, such advantages as the non-destructive nature of the test and the disadvantage of inter-element effect were stressed. The relative merits of X-ray and optical emission methods formed one of the more interesting parts of the symposium.

The extended use of direct-reading spectroscopic instruments in a steel works was described by Mr. L. Gwilliam (Steel Co. of Wales). Samples from the furnace, after some preliminary treatment, were spectroscopically examined for carbon, sulphur, manganese, nickel, copper, tin and phosphorus, and results could be reported by in between 3 and 8 min with some fifty–seventy samples being handled in an 8-h shift. Development work was being carried out to extend these automatic methods to the analysis of iron and steel-making slags. Eventually, it was hoped to replace much of the present routine chemical analysis on refractory materials and slags by spectrographic and X-ray fluorescence methods.

Mr. C. Frith (Brown Bayley Steels, Ltd.) described how control analysis of silicon, manganese, chromium, nickel, molybdenum, copper, niobium, titanium and vanadium for stainless steel production was carried out using direct reading spectroscopic instruments. Attention to calibration procedures and suitable means of applying corrections enabled satisfactory results to be consistently obtained. Out of four thousand analyses of various types of stainless steels made in the past three years only three involved errors which arose from the direct reading method.

Similar applications were found in other metallurgical industries. Some of these were noted by Mr. D. Jukes (Henry Wiggin and Co., Ltd., Hereford) in his description of "Spectrographic Control of Nickel Alloy Production". He emphasized that success in application of direct reading methods depended on meticulous attention to standards and calibration procedure. X-ray fluorescence methods for the determination of major alloying constituents such as chromium, cobalt and molybdenum were adopted and up to 400 determinations of a single element could be made by this method in an 8-h period. Although production analysis will in future place less emphasis on conventional chemical methods, the analytical chemist will be increasingly concerned with the provision of reliable standards.

Both in these papers and the discussion which arose, sample preparation and uniformity of procedure was shown to be extremely important for consistent results. One aspect of this was described in the paper by J. R. Brown and D. Wilkinson (Guest, Keen and Nettlefolds Group Research Laboratory, Wolverhampton) on "The Analysis of High Silicon Steels with a Vacuum Spectrometer". The presence of polythene tubing in the argon circuit (used to flush the spark chamber of a direct reading instrument) increased the impurity-levels of oxygen and water vapour in the gas and this contamination could cause erroneous results in the analysis of steels containing more than 1 per cent of silicon. Replacement by copper tubing and purification of the argon over heated magnesium reduced impurity-levels to 7 and 1 parts per million of water vapour and oxygen respectively, and these levels allowed satisfactory analyses for carbon, silicon, phosphorus, manganese and tin in the steels.

The chairmen during the symposium—E. H. S. van Someren (British Welding Research Association), F. R. Bareham (Aluminium Laboratories, Ltd.), H. T. Shirley (Brown-Firth Research Laboratory) and W. Ramsden (Applied Research Laboratories)—successfully supervised the discussion which arose after the papers. Both the comments made then and at more informal sessions showed the values of such a gathering as a means of exchanging information on common problems, but some disappointment was expressed that very few of the more junior analysts were present to profit from hearing the various points of view. It is expected that the papers and comments will be published by Hilger and Watts later this year.

L. BOVEY

THE ONTARIO RESEARCH FOUNDATION

THE annual report for 1961 of the Ontario Research Foundation[*] includes the reports of the director, Dr. A. D. Misener, and the director of research, Dr. A. E. R. Westman, together with the accounts, lists of scientific and technical papers published in 1961 and of professional and technical staff. Dr. Misener claims that in all categories the growth of research and development in Canada is substantial and compares favourably with the rate of growth in the United States and the United Kingdom. During 1956–58, that financed by industry itself in Canada increased by about 20 per cent per annum; in the same period the Foundation's contract research for industry increased by 22 per cent per annum, but research expenditure by both Government and industry is low by a factor of 3–4 when expressed as a percentage of the gross national product, and in research performed by industry but financed by Government is low by a factor of 11 compared with the United Kingdom and 19 compared with the United States.

Dr. Westman notes an overall expansion in sponsored research in 1961, particularly in chemistry, a reduction in science activities, particularly in engineering and metallurgy, and difficulties in recruiting junior staff. The Department of Biochemistry concluded a study of the effect on the serum cholesterol-level in rats of a diet containing hydrogenated sunflower oil, but a new investigation was commenced on the effect of agitation on the isomeric fatty acids produced in hydrogenation. Basic research was continued in the Department of Chemistry on the study of stereo-specific catalysts for polymerization and the mechanism of the polymerization of butene by the heterogeneous catalyst aluminium triisobutyl-titanium trichloride, as well as work on phosphate glasses, while in physical metallurgy, unsponsored research included studies in metal physics, the magnetic properties of iron ore and copper alloy surfaces. The Department of Parasitology completed a study of the throat bots of deer and established the mode of transmission of 'brain worms' of deer with certain land snails as intermediate hosts. A survey of fish parasites in lakes was extended, and a new study on a warble fly, the larvæ of which live under the skin of certain wild animals, showed that the activity of the animal is reduced if it harbours many of these parasites, which may cause death directly or make the animal unable to escape predators. The Department of Physiography made further examination of the Algonquin Lake plain, and in the Department of Textiles unsponsored research was concerned with the chemical modification of cotton cellulose, wool and hair to give improved fabrics.

ENGINEERING DEVELOPMENTS IN THE BRITISH BROADCASTING CORPORATION

THE excellent series of monographs describing the work of the Engineering Division of the British Broadcasting Corporation (*Nature*, 191, 1356; 1961), has been supplemented by five further issues[*] since September 1961.

As their titles indicate, these monographs deal with a range of subjects from basic research in the techniques necessary for a high-quality broadcasting service, to the actual design and development of the equipment installed at the steadily increasing number of transmitting stations in Britain.

In Monograph No. 39, the director of engineering, B.B.C., Sir Harold Bishop, presents a comprehensive review of the development of the television service in Britain, starting with a reminder of the early history of the subject, thus: "Although all the fundamentals of an electronic transmitting and receiving system were put forward by A. A. Campbell-Swinton in his famous letter to *Nature* as far back as June 1908 [Vol. 78, 151], no practical realization of his proposals was attempted until the early 'thirties".

The earliest B.B.C. television transmissions started in 1926 when pictures from John Logie Baird's laboratory were radiated experimentally; but for nearly ten years thereafter there was much divergence of opinion among engineers and scientists as to the most effective means of scanning a picture or scene, and as to the band-width required in the radio-spectrum for its transmission. However, what has since been generally conceded to be the best public television service in the world was formally opened by H.M. Postmaster-General on November 2, 1936. Sir Harold Bishop's monograph describes in a most interesting manner the fundamental techniques of the British television system, the growth and progress of the public service over the past quarter of a century, together with a brief review of current and future development. In the latter connexion, reference is made to research in colour television, and the problems which will be encountered in the extension of television broadcasting into the ultra-high-frequency bands, and the use of a 625-line scanning standard. This monograph is illustrated with 14 plates, four of which are in colour.

[*] B.B.C Engineering Monograph No. 38: "Operational Research on Microphone and Studio Techniques in Stereophony", D. E. L. Shorter. Pp. 23. No. 39: "Twenty-five Years of B.B.C. Television", Sir Harold Bishop. Pp. 41. No. 40: "The Broadcasting of Music in Television". Part I, Introduction. R. F. A. Pottinger. Part II, Sound and Vision, L. Salter. Part III, Operational Technique, E. G. M. Alkin. Part IV, Acoustic Treatment of Television Studios, C. L. S. Gilford, pp. 23. No. 41: "The Design of a Group of Plug-in Television Studio Amplifiers", K. J. Austin. Pp. 19. No. 42: "Apparatus for Television and Sound Relay Stations", F. A. Peachey, R. Toombs and D. L. Smart. Pp. 22. (London: British Broadcasting Corporation, 1961 and 1962. 5s. each.)

With the extension of the sound and television broadcasting ervice towards the objective of full national coverage, limitations of staff have made it necessary for the B.B.C. to develop remote and automatic control facilities for unattended relay stations. Monograph No. 42 describes the development of such stations, which vary in radiated power from a few watts to several kilowatts, and derive their programme modulation 'feed' either by direct line or radio link, or by normal broadcast reception from the appropriate regional transmitter. Some eleven such stations are in service, and another fourteen are under construction; many of these are in remote areas where difficulties have been experienced by the listening and viewing public in obtaining satisfactory reception. With regard to maintenance, the B.B.C.'s plan is for a regular call to be made by an engineer at each of the new unattended stations. While attempts are made to anticipate a breakdown, such as the replacement of a valve seen to be approaching the end of its useful life, no steps are taken towards major repairs in the field. When necessary, the faulty unit is removed and replaced by a spare; a practice which causes the minimum disruption to the service.

The work described in these and other monographs indicates the realization by the B.B.C. of its responsibility to provide the best and most complete national broadcasting service from a technical point of view; and to take all practicable steps to keep this service up to date. With the encouragement given in the Government's recent White Paper (H.M.S.O., Cmnd. 1770, July 1962), it can be confidently expected that the service will continue to develop in the future on the existing high standard. R. L. SMITH-ROSE

THE JOHN INNES INSTITUTE

THE satisfactory progress made in genetical studies of various economic plants is recorded in the annual report of the John Innes Institute*, and work on cellular mechanisms is aided by the Department of Cell Biology—now a functional unit.

The long-term project of improving varieties of apples has continued, and there is hope eventually of selecting seedlings with resistance to both scab and mildew. The work on selection of cherry varieties has been helped by the discovery that inoculation of the bacterial canker organism into 2-year-old wood in December give results closely resembling those found in the field, and progress has been made in development of reliable methods of testing the resistance of first-year seedlings. Some selections of strawberries show resistance to mildew and give heavy yields of large fruit. It is hoped to combine these attributes with good quality and resistance to other diseases. The possibility of breeding tomatoes resistant to tobacco mosaic virus is being explored; but the occurrence of symptomless carriers is a drawback because a commercial variety with complete tolerance of the virus is undesirable since it is a reservoir of infection.

In the Department of Genetics investigations of genetic control of the enzyme triphosphopyridine nucleotide-linked glutamic dehydrogenase of *Neurospora crassa* has been continued. and methods developed for obtaining pure preparations. Work has continued on the mechanisms of recombination and mutation in *Ustilago maydis* and mutability in *Antirrhinum majus*. From a stock of tomato seed stored at 27° C for 14 years it has been established that there is a much higher incidence of rogues from plants grown from old seed than among those raised from one-year-old seed. Prolonged storage of seed also affected earliness but not total yield of fruit.

In the Department of Potato Genetics advances have been made in classification of cultivated varieties and an extensive range of behaviour has been revealed in the interspecific relationship of Central American wild species. Assessment of scab resistance has been advanced by perfection of a pot test which gives results comparable with field trials. Some scab-resistant clones have been revealed in Andigena stocks and it is hoped to transfer this resistance to a *Tuberosum* background.

The main theme of research in the Department of Cell Biology has been the examination of the structure and function of the ribonucleic acid of the nucleus. There is evidence that nuclear RNA is not necessarily a precursor of the cytoplasmic RNA but is mainly broken down within the cell to low-molecular weight compounds.

The growth rooms and cabinets developed in the Department of Physiology and Plant Culture are now in routine use for various investigations. One of these is the effect of temperature and light-intensity on the development of the shoot apex of the tomato. Considerable enlargement of the shoot apex always takes place during the vegetative phase before the first inflorescence is initiated. The processes of formation of leaf primordia and apical enlargement appear to be independent. More leaves are produced at 25° C before flowering than at 15° C, and the number of extra leaves produced is greater the lower the light-intensity. Experiments have been initiated to define more precisely the nature of the rogue characters in tomato and to express it in quantitative terms.

INTERNATIONAL WEIGHTS AND MEASURES

THE Proceedings of the forty-ninth session of the International Committee of Weights and Measures held during October 4–20, 1960, have now been published*. It contains the reports of the secretary of the Committee covering the period September 1, 1958–August 31, 1960; the director, Mr. Volet, of the International Bureau of Weights and Measures, on the activities of the Bureau during the same period; the commission for the revision of the treaty of the metre; the consultative committee for ionizing radiation standards; the commissions on system of units; and the commissions on the work and administration of the Bureau.

The International Committee recommended, and this was later adopted by the eleventh General Conference on Weights and Measures, that the metre be the length equal to 1,650,763·73 wave-lengths *in vacuo* of the radiation corresponding to the transition between the levels p_{10} and $5d_5$ of krypton-86; the definition of the metre in vogue since 1889, based on the international prototype of platinum iridium, be abrogated; and the international prototype sanctioned by the First Conference of Weights and Measures in 1889 be preserved at the International Bureau of Weights and Measures under the same conditions as those fixed in 1889. The Conference also confirmed the recommendation that the International Bureau undertake the work of international unification of the standards of measurement of ionizing radiation, and the extension of the laboratories of the Bureau and the increase of its equipment for this purpose. In this connexion, the Bureau would take charge of the international standard of radium No. 5430 which the Radium Institute of the University of Paris was willing to have transferred. The Committee was asked to undertake without delay the necessary investigations to fix precisely the units and ideas used in regard to ionizing radiation and to submit its findings to the twelfth General Conference to be held in 1966.

It was agreed that the cubic decimetre and the litre were not equal, but differed by about 28 millionths, and that a report on this matter should be presented to the twelfth General Conference.

The full texts of the sixteen resolutions adopted by the eleventh General Conference are printed in the *Comptes Rendus des Séances de la Onzième Conférence Générale des Poids et Mesures*†. Appendix 5 to this volume is the official French version of the International Practical Scale of Temperature of 1948 (amended edition of 1960), and Appendix 6 gives a detailed description of the progress of the International System of Units based on the metre, kilogramme, second, ampere, degree K and candela.

A RADIOISOTOPE TECHNIQUE FOR TRACING AIR MOVEMENTS IN CLEAR AIR AND IN CLOUDS

By R. A. FOOKES and J. S. WATT

Isotopes Division, Australian Atomic Energy Commission

AND

J. A. WARBURTON

Radiophysics Division, C.S.I.R.O., Sydney

A NEW technique using radioisotopes for tracing air movements in clear air and in clouds is being developed principally for use in experiments related to cloud seeding. The tracer is released from an aircraft and, during a series of passes, the γ-rays emitted by the material about the aircraft are detected by a large crystal scintillometer. From the measurements of γ-ray intensity, the movement of the tracer may be followed and information obtained on its spatial distribution.

The method has been tested in ten separate flight experiments. In the first two xenon-133 was used; but this was abandoned in favour of the more readily available copper-64 (half-life 12·8 h) in the form of finely powdered copper oxide. Up to 2-curie quantities of ^{64}CuO have been released and traced with an omnidirectional scintillation detector for periods up to 50 min. A typical flight record of one pass through a cloud is given in Fig. 1. It shows the variation of detected radiation intensity as the aircraft passed the radioisotope about 1·6 min after its release. The

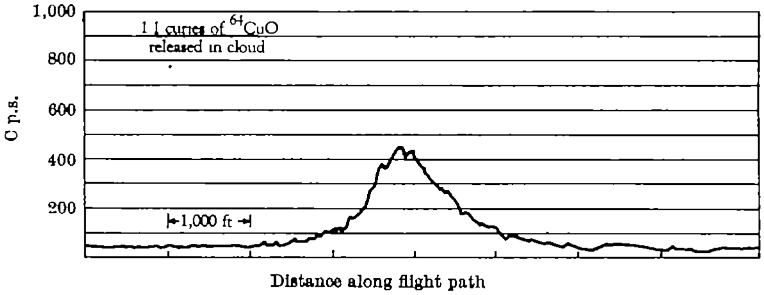

Fig. 1. Record of variation of γ-ray intensity along flight path

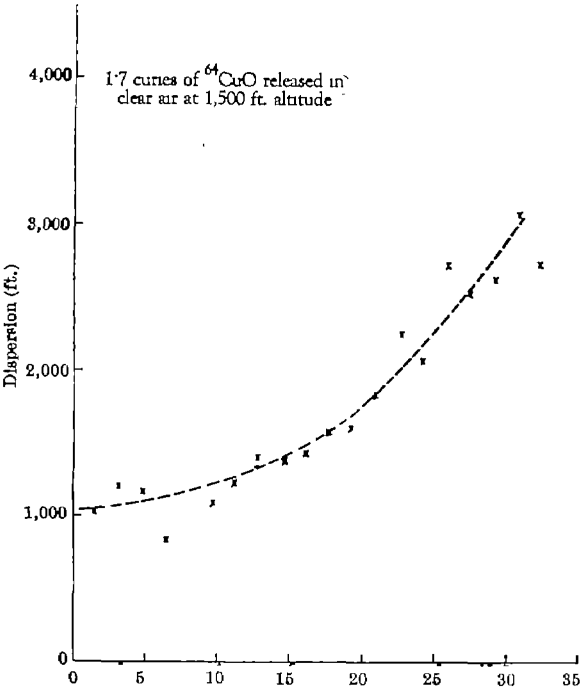

Fig. 2. Dispersion as a function of time after release

background count-rate measured by the scintillometer (the crystal is a cylinder of sodium iodide of 4-in. diameter and 3-in. height) was about 40 counts per second. For altitudes between 4,000 and 12,000 ft., it is usually between 40 and 100 counts per second. Fig. 2 shows dispersion as a function of time after release of the ^{64}CuO for a flight on May 16, 1961. Dispersion is defined as the length of flight path corresponding to the distance between the points on the flight record where the count-rate, after background has been subtracted, has fallen to 10 per cent of that at the peak intensity of the pass.

From Fig. 2 it can be seen that about 30 min after release of the ^{64}CuO its γ-rays were detected throughout 3,000 ft. of flight path. However, soon after release, when the volume containing the radioisotope should be small, the dispersion measured was about 1,000 ft., varying little in the first few passes. These large apparent values of dispersion, indicating poor resolving power of the technique along the line of flight, are due to lack of directivity of the detection device and the large range of the γ-rays in air. To improve the directivity of the system, a collimated detector has been made. It consists of the scintillation crystal sandwiched between two circular lead plates which are mounted in planes perpendicular to the flight axis. If the collimated detector is designed to 'see' only those γ-rays emitted within an angle of ± 10° to the plane perpendicular to the direction of flight, then the resolving power along the line of flight should be improved by about an order of magnitude.

As the radioisotope disperses in the atmosphere, air currents sweep it away from the point of release and so it becomes increasingly difficult with time to return to the region of greatest activity. In clouds, the tracer may be lost completely within a short period. To help locate the activity and hence guide the aircraft back to it, a device can be used which indicates whether the bulk of the radioisotope is above or below to the left or to the right of the aircraft. A prototype unit, giving only left–right indication, has been successfully tested in flight experiments. A more advanced unit has since been constructed, comprising four scintillation detectors, each with a large plastic phosphor. Lead plates, in the form of a cross (×) and mounted with their line of junction in the direction of flight, separate the detectors so that each one effectively views one quadrant of a sphere. Each detector is shielded by a thin lead sheet, which absorbs few of the unscattered copper-64 γ-rays, but most of those scattered by the air. This reduces the number of γ-rays which, although emitted in one quadrant, are scattered into the detector of another quadrant.

There is an upper limit to the volume throughout which quantitative measurements of γ-ray intensity may be made with the present technique using the omnidirectional detector. Consider the case of the radioisotope uniformly dispersed in this volume. The upper limit will depend on four factors; the sensitivity of the scintillometer, the absorption of γ-rays in air as measured by it, the background detected by the scintillometer, and the maximum amount of activity that may be released. The first two factors have been determined by measuring the count-rate of the scintillation detector as a function of distance between it and a calibrated source of copper-64. To reduce interference by the ground, both source and detector were suspended more than 100 ft. above ground-level. From the measurements made, it has been calculated that the scintillometer will record a count-rate of about 70 counts per second above background when in air containing a uniform concentration of 30 μμc. of copper-64 per cubic foot. This count-rate is sufficiently greater than background for quantitative measurements to be made. It is possible to handle and release at least 20 curies of ^{64}CuO. Hence the upper limit of volume throughout which measurements of radioisotope concentration can be made is at least four cubic miles.

MECHANISMS OF THE WEAR OF GRAPHITE SLIDING ON STEEL—WITH AND WITHOUT AN ELECTRIC CURRENT PASSING ACROSS THE INTERFACE

By Dr. J. E. THOMPSON and M. J. B. TURNER
English Electric Co., Ltd., Nelson Research Laboratories, Blackheath Lane, Stafford

THE reasons for the low coefficient of friction of graphite under normal atmospheric conditions, and the nature of the mechanism of the wear of graphite, have been considered and discussed by various authors. Savage[1] suggested that various vapours, for example, water vapour, form a thin surface layer on the graphite, which provides boundary lubrication. Deacon and Goodman[2] have discussed experimental results with various vapours and the effects of temperature, in terms of weak bonding between the planar faces of graphite platelets and strong bonding at their edges.

Recently, it has been shown by Bollman and Spreadborough[3] that groups of graphite planes can roll up to form small roller bearings. They consider that such rollers are responsible for the low frictional properties of graphite. Further work by Spreadborough[4] with a small copper stylus sliding over graphite has suggested that lubrication by this method involves the surface orientation of crystallites, and the subsequent formation of these rollers. The mechanism of wear is, presumably, the formation of these rollers by a 'ploughing' action.

A detailed investigation has been carried out by us[5] into the factors influencing the rate of wear of one grade of graphite brush sliding on steel slip-rings. The aim of the present article is to report the results of further studies on one aspect of this work—the mechanism of wear. By using various electron-microscope replica techniques, it has proved possible to confirm that the wear mechanism changes with the sliding conditions, and to identify the mechanisms of wear by means of subsidiary experiments. Examination of wear debris collected from the apparatus, the surface of the brush, and the surface of the slip-ring failed to show the presence of graphite rollers. However, abundant evidence of such rollers (though usually of smaller dimensions) was found on examination of thin sections of new brushes produced with an ultra-microtome, suggesting that the mechanism of wear involving roller production is probably confined to low speeds of sliding, and involves ploughing or cutting actions.

Rate of Wear

The apparatus was designed to measure accurately the rate of wear of graphite brushes sliding on a steel slip-ring of 6-in. diameter. These brushes ran on two separate tracks and the rate of brush wear could be obtained from two sensitive dial gauges, the plungers of which operated on the rear surface of the brushes (Fig. 1). Brush loading was applied by means of a system of pulleys and weights, so that the load remained constant as the brush wore away. Electric current could be passed across the interfaces.

The results of particular interest here involve the dependence of the rate of wear on load, brush area, and current. With no current, equilibrium wear conditions are established fairly rapidly, and the rate of wear is then proportional to load and independent of the apparent area of contact. This means that the surface conditions remain the same as the load is changed, and no additional variables are introduced[6]. An electric current passing across the interface removes the proportionality with load, and its effect is, therefore, to change the nature of the interface. The current has a greater effect on the positive interface than on the negative interface. Earlier results were confirmed by using brushes of the same grade, but from different batches. The magnitude of the results differed by about 20 per cent, but the same shape and character of the curves remained.

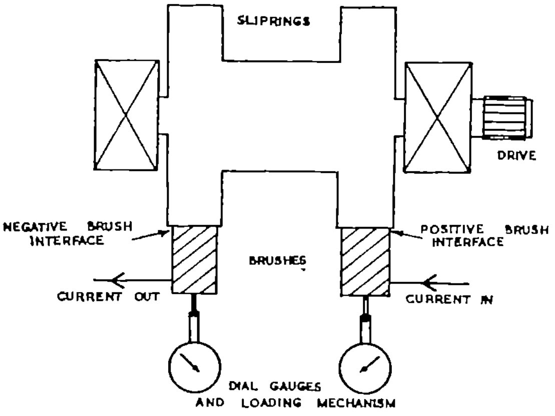

Fig. 1. Diagram of the wear apparatus showing arrangement of the brushes

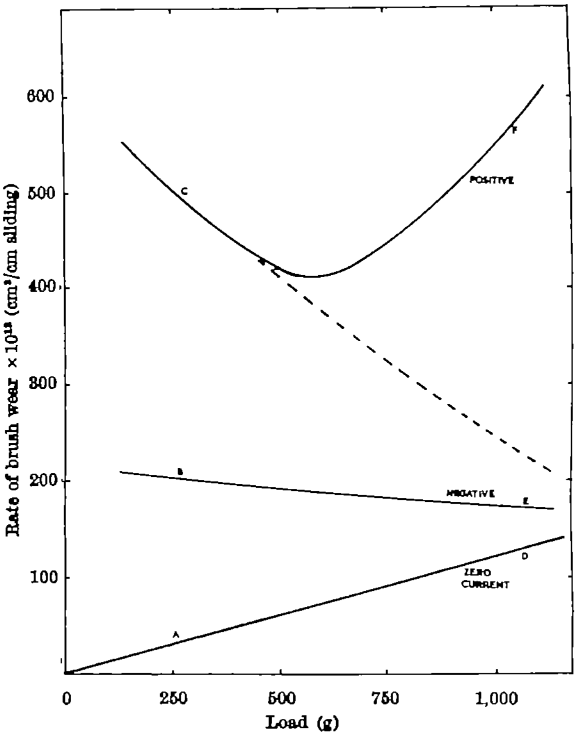

Fig. 2. Rate of brush wear versus load (*HM* 6 brush; 4,000 cm/sec; 60 amp and 0 amp)

The results for the (total) rate of wear of Fig. 2, with current passing through the brushes, can be considered as being composed of two parts : a contribution from a mechanical process of wear, and a contribution due to the passage of current (an electrical process of wear), though this may be merely a modification of the mechanical process. At low loads, as the load is increased the mechanical contribution increases, the electrical contribution decreases, so that the total rate of wear for both negative and positive brushes decreases. This is true for the negative brush, even at higher loads, though for the positive brush the rate of wear suddenly increases rapidly. This suggests that a change in the mechanism of wear takes place at higher loads under the positive brush. To examine this point, brushes were run under various conditions (points *A*–*F* in Fig. 2,) and the brush faces were examined by means of replica techniques and the electron microscope.

Electron Microscope Investigation

Replicas of the brushes after running under various conditions were made in the following manner.

The brushes were masked off with 'Lacomit' stopping-off medium, leaving only the rubbed faces exposed. Primary copper replicas were taken from each brush by electro-deposition of copper from a solution containing 250 g/l. copper sulphate, 75 g/l. sulphuric acid, at a current density of 150 m. amp/in^2. to produce a deposit approximately 0·002 in. thick. The copper replicas were carefully stripped from the brush surfaces, together with a large quantity of adhering graphite. A considerable amount of this graphite was removed by pressing adhesive tape on to the copper surface, then stripping off the tape, together with some of the graphite particles. Repeated application of the adhesive tape was carried out until no further graphite could be removed. Any residual adhesive from the tape was removed from the copper by a thorough washing in warm petroleum ether. Secondary carbon platinum replicas, self-shadowed at 3 : 1 parallel to the rubbing direction, were then taken from the primary copper replicas. The negative replicas thus produced were examined in an Elmiskop I microscope.

Fig. 3 shows a typical photomicrograph from points *A* or *D* on Fig. 2. The brush surface is fairly smooth, apart from tongues of graphite protruding from the surface, as might be expected from an aligned graphite layer[7]. Fig. 4 shows a typical photomicrograph from points *B*, *C*, *E*. Here the general features are of a smooth surface covered with numerous smooth-sided protuberances of variable size and frequently almost hemispherical in character. These protuberances could be formed by some erosion process, for example, by small hard particles from the metal ring (perhaps oxide). In Fig. 5 a typical photomicrograph from point *F* is shown. Many deep, sharply angled and step-sided hollows are seen, which are probably formed when particles of graphite are torn from the brush face in a brittle manner.

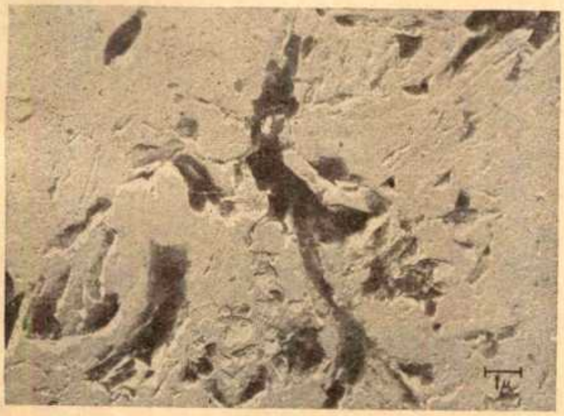

Fig. 3. Electron micrograph typical of points *A* and *D*, showing tongues of graphite present in the brush surface

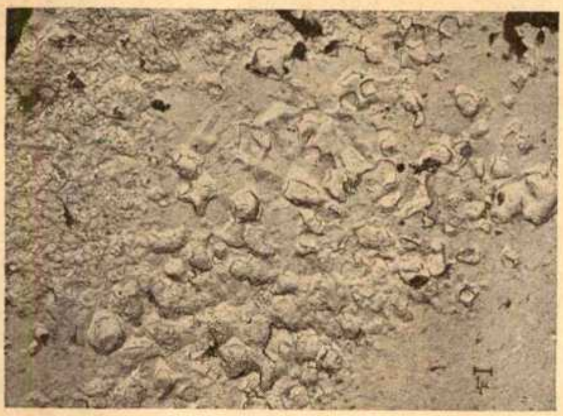

Fig. 4. Electron micrograph typical of points *B*, *C*, and *E*, showing many smooth-sided protuberances

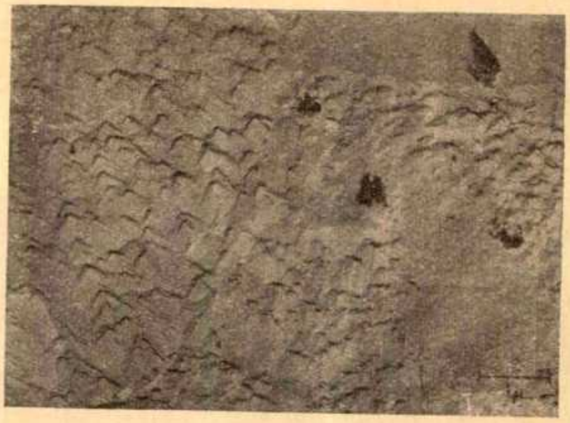

Fig. 5. Electron micrograph typical of point *F*, showing step-like fractures

To examine these interpretations placed on the electron micrographs, new brushes were rubbed on (*a*) the smooth surface of a paper card ; (*b*) a piece of glass on which a copious supply of loose 'Carborundum' powder (600 grade) had been placed ; (*c*) a piece of new 'Carborundum' paper (600 grade). The resulting photomicrographs corresponded : (*a*) above was similar to Fig. 3, (*b*) to Fig. 4, and (*c*) to Fig. 5.

Conclusions

Previous work by us[5] has shown that asymmetric wear at the positive and negative brushes was most probably due to the preferential removal of graphite wear fragments comprising graphite lamellæ held between asperities on the positive metal wear track, so that an increased filing action by the metal asperities on the positive brush arose.

The present work supports this view. Furthermore, at high loads and high currents, the wear process at the positive brush changes, so that wear particles are torn from the brush in a brittle manner.

No evidence of graphite rollers was found in wear particles collected from the wear debris, the face of the brush, and the ring surfaces, though they could be easily recognized in thin sections of brushes made with an ultra-microtome. It would appear that a mechanism producing graphite rollers, and an explanation of a low coefficient of friction arising from such rollers, are not universally applicable ; they are, perhaps, limited to low velocities of sliding.

We thank Mr. J. K. Brown, director of research, for permission to publish this article, and G. P. Buchi for development of the replica technique.

MODE SEQUENCES IN RUBY LASER EMISSION

By T. P. HUGHES and K. M. YOUNG

Associated Electrical Industries Research Laboratory, Aldermaston Court, Aldermaston, Berkshire

TIME-resolved observations of the intensity distribution and wave-length of the output light from a ruby laser, operated well above threshold pumping power, have already been reported[1]. This article describes a more detailed investigation, by similar methods, of the near-field patterns and wave-lengths of the first few spikes emitted by a laser operated very close to threshold conditions. Transverse mode patterns are observed, similar to those already reported for single spikes from ruby lasers[2,3] and in the output from gas discharge lasers[4,5]. The experiments recorded here show each spike to be associated with a single mode of oscillation, in agreement with the results of Hanes and Stoicheff[6]. In addition, however, they show that in the early spikes one or more sequences of modes occur, overlapping in time, each sequence being associated with a certain region of the crystal face. The steady progression towards longer wave-lengths noted previously[1] is observed during a sequence: the longitudinal mode number decreases regularly by one, or sometimes two, from one member of the sequence to the next. The transverse mode patterns do not change systematically with time, but a general trend towards more complex and extensive patterns is apparent.

A cylindrical ruby crystal 5 cm long and 0·6 cm in diameter, with the crystal axis perpendicular to the cylinder axis, was used. The polished ends were coated with dielectric multilayers of high reflectivity. The crystal was mounted inside an A.E.I. type *FA*26 helical xenon flash tube, the assembly being cooled by a flow of air at room temperature.

Figs. 1*a* and 1*b* are rotating-mirror camera photographs of the front face of the crystal, for the initial spikes of two successive pulses close to the threshold pumping energy. The modes occurring in the first few spikes appear to be fairly simple. The first four come from the same region of the crystal face. About the time of the fourth spike a new region, at the same level in the photograph, begins to emit in different modes. Soon afterwards a third region, below the first two, begins another sequence, while the earlier sequences continue. The different regions of the crystal face emit independently of each other, as was noted by Sorokin and Stevenson[7] for calcium fluoride doped with trivalent uranium and by Statz *et al.*[8] for ruby.

It should be noted that inhomogeneities and strain cause significant variations in the optical length of the crystal, amounting to several wave-lengths over the end faces of a typical crystal[9]. Thus the optical path between the two surfaces is constant only over small areas, which are the regions where the more easily excited modes may be expected to appear.

On the photographic plate, the separation of the individual mode patterns is sometimes smaller than the diameter of the image of the crystal face. Thus, the patterns from different regions of the crystal face sometimes appear on the plate in an order different from that in which they were emitted. Most of the spikes are of short duration (< 0·25 μsec), but a few persist for several μsec, as has been observed previously[1,5]. Occasionally two spikes are apparently linked in the same mode, as may be seen in Fig. 1*b*. The sequence of transverse mode patterns does not

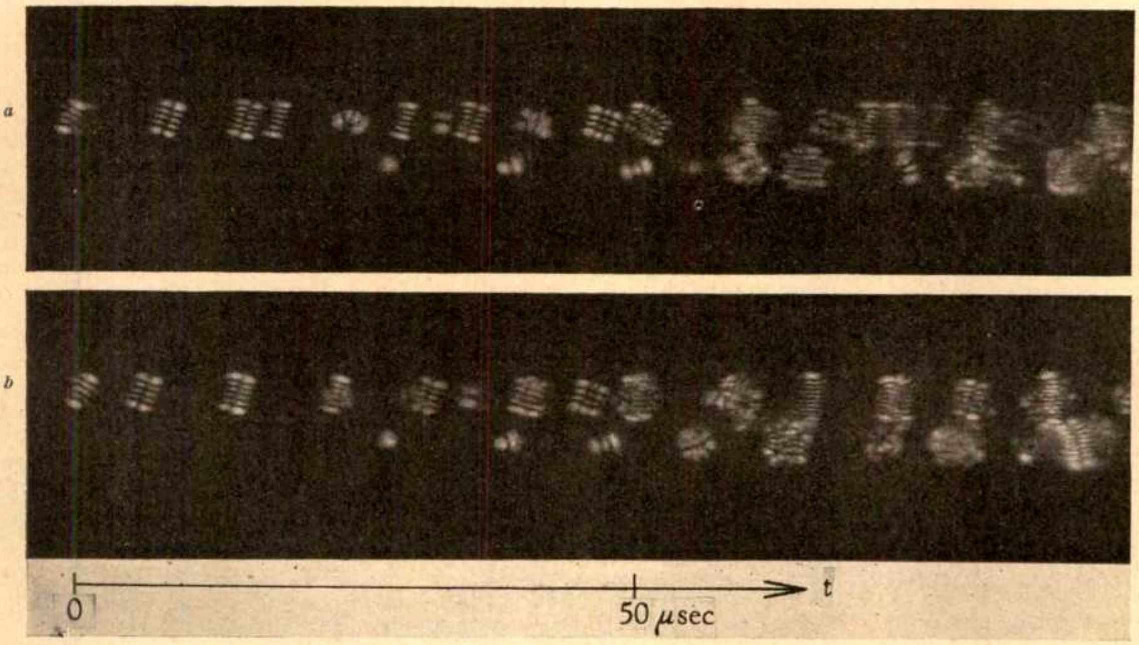

Fig. 1. Transverse mode sequences in two successive pulses

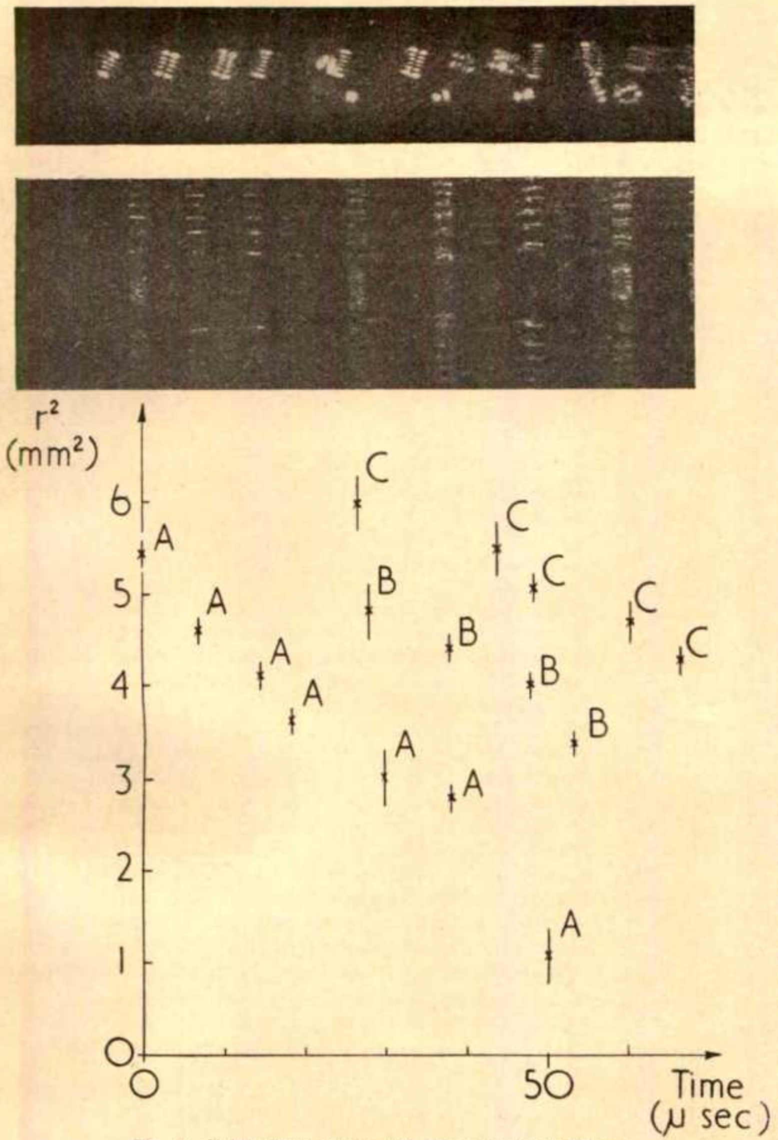

Fig. 2. Fabry–Perot fringes and transverse mode patterns

change much in a series of pulses at short intervals, though the wave-length of the first spike is known to change appreciably from pulse to pulse as a result of heating[1].

The laser was also operated with the crystal rotated about the cylinder axis into four different positions 90° apart. The mount and the flash tube were not rotated. The order in which the various regions of the crystal face began to emit depended on the position of the crystal, an effect probably due to asymmetry in the pumping light distribution, as suggested by Evtuhov and Neeland[2]. However, each region always exhibited its own characteristic mode sequence.

By splitting the output beam and passing the two parts through different optical systems it was possible simultaneously to record near-field patterns and Fabry–Perot interferograms of the spikes with the rotating-mirror camera. Fig. 2 shows part of a plate taken in this way, with a plot of the squares of the fringe radii added below. Some of the fringes were too faint to be measured. As in Fig. 1, the order of the transverse mode patterns is not always the temporal order of emission. However, the corresponding fringe patterns were obtained with a diffuser and a narrow slit, and are thus in correct time order. The Fabry–Perot etalon had an 8·29 mm spacer, for which the inter-order fringe separation corresponds to 0·29 Å at 6943 Å. The fringe-forming optical system was such that the difference in wave-length between successive longitudinal modes in the ruby crystal (0·025 Å) corresponded to a difference in the squares of the fringe radii of 0·50 mm².

As may be seen in Fig. 2, the wave-lengths of spikes emitted from a particular region of the crystal face become progressively longer. Within the experimental errors indicated the wave-length steps correspond to integer decrements in the longitudinal mode number. The effect is too rapid to be explained by thermal changes. When a new region begins to emit, an independent new sequence is started. No simple relationship has been found between the wave-lengths at which the various sequences begin. Three regions may be distinguished, giving rise to the sequences *A*, *B* and *C* in Fig. 2. The situation becomes too confused for analysis after the first twenty spikes or so, because each mode then extends over a large fraction of the area of the crystal face. The beat frequencies observed by McMurtry and Siegman[10] are likely to be due to coincidences in time between members of two sequences from different regions.

A second ruby crystal of similar dimensions and the same orientation was also studied. Its end faces were aluminized, the output surface having 2 per cent transmission. As the intensity of its light emission in each spike was only one-hundredth of that of the first crystal, the transverse mode patterns and fringes had to be examined separately. A single ill-defined transverse mode was found during the initial spike sequence. A different pattern was observed on rotating the crystal. Marked linking occurred between spikes. The wave-length variation in the early spikes followed similar trends to those observed with the first crystal.

It is suggested that a crystal will resonate in different modes in two successive spikes, because in the vicinity of antinodes of a standing wave the density of excited ions will be depleted by emission. Also, as suggested previously[1], the longitudinal mode corresponding to the eigen wave-length nearest to the R_1 line centre is most likely to reach threshold first, followed by modes corresponding to wave-lengths successively more distant from the centre. However, this still does not explain why the wave-length of the emission from a given region always increases during the first few spikes.

We thank Dr. A. A. Ware for his support and encouragement, and Dr. R. Dunsmuir of the Associated Electrical Industries (Rugby) Research Laboratory for stimulating discussions. Mrs. M. R. Harraway, Mr. R. P. de Ste. Croix and Mr. D. L. Warren assisted with the experiments. Mr. A. E. Ennos kindly aluminized the faces of one of the laser crystals. Thanks are also due to Dr. T. E. Allibone, director of this Laboratory, for permission to publish this article.

ELECTRON SPIN RESONANCE IN WOOD-GRINDING AND WOOD-PULFING

Formation of Free Radicals in Wood Grinding and Pulp Beating

It is known that the mechanical disintegration of high-molecular-weight substances results in degradation. For example, Hess and Steurer[1] have shown that the molecular vibrational energy available in ball-milling of cellulose is sufficient to rupture covalent bonds. This was substantiated by Lindberg *et al.*[2], who found that carbon–carbon as well as carbon–oxygen linkages are ruptured, and that this degradation is entirely mechanical. The majority of organic substances have been found to undergo thermal decomposition by mechanisms[3] in which free radicals are formed as intermediates. Furthermore, a recent study of the cryolysis[4] of high-molecular-weight compounds demonstrated that bond rupture and radical formation are due to the pressures deriving from phase transitions.

In view of these findings we have attempted to determine whether mechanical wood-grinding and pulp-beating, as practised commercially in the pulp and paper industry, involves the formation of macroradicals in lignin and carbohydrates respectively. This was investigated by electron spin resonance measurements in wood with increasing grinding time, and in paper pulps with increasing beating time.

Air-dried wood from black spruce (*Picea mariana*), and strong kraft pulps produced from the same wood were used in these experiments. Weighed samples of these materials in open 'Pyrex' glass capillaries were placed in the cavity of an electron spin resonance spectrometer (Varian Associates, model V-4500) at room temperature, and the signals were recorded. In one series of experiments, the wood was studied first in the initial (mechanically undamaged) state, then after it had been ground through mesh 40 of a laboratory Wiley mill, and finally after a further ball milling. The electron spin resonance signal areas were measured planimetrically. In all samples studied, free radicals were found to be present, their concentration increasing as the wood particle-size became smaller, as illustrated in Fig. 1. Care was taken to keep the spectrometer sensitivity constant throughout the experiment.

For comparison, the smaller signal (*d*) from a bleached, high-purity pulp, ball-milled to about the same fine grain as the ball-milled wood (*c*), is also shown. In addition, it was observed that the macroradicals in ground wood are relatively unstable, and that their total amount decreases rapidly when the temperature is raised.

The reason that the wood signal is so much greater than the pulp signal may be that the lignin present in wood, because of its three-dimensional, rather rigid structure, is less resistant to grinding than the cellulose. Thus, more bonds are ruptured and free radicals formed in the lignin portions of the wood than in its cellulose portions. Alternatively, more free radicals may have been trapped in the ground lignin than in the ground cellulose.

In another series of experiments the electron spin resonance of two unbleached kraft pulps was studied

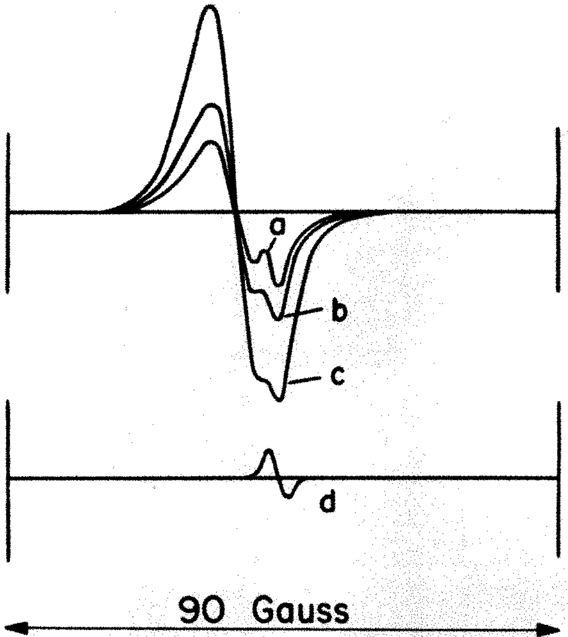

Fig. 1. Electron spin resonance signals of wood (*Picea mariana*) in progressive stages of sub-division. *a*, Initial undamaged wood; *b*, wood ground through mesh 40 of a Wiley mill; *c*, wood ground according to (*b*) and afterwards ball-milled; *d*, high-purity bleached pulp, ball-milled like (*c*).

at room temperature with increasing time (0–125 min) of beating in a Valley beater. Specimens of equal weight (0·0134 g) were cut from 1-g standard sheets of the various pulp samples, and in rolled form they were inserted into the glass capillaries. The electron spin resonance signals were recorded and evaluated. No significant difference in the size of the signals was found irrespective of the duration of beating.

Tentatively, the following explanation is given. By the mechanical damaging of the fibres in pulp beating, covalent bonds are broken; thus, macroradicals are formed, and the specific surface is increased. Concurrently, water association and fibre swelling take place, influencing the wet-web behaviour[5]. When water is removed from the wet sheet during drying the macroradicals would contribute to interfibre bonding. This theory would also explain why sheets formed from pulps which were never dried exhibit superior strength properties compared with those from pulps which had been dried. The rather uniform free radical content found in pulps beaten to decreasing Canadian Standard Freeness (CSF) is probably related to the macroradicals stabilized and trapped in the residual lignin. This is supported by the finding that the initial wood and the unbleached kraft pulps exhibit electron spin resonance signals which are similar to each other in shape, but different from the signals from isolated lignins.

Electron Spin Resonance in Alkaline Wood Pulping

We have recently carried out alkaline pulping of wood in the cavity of an electron spin resonance spectrometer (Varian Associates, model *V*-4500) and have found that strong signals were recorded at the pulping temperature, thus indicating the formation of free radical centres. Results from a kinetic investigation[6] of the alkaline delignification of wood have also suggested the participation of free radicals. Lignin preparations isolated in various ways (milled wood lignin, ethanol lignin, dioxane lignin, periodate lignin, ligninsulphonic acid, alkali lignin) were also found to contain free radical centres even after long periods of storage.

In our pulping experiments, air-dried wood from black spruce (*Picea mariana*) was ground through mesh 40 of a Wiley mill. Part of this material was soaked for 10 min at room temperature in a 4 per cent sodium hydroxide solution (ratio 1 : 20). Afterwards, the excess lye was pressed off, and the impregnated material was freeze-dried, to avoid the effect of moisture on the cavity *Q*. As found earlier[7], alkaline lignin solubilization at elevated temperature occurs whether large amounts of moisture are present or not. The spectrum of both the air-dried initial wood powder and the freeze-dried, alkali-impregnated wood material was measured in 'Pyrex' glass capillaries at room temperature and also at the pulping temperature (180–190° C). Rapid heating to this temperature was obtained by means of a stream of hot nitrogen. A single line near the free-spin *g*-value was observed in all experiments, the maximum slope line-width being approximately 10 gauss. The areas of the signals obtained in the various experiments were estimated planimetrically, and the results were calculated on a uniform weight (0·015 g).

Two series of experiments were carried out, namely, in open capillaries, and in evacuated capillaries. Alkali-impregnated wood was also examined in the presence of 10 per cent elemental sulphur and of 10 per cent 2,6-di-*tert*. butyl-*p*-cresol, the latter being known as an efficient scavenger for free radicals. As a control, a high-purity, bleached cellulose pulp was investigated at room and at pulping temperature with and without preceding alkali impregnation. As in the wood experiments, a 4 per cent sodium hydroxide solution was used in a ratio of 1 : 20, and after pressing off the excess of lye, the impregnated cellulose was freeze-dried.

In a preliminary series of experiments, it was found that both wood and pure cellulose exhibited greater electron spin resonance signals (preceding section) after grinding than did the initial materials. Interestingly, the signal of the ground wood was about ten times larger than that of the ground cellulose. However, when heating ground wood and ground cellulose respectively to pulping temperature, the electron spin resonance signals dropped in both cases to low values. On the other hand, when ground wood or ground cellulose was alkalized and freeze-dried, the signals obtained at room temperature increased in both cases only slightly. However, when the alkalized samples (wood or cellulose) were heated to pulping temperature, very strong electron spin resonance signals were found, exhibiting a maximum value when reaching maximum temperature, and afterwards decreasing with increasing time while keeping the sample at this temperature. This decay of the free radicals formed was found to follow an exponential function, and finally to level off.

Comparative experiments in open (air-filled) and evacuated capillaries showed that oxygen reduced the maximum signal intensity. It may be that the oxygen acted as scavenger for free radicals. A similar influence was found to be exerted by elemental sulphur, when the alkalized samples mixed with small amounts of sulphur were heated to pulping temperature in evacuated capillaries. This seems to indicate that the role of the sulphur in kraft pulping is partly that of a free-radical scavenger. This view appears to be supported by the fact that when adding known scavengers for free radicals to alkalized, freeze-dried wood, like 2,6-di-*tert*. butyl-*p*-cresol, and heating the mixed samples to pulping temperature, the electron spin resonance signals dropped to relatively low values, compared with those previously obtained under the same conditions.

The investigations show that in alkaline pulping of wood, lignin and carbohydrates both are being degraded with the formation of free radical centres. The fact that a relatively narrow single line was observed indicates that no free radicals of distinct structure, such as quinone methides, are formed during pulping. The macro-radicals, because of their high reactivity, undergo various secondary reactions. For example, it can be visualized that there is not only lignin condensation but also some combining of free radicals from lignin with those from carbohydrates. In other words, the possibility exists that part of the residual lignin in pulps from alkaline pulping is grafted on the fibrous pulp portions by secondary reactions. An important role of the chemicals present in alkaline pulping is probably that of scavenging the free radicals and thus avoiding these reactions. These conclusions are supported by the work of Rex[8], who has found that tannins and humic acids such as are present in soils and coals contain free radicals, and that the latter are stable over long periods of time. In air-dried samples of fresh wood, the same author found very low concentrations of free radicals, and he postulated that free radicals do not occur in protolignin. However, lignin portions solubilized from wood with acidified dioxane, and also portions of the wood extracted by water in presence of the organic acids formed from the wood itself, exhibited strong electron spin resonance. Rex suggested that semi-quinone free radicals are related to this phenomenon. Furthermore, Freudenberg[9], Adler[10] and other authors studying biogenesis of lignin, postulated that free radicals of the quinone methide type are involved in the lignification of plant tissues.

ELECTROPHORETIC AND IMMUNOLOGICAL CHARACTERISTICS OF NATIVE AND PURIFIED HUMAN GROWTH HORMONE

By DR. SELNA L. KAPLAN* and PROF. MELVIN M. GRUMBACH†

Department of Pediatrics, College of Physicians and Surgeons, Columbia University, and Babies Hospital, New York

THE immunochemical characteristics of the human growth hormone antigen–antibody system have been described previously and a high degree of antigenic homogeneity demonstrated (reviewed in ref. 1). On electrophoresis in agar gel (*p*H 8·2, barbital buffer) the Raben preparation of human growth hormone (HGH) migrated as a single broad zone located between the α-$_2$ and β-1 globulin regions. Immunoelectrophoresis in agar gel of Raben HGH and rabbit antiserum to HGH gave a single, elongated ellipsoidal arc of precipitation which was considerably lengthened by increasing the voltage gradient across the gel. These observations suggested the presence in preparations of HGH of multiple components with distinctive mobilities which had similar antigenic determinants. Barrett, Friesen, and Astwood[2] and Ferguson and Wallace[3] clearly demonstrated by means of zone electrophoresis in starch-gel electrophoretic heterogeneity in purified HGH prepared by three different methods. The components assayed by Ferguson and Wallace exhibited both growth hormone and prolactin activity. In the work reported here, evidence has been found which suggests that at least some of the electrophoretic heterogeneity is attributable to artefact arising from denaturation of the hormone during fractionation or storage.

Vertical starch-gel electrophoresis[4] of Raben preparations of HGH were carried out using the discontinuous buffer system of Poulik as modified by Ferguson and Wallace[3]. HGH prepared by Raben[5], dissolved in a small amount of 0·1 N sodium hydroxide and buffer, was subjected to electrophoresis for 17 h with a voltage gradient of 5 V/cm gel at 4° C. After completion of electrophoresis the gel was scored along its longitudinal axis at intervals of 1 cm from the origin and immediately removed from the tray. A layer of the gel was sliced off the top, stained for 45 sec with a saturated solution of amido black 10*B* in methanol/acetic acid/water (45:10:45) and washed with solvent alone. Sections corresponding to the stained components were cut out of the unstained half of the gel. Eluates from the sectioned gel were examined by immunoelectrophoresis[6] and by a micro-modification of the double diffusion gel plate technique of Ouchterlony[7] using rabbit antiserum to HGH as the developing serum. The reactions of the gel eluates with antiserum were compared with the results obtained with saline homogenates of fresh human pituitary glands and with a solution of purified HGH (Raben).

Three major bands and several minor bands were detected in the stained portion of the starch gel (Fig. 1) comparable with the pattern described by Ferguson and Wallace[3]. Following immunoelectrophoresis of the eluates and development with anti-HGH serum single precipitin arcs of different mobilities were formed corresponding to each of the three major bands in the stained gel. The most cathodal of the major components (No. 1) formed a precipitin arc situated at the cathodal end of the precipitin arc to HGH, whereas the crests of the arcs to components No. 2 and No. 3 were located respectively at the mid-portion and at the anodal end of the precipitin arc to Raben preparations of HGH (Fig. 1). A composite of the three types of precipitin arcs formed to the components separated by electrophoresis in starch gel was identical to the single arc of precipitation which develops when purified HGH[1,8] is reacted with its antiserum. None of the eluates reacted with undiluted or diluted horse hyperimmune anti-human serum. Complete fusion of single bands was demonstrated by the double diffusion gel plate technique of Ouchterlony when rabbit antiserum to HGH was placed in the central well and tested against the eluates, HGH, and a saline homogenate of fresh human pituitary gland placed in circumferential wells (Fig. 2).

It is noteworthy that the immunoelectrophoretic pattern of saline homogenates of fresh human pituitary glands revealed by rabbit anti-HGH serum lacked the distal portion of the anodal segment of the precipitin arc to purified HGH (Fig. 3). The location and shape of the single arc of the pituitary homogenates was comparable with the arc formed to

A representative micro-Ouchterlony gel plate illustrating the fused single bands without spur formation obtained when: (1) component 1, (2) component 2, (3) component 3 of the starch gel eluates, (4) HGH 50 μg/ml., and (5) HGH 200 μg/ml. in peripheral wells were reacted with rabbit anti-HGH serum (*AB*) placed in the central well

component 1, the most cathodal of the major bands separated by electrophoresis in starch gel. Further evidence that the single precipitin arc which developed when pituitary homogenates were reacted with antiserum to Raben's HGH is HGH was obtained by using a modification of the technique of immunoelectrophoresis described by Osserman[9]. The line of precipitation of the reaction of HGH and antiserum to HGH fused with the arc formed to the pituitary homogenate (Fig. 4).

The results indicate that the major components of HGH prepared by Raben have similar and possibly identical antigenic determinants. Ferguson and Wallace[3] have demonstrated by bioassay both growth-promoting and prolactin activity in the three components of purified HGH and suggested that HGH has intrinsic prolactin activity, a possibility supported by the findings of Chadwick, Folley and Gemzell, Lyons, Li and Johnson, and of Wilhelmi[10]. The differences in the immunoelectrophoretic pattern of growth hormone in saline homogenates of human pituitary gland and of Li and Raben preparations of HGH suggests that the multiple components of purified HGH separated by means of electrophoresis in starch gel are mainly attributable to artefacts arising from alterations in the growth hormone molecule prior to or during isolation. The major component, located closest to the cathode, stained more darkly than the other components, and in its immunoelectrophoretic pattern was comparable with that of growth hormone in saline homogenates of fresh human pituitary glands. Additional support for the contention that the electrophoretic heterogeneity of HGH is related to physical or chemical changes[11,12] in the growth hormone molecule during purification may be adduced from the results of immunoelectrophoretic analysis carried out in our laboratory of HGH prepared by either Elrick, Li, Raben, or Wilhelmi. Differences were observed in the mobility and length of the precipitin arc(s) of these various preparations when developed with antiserum to Raben's HGH. Polymorphism might also account for the multiple protein components in purified preparations of HGH since these are obtained from large numbers of pituitary glands, from a heterogeneous population. Immunoelectrophoretic analysis of individual pituitary glands, however, does not support this idea, and the possibility that different molecules of native growth hormone may exist does not seem to account for the heterogeneity of purified HGH found by starch-gel electrophoresis.

This work was supported by a grant from the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, U.S. Public Health Service. We gratefully acknowledge the samples of purified growth hormone supplied by Dr. M.

CYTOCHEMICAL OBSERVATIONS ON THE EFFECT OF PHYTOHÆMAGGLUTININ IN SHORT-TERM TISSUE CULTURES

By DR. D. QUAGLINO, DR. F. G. J. HAYHOE and R. J. FLEMANS

Department of Medicine, University of Cambridge

THE addition of phytohæmagglutinin (PHA) to human leucocytes cultured *in vitro* causes the appearance within a few hours of large basophilic primitive 'blast' cells, capable of synthesizing DNA[1] and of undergoing mitoses[2]. The emergence of large numbers of dividing cells, under the influence of PHA, has been widely utilized for the investigation of chromosome morphology in the peripheral blood of normal individuals.

How and from where the blast cells stem has been the object of considerable speculation. *In vitro* experiments by Nowell[3] appeared to indicate that the dividing cells in normal peripheral blood were derived either from monocytes or from some immature members of the lymphoid series. Mature lymphocytes and mature polymorphs were considered incapable of synthesizing DNA and undergoing mitoses.

Autoradiographic studies, using tritiated thymidine[4], have shown the presence in the peripheral blood of normal individuals of small numbers of large mononuclear cells which showed evidence of thymidine uptake and therefore of active DNA synthesis. These cells probably constitute a mobile pool of primitive and multipotential progenitor cells which, in special circumstances, could give rise to large numbers of dividing cells.

A recent investigation, based on morphological observations[5], suggests that the PHA-induced blast cells are derived from nucleolated intermediate lymphocytes. With the view of exploring further the nature and genesis of the blast cells present in cultures from the peripheral blood of normal individuals and with the secondary purpose of obtaining some insight into metabolic changes which occur in these cultures, we have carried out a number of cytochemical studies in cultures from 12 normal individuals. In addition to Romanowsky stains, the following cytochemical staining reactions were used: an azo-dye method for alkaline phosphatase[6], the periodic acid–Schiff reaction[7] the sudan black *B* reaction[8], a modified Graham–Knoll peroxidase technique[9], and methods for non-specific esterases[10], for phosphorylases[11] and for demonstrating succinic, DPN- and TPN-linked dehydrogenases[12].

In 8 of the 12 cases leucocytes were cultured both with and without phytohæmagglutinin. The following procedure was adopted. Twenty ml. of venous blood from a normal person were collected in a sterile Universal bottle, containing 0·1 ml. of heparin, and left to sediment in iced water for 30–60 min, depending on the rate of sedimentation. The blood was then centrifuged at 300–350 r.p.m. for 5 min and the supernatant removed. A white cell count was carried out on an aliquot of the supernatant to determine the initial cell concentration, and, following this, a calculated amount of *T.C.*199 and the subject's own serum were added to adjust the count to 1,000–2,000 cells/mm^3. The medium was then transferred to two other Universal containers, to one of which 0·4 ml. of PHA (Difco, batch No. 452131) was added.

Samples from both bottles were usually aspirated after 18–24 h, after 42–48 h, after 72 and occasionally 96 h. In one case samples were obtained initially at the second hour, and then after 4, 6, 18, 26 and 48 h. The amount aspirated was centrifuged at about 500 r.p.m. and smears made of the sediment. Smears stained by the Leishman or May–Grunwald–Giemsa methods showed, in material from cultures containing PHA, a rapid fall in the numbers of neutrophil polymorphs and degenerative changes such as conspicuous vacuolation and pyknosis in the few that survived. Monocytes, eosinophils and basophils, when present, usually persisted for the whole duration of the culture. Serial differential counts on the specimens obtained at different times showed the appearance during the first 18–24 h of varying numbers of nucleolated lymphocytes which persisted at the 48th hour but were gradually replaced and outnumbered usually by the 72nd hour by large numbers of primitive, nucleolated and basophilic mononuclear cells.

In cultures with no added PHA, neutrophil polymorphs were present in greater numbers than in specimens obtained at the same time from cultures containing PHA, and degenerative phenomena appeared much later and at a slower rate. Eosinophils, basophils and monocytes persisted in these cultures without conspicuous signs of degeneration. Lymphocytes showed no change in their morphology and only exceptionally were more primitive nucleolated lymphocytes encountered.

The alkaline phosphatase reaction, in cultures both with and without PHA, was negative in all mature polymorphs, even when an initial high alkaline phosphatase-level was observed in the peripheral blood of the same individual.

The periodic acid–Schiff reaction showed a distribution and staining pattern in the different cell types similar to that obtained from normal peripheral blood, although the reaction in mature granulocytes was coarser and more uneven. Prior treatment with salivary amylase abolished the reaction in all cell types. The reaction was studied semi-quantitatively in both lymphocytes and blast cells. In the material obtained from cultures with PHA, an increase in the amount of periodic acid–Schiff-positive material was nvariably observed in the lymphocytes. This ncrease usually reached a maximum at 18–24 h, ersisted up to 48 h, and was most conspicuous n some of the nucleolated lymphocytes, where locks of periodic acid–Schiff-positive material were resent together with coarse granulations. From he distribution of the scores, it was noted that he rise in periodic acid–Schiff positivity was due o a very rich content of glycogen in certain dividual lymphocytes rather than to a general ght increase among the lymphocytic population, although in some cases the proportion of eriodic acid–Schiff-positive lymphocytes rose coniderably. One of the most striking features observed in many specimens from PHA-containing cultures was the occurrence of clusters of lymphocytes surrounding degenerating polymorphs or clumps of platelets (Figs. 1, 2 and 3). No such appearance was seen from the cultures without PHA, where lymphocytes were more evenly distributed. Periodic acid–Schiff scores on mature lymphocytes from cultures without PHA showed a progressive decrease, more rapid in some cases than in others. Periodic acid–Schiff reactions on the blast cells were usually negative, although a diffuse tinge or a few rather fine granules were sometimes seen. Occasional strong positivity was encountered in cells which were classified as blasts because of their nuclear immaturity and cytoplasmic basophilia, but which were of smaller size than the great majority of the large periodic acid–Schiff-negative primitive cells.

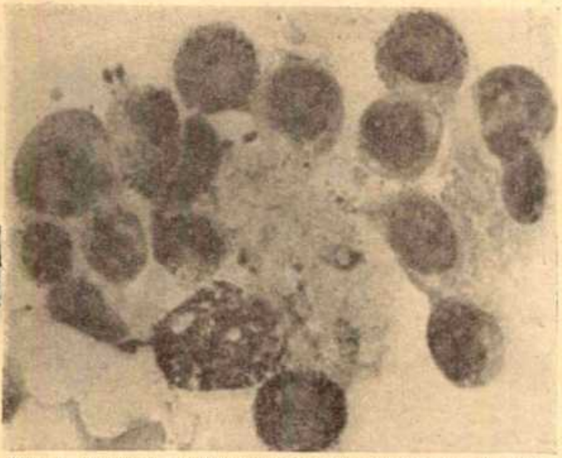

Fig. 1. Group of variably periodic acid-Schiff-positive lymphocytes, including a nucleolated cell on the left, surrounding a mass of degenerating platelets. At bottom centre is a strongly periodic acid–Schiff-positive lymphocyte next to a vacuolated polymorph

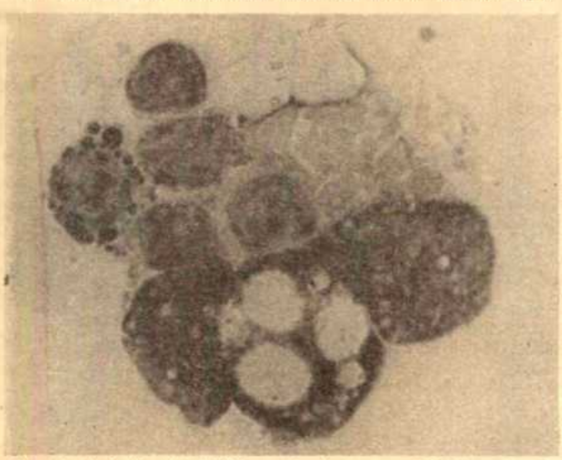

Fig. 2. Periodic acid–Schiff reaction in group of closely apposed lymphocytes and polymorphs. Of the 4 polymorphs two show gross degenerative changes, with huge vacuoles in one (lower centre) and with cytolysis and loss of granules in the other (upper right). The lymphocytes show varying degrees of periodic acid–Schiff positivity, that on the extreme left having very coarse globules or blocks

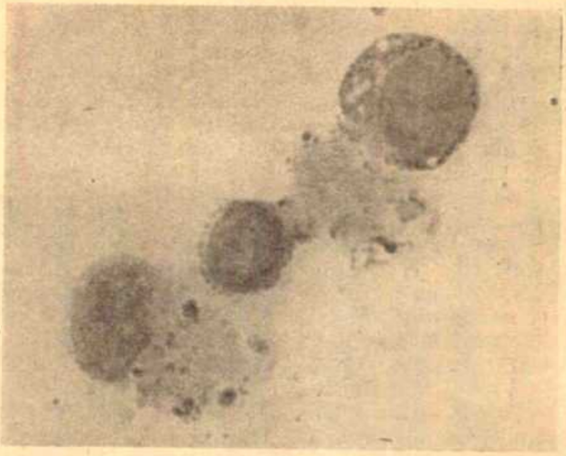

Fig. 3. A sequence of 3 lymphocytes, the upper a transitional nucleolated cell, in close relation to degenerate platelet masses, and showing variable periodic acid–Schiff positivity. The periodic acid–Schiff reaction is moderately intense in the nucleolated cell

Examination of smears stained with the sudan black *B* reaction showed the blast cells to be completely negative in all the specimens studied. Polymorphs generally showed a fairly strong reaction in the spaces between the areas of cytoplasmic degeneration and vacuolation. Some of the monocytes showed a scattering of discrete granules, comparable with that of normal monocytes, although a larger proportion, especially in smears from cultures containing PHA, showed evidence of active phagocytosis, with vacuoles, globules and sudanophilic fragments of degenerate polymorphs.

The peroxidase reaction was similarly negative in the blast cells, while monocytes showed peroxidase-positive fragments from ingested polymorphs. In contrast to the sudan black reaction, peroxidase positivity was weak in mature polymorphs, especially in those from cultures with added PHA.

Non-specific esterases were absent from many blast cells, but weakly demonstrable in others as a few fine granules of positivity. Lymphocytes sometimes showed a peripheral clump of positive material, but otherwise showed only a few minute granulations. Polymorphs reacted very weakly whereas monocytes contained strongly positive granules, similar to those seen in monocytes from normal peripheral blood, together with globules and vacuoles, which also showed a positive tinge.

The phosphorylase reaction was generally weaker than normal in most polymorphs, those obtained from cultures containing PHA being the least reactive. Platelets showed a normal, strong staining reaction, and lymphocytes showed crowns of dark blue or violet granules, similar in distribution to those seen with the periodic acid–Schiff reaction. Blast cells were substantially negative.

Dehydrogenases were studied in the cells from both types of culture, utilizing three different substrates: sodium succinate, sodium lactate and glucose-6-

phosphate. Increased dehydrogenase activity was observed in all specimens from cultures containing PHA. In these, the increase in positivity was observed in the lymphocytes in the first 18–24 h and was most intense with sodium lactate. Blast cells were invariably characterized by coarse granular positivity, most conspicuous with sodium lactate (Fig. 4), but also very intense with sodium succinate and glucose-6-phosphate. Omission of the substrate prevented the appearance of a positive reaction. No significant increase in dehydrogenase positivity was observed in the lymphocytes from cultures without PHA. The only cells showing fairly strong reactions in material from both types of culture were monocytes and eosinophils, both of which reacted most intensely when glucose-6-phosphate was used as a substrate.

All these cytochemical observations appear more in keeping with a lymphocytic than a monocytic or granulocytic origin for the blast cells. The negative peroxidase and sudan black reactions and the feeble non-specific esterase activity are of the kind found in the lymphocyte cell series, whereas if primitive cells were to be derived from monocytes or granulocytes they might be expected to show, at least during early phases of transition, some reflexion of the fairly conspicuous positivity with one or other of these reactions characteristic of those cell lines. Again, the remarkable increase in periodic acid–Schiff positivity of lymphocytes in cultures with PHA contrasts sharply with the consistent fall in positivity in similar cells in cultures without PHA, and points to the involvement of lymphocytes in the transformation and proliferation induced by PHA. It may well be that a rich supply of glycogen, either preformed or freshly synthesized, is a necessary preliminary requirement for the metamorphosis from lymphocyte to blast cell. In this connexion the observed distribution of lymphocytes in PHA-cultures around degenerating polymorphs and clusters of platelets raises the possibility that a transfer of glycogen from these formed elements to the lymphocytes may be occurring by some process of pinocytosis or phagocytosis. The cytological appearances are sometimes highly suggestive of such a process (Figs. 5 and 6). The more rapid rate of degeneration of polymorphs in cultures with PHA as compared with that in cultures without PHA, observed in this work and also by Elves and Wilkinson[5], may perhaps be related to the capture of glycogen from these cells by lymphocytes. Experiments to determine more precisely the role of polymorphs and platelets in peripheral blood cultures with PHA are now in progress.

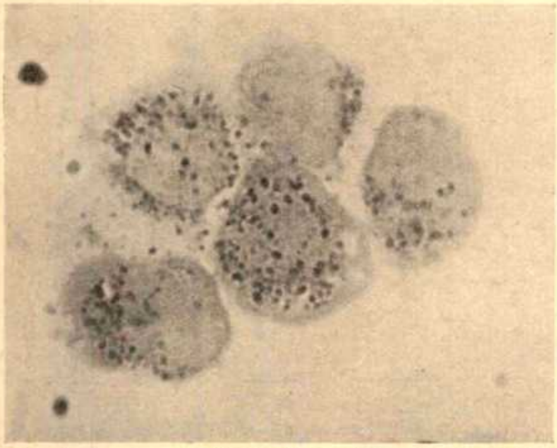

Fig. 4. A group of 5 blast cells showing a strongly positive reaction for lactic dehydrogenase

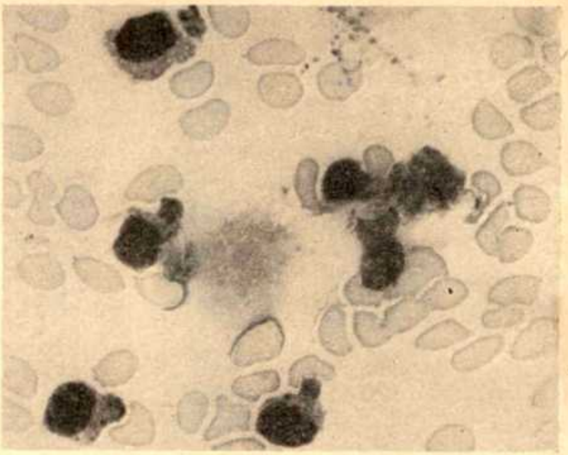

Fig. 5. Cytological relationship of lymphocytes and platelets. There is an appearance from above downwards of successive stages in incorporation of platelet material into the lymphocyte cytoplasm. Leishman's stain

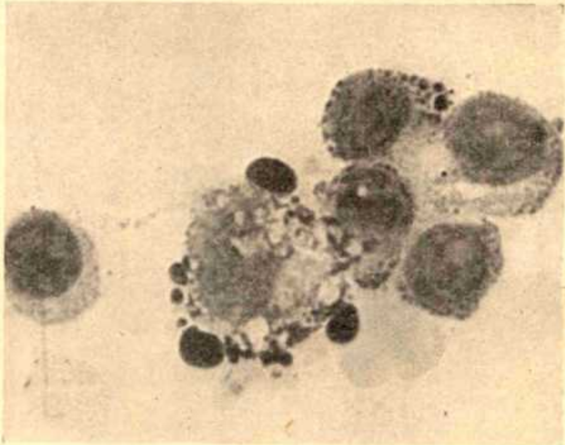

Fig. 6. In the centre is a degenerating polymorph with very coarse periodic acid–Schiff positivity at the periphery. To the right and in close contact with this cell is a clump of 4 lymphocytes, all having periodic acid–Schiff positive granules; the lymphocytes nearest to the polymorph are very coarsely positive. A separated lymphocyte to the left of the field remains periodic acid–Schiff negative

The emergence of large proliferating blast cells must call for considerable synthesizing activity with a substantial energy requirement, and the absence of glycogen from most of the developed blast cells would be expected if glycolysis provided a main energy source. Suggestive evidence that this may indeed be so is provided by the high activity of the dehydrogenase systems involved in glycolysis which is demonstrable cytochemically in both the blast cells and the lymphocytes.

CHEMICAL STIMULATION OF THE PERIPHERAL TRIGEMINAL NERVE

By WILLIAM W. DAWSON*

Division of Physiology, Biological Sciences Department, Florida State University

IT is generally accepted that the trigeminal nerve endings in the nasal mucosa play some part in the detection of odour[1-5]. In 1937 Allen[6] reported that dogs with bilaterally ablated olfactory bulbs would still detect the vapour of certain acids while other animals, the trigeminal nerves of which had been transected, could not do so. Katz and Talbert[5], Parker and Stabler[7], and Schiff[8] have also reported that information on the presence of certain chemicals may be transmitted by the trigeminal nerves. These investigators agree that stimulation of trigeminal nerve endings is likely to occur only with highly concentrated irritants such as volatile acids and pungent organic compounds.

Recent investigations, utilizing the methods of electrophysiology, indicate that the role of the trigeminal nerve in odour reception may be greater than previously suspected[9,10]. The sensory nerve supply of the cornea is trigeminal in origin and is historically a highly sensitive network[11]. Those who have investigated corneal sensitivity have confined their stimuli to contact and temperature change[11,12], while those who have studied the endings of the nasal mucosa have examined only the chemical stimuli[9,10]. The expanded odour responsiveness of the nasal trigeminal nerves described by Beidler[13] generates the question of a sensitivity comparison between this and other areas served by trigeminal afferents. A favourable site for examination of this question is the cornea, where many of the endings of the trigeminal nerves are known to rest between the epithelial cells[14].

Recent examinations of primary nerve data from the corneal afferents by Lele[12] and Dawson[11] have indicated that it is possible to secure the long ciliary nerve as it travels toward the rear of the orbit with the optic nerve. In the present investigation the long ciliary nerves of the frog (*Rana catesbiana*) were treated as previously described by Dawson[11].

Dissection of an animal previously anæsthetized with ethyl carbamate (3 g/kg) provided access to the long ciliary nerve in surgically produced depression at the rear of the orbit. The proximal end of the nerve was severed and dissected twigs were placed on 100μ stainless steel recording electrodes. These led, in a differential mode system, to a Grass pre-amplifier, oscilloscope arrangement through which spike potentials could be photographed or recorded by the electronic summation technique of Bernhard and Granit[15] and Beidler[16]. A second recording method utilized the spike impulses from the oscilloscope to drive a modified Schmitt trigger circuit and in turn provided uniform pulses to a Tracer-Lab electronic counter[17]. By this means, data about events per second could be obtained. The latter method is considered much more sensitive to small changes in neural activity-level than the summation technique which assumes all activity to be of the same amplitude.

Stimulation of the corneal nerves was achieved by liquid application of three chemicals. These were ammonium hydroxide, amyl acetate (1-pentanol acetate), and β-phenyl-ethyl alcohol (benzyl carbinol). The inorganic stimulus was applied in concentrations of 0·03–1·0 molar in distilled water. Saturated samples of the organic stimuli were made by equilibrating each chemical with distilled water. Solubility published for amyl acetate is 0·18 g/100 g water[18] and for β-phenyl-ethyl alcohol is 1·6 g/100 g water[19]. Fractionation of these saturated solutions provided dilute stimuli in the range of $1\cdot125–131\cdot0 \times 10^{-3}$ molar for phenyl-ethyl alcohol. The concentrated amyl acetate solution at 14×10^{-3} molar was diluted in steps to $0\cdot437 \times 10^{-3}$ molar. Animal and stimulus temperature varied between 20° and 23° Celcius. Stimulus solution *p*H values were 6·80 ± 0·25.

The stimulation procedure began by placing one drop of distilled water on the cornea from which a basal activity-level was derived by either the counting or the summating technique. Then one drop of the stimulus solution was placed on the cornea. The number of impulses produced during the next ten seconds was recorded on the electronic counter and an overall curve of activity was derived from the recording device. The activity count for this period read from the electronic counter was recorded as impulses per second. The counter used in this experiment was a hybrid type which displayed two digits electronically and three mechanically. As a result of the mechanical speed limitation, its use was confined to fibre bundles which contained only a few active fibres. Where larger bundles were examined, the data was recorded by the electronic summator. Previous reports using the summator have displayed only raw data[10,11].

Reports of maximum amplitude of the summated response are valid for only one preparation and one fibre bundle. A comparison of more than one of these implies that the nerves in each record are similarly distributed for spike amplitude and receptor sensitivity. The summated data presented in this paper were taken from many nerve bundles. However, each summated datum point is a ratio between amplitude (mm) × time (sec) for the experimental stimulus to a similar value which was produced by a control stimulus. Since the control stimuli were constant from preparation to preparation the final ratios are corrected for differences in between preparation basal sensitivity and differences in the numbers of active fibres. The time value in each case was the number of seconds from the initial increase in summated response to the point at which the response amplitude had fallen to 50 per cent of the maximum. Similar ratios were calculated

---

* Present address: U.S. Army Medical Research Laboratory, Fort Knox, Kentucky.

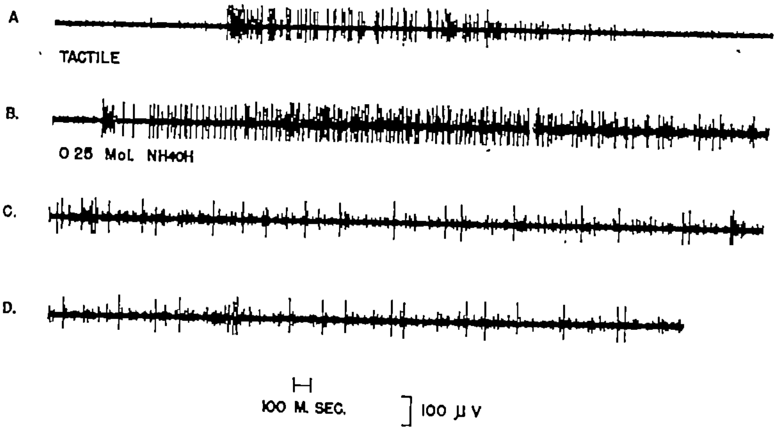

Fig. 1. Oscillographic record of discharges produced in the long ciliary nerve during stimulation of the frog cornea. Record *A* is the result of corneal contact by a polished glass rod. Records *B–D* are the result of corneal application one drop 0·25 *M* ammonium hydroxide. The artefact over the letter *B* indicates application of the chemical

for the counted impulse data where the preparation allowed this technique. The mean activity ratios which appear later in this article contain both the counted and summated ratios but only one type for a particular preparation.

In most cases the afferent activity elicited by the stimulus fell to the baseline after three minutes. In such instances the cornea was rinsed with a few ml. of distilled water and stimulated again after five minutes. At high stimulus concentrations of the inorganic solution, response-levels were frequently maintained past the three-minute duration. In these cases the cornea was rinsed and sufficient time was allowed for return of activity to the basal level.

The photographically recorded results of light tactile stimulation of the corneal surface as seen in Fig. 1 are comparable with those previously demonstrated by me for the mammalian cornea[11].

The tactile response demonstrates a different temporal character from that produced by the inorganic hydroxide. The hydroxide response begins with a relatively slow rate of spike potential output which reaches an extended peak and then gradually decreases with several large fibres remaining active for an extended period of time. The characteristic tactile response, however, shows an initial burst of activity followed by a sharp decrease which terminates as the polished glass stimulating rod is removed from the corneal surface.

A further change in character appears in Fig. 2 following stimulation on the cornea by one drop of 37 millimolar (mM) phenyl-ethyl alcohol. This

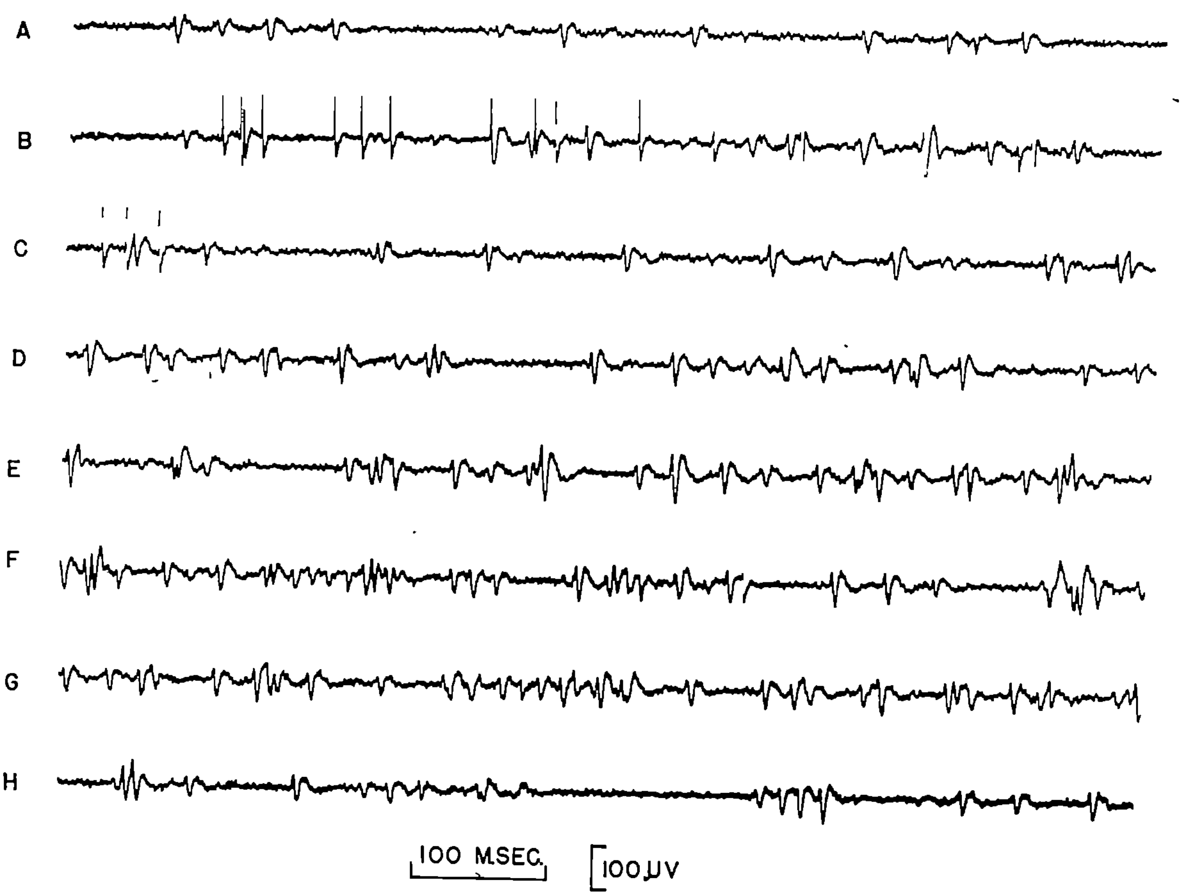

Fig. 2. A few fibre discharge records from the long ciliary nerve. Record *A* indicates resting activity-level; *B* the result of contact stimulation. The spikes at the beginning of *C* are the chemical stimulus artefact. The remainder, *C–G* are produced by 37 mM phenyl-ethyl alcohol. Record *H* is a continuation of *G* after a 30-sec lapse

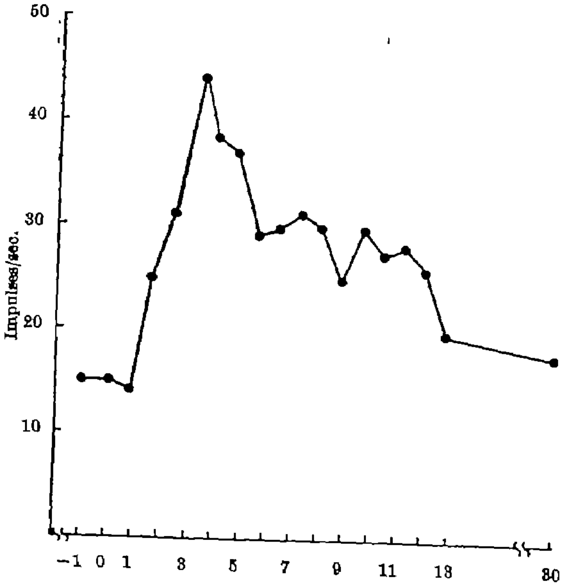

Fig. 3. The temporal course of 'slow fibre' activity produced by 37 mM phenyl-ethyl alcohol stimulation of corneal surface. Contact with the chemical occurred at time 0

few fibre record exhibits a much lower noise-level than that of Fig. 1 and also was recorded at a more rapid rate. Here 'slow fibres' are seen responding in record *A* at a basal level where no stimulation has been applied. On tactile stimulation the large, very fast spikes previously seen in Fig. 1 appear. However, these fibres do not discharge except as a tactile artefact produced by initial contact of the stimulating liquid as seen in line *C*. The burst of 'fast' fibre activity at the beginning of line *C* signals the application. Following this artefact, only small fibre activity appears which gradually increases to a maximum in records *E* and *F* and then diminishes so that after 30 sec, in line *H*, the basal level has almost returned. Examination of the spike dimensions for these two discharge types disclosed a duration of 200 μsec for the 'fast' fibres and a range of from 5–10 msec for the 'slow' fibres. These fall within the limits described for '*A*' and '*C*' fibres by Gasser and Grundfest[21].

The temporal course of the small fibre activity in Fig. 2 is illustrated in Fig. 3. As in Fig. 1 the nature of the discharges departs from those produced by contact stimulation. No high-voltage, short-duration spikes, which are indicative of large diameter axons, are seen during chemical stimulation. Earlier records of chemically excited nasal trigeminal activity indicate the presence of 'fast' fibre activity in nerve bundles[10].

An interesting initial depression of slow fibre response occurs following the stimulus artefact. Although total response time appeared related to the organic stimulus concentration most activity was maintained for at least twenty seconds, while for high concentrations excitations persisting over a minute were not uncommon.

The mean activity ratios produced by both the organic and inorganic liquid stimulants are described in Fig. 4. Each point includes activity data from five to seven preparations utilizing both the electronic summation and counting techniques. Variability in the number of active neural elements seen by the recording electrodes between preparations necessitated the development of a uniform index of response. This was accomplished by the use of the ratio of experimental response to control response. The ordinate values are then either: (1) the ratio of impulses per second produced by the (experimental) stimulus to the impulses per second produced by (control) distilled water application or, (2) a similar ratio between summated activity (Fig. 5) in mm multiplied by the duration of 50 per cent amplitude (experimental) to a similar measure for the (control) distilled water application. These datum points then reflect the means of many ratio values for both summated and/or numbers of spike potentials per unit time. During the course of experimentation the hypothesis was tested and verified (for equivalent stimulation):

$$\frac{N\text{exp./sec}}{N\text{cont./sec}} \approx \frac{R\text{exp.}}{R\text{cont.}} \approx \frac{Y\text{max.}_{\text{exp.}}\ X\ ty_{50}}{Y\text{max.}_{\text{cont.}}\ X\ ty_{50}}$$

where Ymax. = maximum amplitude of the summated potentials; ty_{50} = time required for y to reach Ymax. and fall to 50 per cent of Ymax.; and N = number of recorded spike potentials.

It is of particular interest that the curves for the organic stimulus begin and terminate prior to onset of threshold for the inorganic stimulus. Also, the resulting peak activities are lower. It appears that an optimal stimulation range is effective for the organic stimuli. Each produced an activity peak at about 1·5 log molar concentration units above the threshold. Increased stimulus concentration served to reduce rather than enhance the level of excitation. Similar losses in excitability during high concentration stimulation have been reported by Mozell, who recorded olfactory bulb potentials produced by amyl acetate and heptane[22]. It is difficult to explain this decrement on the basis of adaptation since there is no evidence of excitability loss during ammonium hydroxide stimulation. Those activities produced by ammonium hydroxide approach a power function at

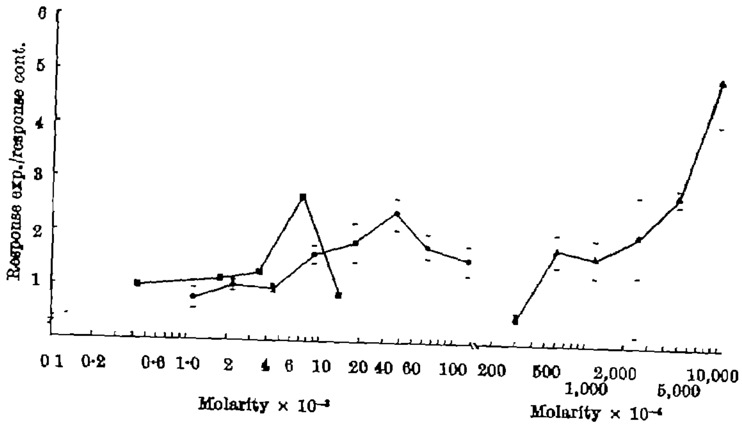

Fig. 4. Response of the corneal afferent nerves to concentrations of organic and inorganic stimuli. The ordinate ratio is discussed in the text. Values for phenyl-ethyl alcohol and ammonium hydroxide are the means of 5–9 measures. Those of amyl acetate are for two measures each. Limit marks indicate the standard errors of the mean. ●, phenyl-ethyl alochol; ■, amyl acetate; ▲, ammonium hydroxide, Ξ, σ_m

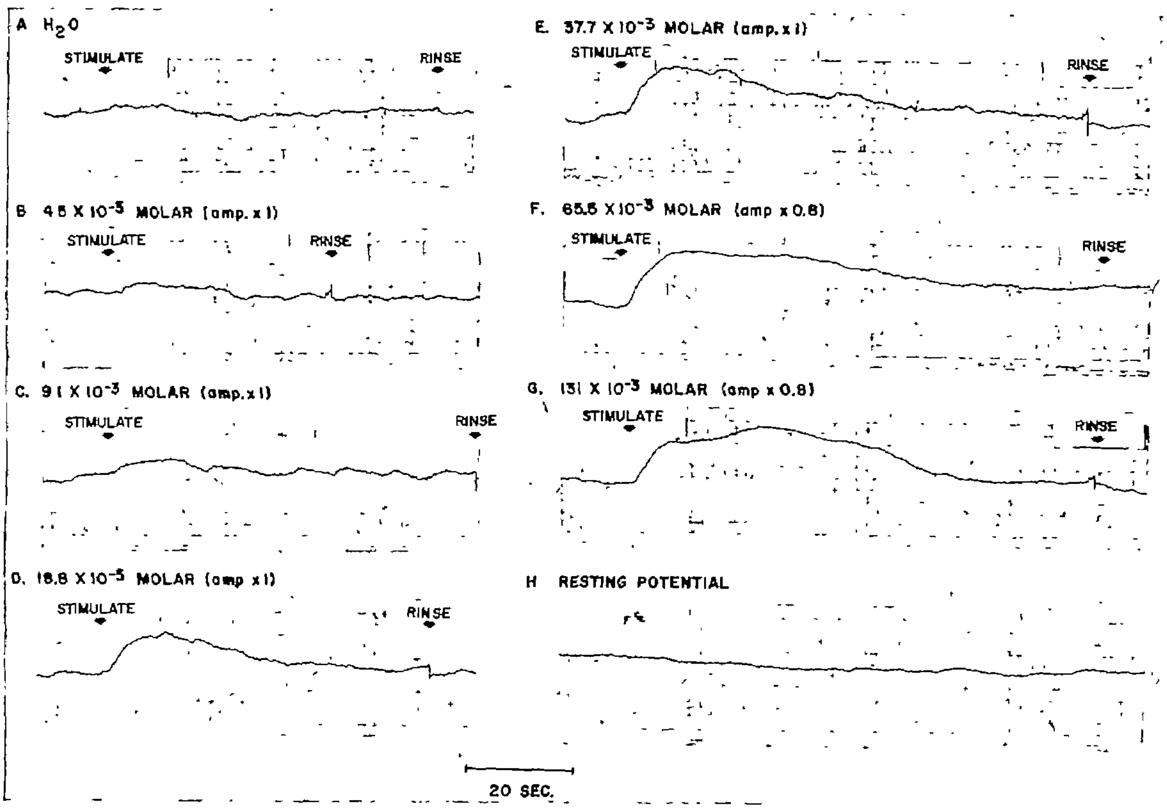

Fig. 5. Electronically summated responses of the corneal afferent nerves to liquid phase stimulation by 87 millimolar phenyl-ethyl alcohol. Record *A* is the standard response to distilled water. *B–G* are responses to increases in stimulus concentration, and *H*, variation in resting response. Amplification was reduced in *F* and *G* to compensate for increased excitation

medium and high concentrations. Activities at the one molar level suggested that, for some preparations, all fibres present were firing at very high rates. Irreversible damage to the nerve terminals may be indicated by continued rapid discharge long after the stimulus had been washed away.

Responses to the inorganic stimulus are not necessarily confined to large-diameter fibres. The records of Fig. 1 are misleading in this respect. There is a strong tendency for the high amplitude signals and the considerable noise level of these data to obscure any slow activity which might be present. However, at no time were the high-frequency, short-duration spikes seen during stimulations with the organic stimuli. If the receptor action of the organic solutions is confined only to small fibres and is reversible, it is quite likely that the irreversible action of the higher levels of inorganic stimuli is effective for fibres of both small and large diameters.

If factors influencing chemical access to the corneal nerve endings are considered with those controlling access to the endings in the nasal mucosa, the data presented can support the hypothesis that the sensory capacities of the two systems are similar. The threshold for amyl acetate from Fig. 4 is about 10 times the 40 μM psychophysical corneal threshold calculated from the earlier work of Katz and Talbert[5]. The 40 μM threshold of these authors is in turn larger by a factor of 10 than the nasal trigeminal threshold of rabbit reported by Beidler and Tucker[10].

A characteristic of the data which have been presented remains unexplained. There are peaks in response followed by a decrement in activity at higher stimulus-levels which in some cases produced excitation-levels below that of the controls. At present there is no satisfactory explanation as to what the role of this particular characteristic could be in human detection of organic vapours.

Other recent electrophysiological evidence also indicates that all stimulation of these nerves need not be from 'obnoxious stimuli' although it is recognized that the role of the trigeminal nerve in the production of odour sensations is unknown[13]. It has been demonstrated that non-noxious chemicals can produce trigeminal discharges at levels comparable and, in some cases, lower than the thresholds for olfactory stimulation. Trigeminal nerve inhibition of certain reflexes has been studied to determine if disruption might occur during odour reception[9]. Two effective stimuli were coffee and asafœtida, which have been previously considered pure olfactory stimulants[6,14].

Tucker has reported that in animal studies it is often difficult to predict whether threshold value for a specific stimulus will be lower for the olfactory or trigeminal innervation of the nose[11]. A subjective criterion based on irritability is no longer adequate for the selection of olfactory or trigeminal stimuli in chemical sense studies.

Primary afferent nerve recordings were made from the sensory trigeminal nerves which innervate the cornea of frog (*Rana catesbiana*). Temporal patterns and mean activity ratios were derived from the afferent discharges elicited by an inorganic irritant, an organic stimulus previously used as a stimulus for trigeminal fibres in the nose, and an organic solution classically considered "pure olfactory" stimulants. Thresholds were discussed and response magnitude-concentration curves presented.

The following conclusions are drawn: (1) neural elements of the corneal afferent supply which respond to surface contact are not the same elements which respond to liquid phase applications of dilute amyl acetate or phenyl-ethyl alcohol; (2) the temporal patterns of spike potentials differ for contact and NH_4OH excitation; (3) the organic stimuli used produce a decrement in afferent output at the higher concentrations; (4) threshold for amyl acetate is higher for the corneal afferents of frog than previously reported for nasal trigeminal units of rabbit.

This work was supported under a grant from the National Institute of Neurological Diseases and Blindness to the laboratory of Dr. L. M. Beidler.

PROBLEMS OF ETHYLENE METABOLISM

By D. F. MEIGH

Ditton Laboratory, Agricultural Research Council, Larkfield, Maidstone

THE theory that ethylene plays a key part in fruit ripening as a natural hormone has received fresh support from recent investigations of ethylene production in preclimacteric fruits[1,2]. But though there is now an adequate analytical tool for measuring the small amounts of ethylene produced in plant tissues, namely, the gas chromatograph with flame ionization detector[3], no appreciable progress has yet been made towards an understanding of the mechanism by which ethylene is produced or its site of production in the cell[4].

The theory that this site lies in a sub-cellular particle received indirect support from an examination of apple tissue, where the tonicity of the enveloping solution was found to have a marked effect on ethylene production[5].

Reports that mitochondria produce ethylene have come from two groups of workers, led by Spencer and by Lieberman. Spencer[6] reported that a mitochondrial fraction from tomato fruit evolved ethylene in the presence of malic acid and co-factors, but this procedure remained unverified[7]. In a later paper Chandra and Spencer[8] showed that high rates of ethylene production could be obtained by fragmenting the particles with ultrasound.

Lieberman and Craft[9] first reported that sub-cellular particles of various types evolve ethylene under acidic conditions in the presence of thiomalic or thioglycollic acids. Burg and Burg[10] re-investigated this reaction with tomato fruit and found that the evolved hydrocarbon was not ethylene but a closely related compound. In our work with apples we reached a similar conclusion and identified the gas as ethane (unpublished). Recently, Lieberman and Mapson[11] have extended the work on the thiomalic acid reaction by finding that linolenic acid forms a component of the system. They consider that the system producing ethane bears a close relationship to the one producing ethylene in Nature.

We have now re-examined the effects on particulate suspensions of sonication and the addition of thio-acids. Our conclusions do not confirm those outlined here, because: (*a*) although preparations treated with ultrasound do evolve ethylene, along with other hydrocarbons, the reaction does not require the presence of active particles; (*b*) the production of ethane in the presence of thio-acids can be simulated without subcellular particles.

We used a detecting system and separating column which were similar in general to those used previously[7], but the amplifier was a Vibron electrometer type 33*C*/*B*33*C* and the stationary phase was squalane, which provides a better separation of the relevant compounds than silicone oil. The sensitivity of the apparatus was such that 0·004 μl. of ethylene per litre of air was detectable in a 1-ml. gas sample.

(1) *Sonication*. The method of isolating subcellular particles from tomato fruit and disintegrating them with ultrasound followed as closely as possible the procedure of Chandra and Spencer[8]. It differed at two points. (*a*) The particles were subjected to a total of 4 min in a 60 W 20 kc/s M.S.E. ultrasonic disintegrator fitted with a 19-mm diam. titanium probe and adjusted to maximum output ($\sim 1 \cdot 3$ amp). The tube containing the preparation was immersed in a freezing mixture at $\sim -20°$ and sonicated for eight 30-sec periods interspersed with periods of rapid stirring to reduce the temperature to 0°. In this way the overall temperature of the solution was kept below 7°. (*b*) The particles were incubated in 12-ml. flasks, each containing 3 ml. liquid and fitted with a short length of rubber tubing closed with a glass

bead. Samples of air were removed by connecting an evacuated 30-ml. gas sampling tube to each flask. They were analysed directly without the use of mercury perchlorate.

Initial experiments showed that not only ethylene but also acetylene and ethane were produced in appreciable quantities. (The latter two would not be detected where the mercury perchlorate method was used.) Then a sonicated preparation was fractionated by centrifugation at 105,000*g* for 30 min and it was found that the supernatant retained most of the activity of the original preparation. The effects of boiling or evacuating the mitochondrial fraction immediately before or after sonication were compared. It was found that whereas treatment before sonication had little effect, treatment afterwards resulted in a marked decrease in hydrocarbon production. Furthermore, the sonication of a solution of sucrose and adenosine triphosphate produced measurable quantities of the same hydrocarbons. The results of these experiments are given in Table 1.

Table 1. EVOLUTION OF HYDROCARBONS BY SONICATED SUB-CELLULAR PARTICLES FROM TOMATO FRUIT

Flask contents	mμl./h/ml. particulate suspension at 25° Acetylene	Ethylene	Ethane
Particulate suspension, sonicated	32·3	10·1	1·4
Particulate suspension, boiled before sonication	41·4	12·2	1·4
Particulate suspension, boiled after sonication	9·2	0·9	0·3
Particulate suspension, evacuated before sonication	25·3	12·4	1·4
Particulate suspension, evacuated after sonication	< 0·001	0·2	< 0·002
Sonicated particulate suspension, supernatant from 105,000*g* centrifugation	15·2	5·7	0·6
Sonicated particulate suspension, particles from 105,000*g* centrifugation	0·4	0·4	0·2
Solution of sucrose (0·5 *M*) and adenosine triphosphate (1·98 × 10^{-3} *M*)	7·1	1·7	0·04

Reaction conditions: each flask contained 1 ml. particulate suspension (derived from 62 g fruit) in a total volume of 3 ml with the following—0·5 *M* sucrose, 0·125 *M* potassium dihydrogen phosphate, 10^{-3} M magnesium sulphate, 10^{-3} M manganese sulphate, 0·05 M L-malic acid, adjusted to *p*H 7·0 with sodium hydroxide, 1·98 × 10^{-3} M adenosine triphosphate and 3·3 × 10^{-4} M diphosphopyridine nucleotide. Incubation period 2 h. The homogenate of the fruit was centrifuged at 3,000*g* and the resulting supernatant recentrifuged at 85,000*g* to obtain the particulate suspension.

There is at present no established method of comparing the behaviour of sonic disintegrators of different design; but our results are consistent with the known features of the disintegrating process. Thus the cavitation which occurs in the liquid is followed by the generation of extremely high local pressures and temperatures as the cavities collapse[11]. Free radical formation is usually associated with this phenomenon, and the production of small quantities of hydrocarbons can be visualized as a result. The possibility that fragmented mitochondria might produce ethylene, under conditions which we were unable to achieve, is not ruled out, but the physiological reaction should be distinguished carefully from the extraneous effects of sonication.

(2) *Treatment with thio-acids.* The ethane-producing reaction requires the presence of thiomalic or thioglycollic acids, or (as we have found) thiolactic acid. These compounds have in common the structure HS.CH*R*.COOH. An investigation by Maier and Tappel[13] into the catalysis of fatty acid oxidation by hæmatin compounds suggested to us that the ethane reaction might be analogous. When linolenic acid was incubated in a reaction mixture containing cytochrome *c* in place of subcellular particles, ethane was produced. Later it was found that adenosine triphosphate or a ferric or ferrous salt were more effective catalysts of the reaction. Typical results are shown in Table 2.

Table 2. EVOLUTION OF ETHANE BY A MIXTURE OF LINOLENIC ACID AND THIOGLYCOLLIC ACID IN THE PRESENCE OF CATALYSTS

Flask contents*	mμl. ethane/h at 30°
Thioglycollic acid + linolenic acid	4·5
Thioglycollic acid + linolenic acid + ATP + cytochrome *c*	168
Thioglycollic acid + linolenic acid + cytochrome *c*	21·4
Thioglycollic acid + linolenic acid + ATP	295
Thioglycollic acid + linolenic acid + 0·0001 M $FeCl_3$	315
Thioglycollic acid + linolenic acid + 0·00001 M $FeCl_3$	183

* Each flask, in a total volume of 3 ml., contained 1 mg linolenic acid (as the potassium salt), 0·02 M thioglycollic acid, 0·125 M *tris*-citrate buffer *p*H 5·0, 0·5 M sucrose, and where indicated, 0·002 M adenosine triphosphate (ATP) and 0·1 mg cytochrome *c*. Incubation period 2 h.

There are several respects in which this reaction resembles the particulate one.

(1) The reaction with linolenic acid is more than 90 per cent inhibited by 0·001 M ethylenediaminetetraacetic acid or 0·001 M diethyldithiocarbamate under the experimental conditions shown in Table 2.

(2) A number of other thio compounds are ineffective by comparison with the type HS.CH*R*.COOH. Thus in the presence of cysteine, 2-mercaptopropionic acid, thiodiglycollic acid and methionine the rate of production of ethane is 11, 9, 1 and 1 per cent respectively of the rate in presence of thioglycollic acid (conditions as in Table 2).

(3) The rate of production of ethane in the presence of C_{18} acids lies in the order linolenic $\gg$ linoleic > oleic and stearic. A comparison between the particulate and non-particulate reactions is shown in Table 3.

(4) Several other volatile compounds are produced by the reaction and can be separated by gas chromatography. Of these the more prominent components

Table 3. COMPARISON OF ETHANE PRODUCTION IN THE PRESENCE OF C_{18} ACIDS IN A REACTION MIXTURE WITH OR WITHOUT A PARTICULATE SUSPENSION FROM TOMATO FRUIT

Added C_{18} acid	mμl. ethane/h at 30° Without particles*	With 1 ml.† particulate suspension
Stearic acid	0·2	10·1
Oleic acid	0·2	11·7
Linoleic acid	4·5	92·3
Linolenic acid	101	437

* Reactants, in a total volume of 3 ml.—1 mg C_{18} acid (as the potassium salt), 0·02 M thioglycollic acid, 0·002 M adenosine triphosphate, 0·1 mg cytochrome *c*, 0·125 M *tris*-citrate buffer *p*H 5·0, 0·5 M sucrose.

† Each flask contained, in a total volume of 3 ml., 1 mg C_{18} acid (as the potassium salt), 0·02 M thioglycollic acid, 0·002 M adenosine triphosphate, 0·2 M *tris*-citrate buffer *p*H 5·0, 0·5 M sucrose and 1 ml. particulate suspension (derived from 25 g fruit).

Tomato fruit without seeds and surrounding pulp (250 g) were homogenized at 1° in 0·2 M *tris*-citrate buffer and 0·5 M sucrose (400 ml.), using a blender fitted with polytetrafluorethylene-covered spindle and nylon impeller blades. The homogenate (*p*H ~ 7) was filtered through four thicknesses of muslin and centrifuged at 1,000*g* to remove debris. The particles were isolated at 10,000*g*, washed once in 0·5 M sucrose and recentrifuged at 10,000*g*.

Table 4. PRODUCTION OF HYDROCARBONS BY PARTICULATE SUSPENSIONS AND BY A MIXTURE OF LINOLENIC AND THIOGLYCOLLIC ACIDS

Hydrocarbon	mμl./h at 30° Linolenic and* thioglycollic acids	Particles with† thioglycollic acid	Particles without† thioglycollic acid
Ethylene	0·5	0·1	0·4
Ethane	295	56	4·2
n-Propane	1·3	1·4	< 0·03
n-Butane	6·1	5·9	0·3
n-Pentane	56	107	10·0

* Reactants, in a total volume of 3 ml.—1 mg linolenic acid (as the potassium salt) 0·02 M thioglycollic acid, 0·002 M adenosine triphosphate, 0·125 M *tris*-citrate buffer *p*H 5·0, 0·5 M sucrose.

† Each flask contained, in a total volume of 3 ml., 0·02 M thioglycollic acid (where indicated), 0·002 M adenosine triphosphate, 0·2 M *tris*-citrate buffer *p*H 5·0, 0·5 M sucrose and 1 ml. particulate suspension (derived from 125 g fruit). The particles were prepared from tomato fruit by the method given in Table 3.

were each located on three columns of varied polarity (squalane, tritolyl phosphate, polyethylene glycol 400) and identified on this basis as *n*-propane, *n*-butane and *n*-pentane. A comparison between the particulate and non-particulate reactions is shown in Table 4.

It cannot be concluded from these results that the ethane-producing reaction bears a close relationship to the natural reaction which produces ethylene. The strongest evidence in favour of the conclusion of Lieberman and Mapson is that the particulate preparations evolve small amounts of several of the hydrocarbons which are produced in large amounts in the presence of thioglycollic acid (Table 4). Since, however, a reaction of this type can be sustained without the assistance of enzymes it is possible to visualize it proceeding in the particulate preparation in a manner irrelevant to its physiological reactions.

The production of hydrocarbons in the absence of particles might be explained as a result of peroxidation of the fatty acid, which would be followed by the formation of free radicals through homolytic fission of the peroxide. It is possible that an analogous reaction, but with different starting products, might yield the preponderance of ethylene that is characteristic of the natural process in the intact fruit.

SYNTHESIS OF HÆMOGLOBIN IN RELATION TO THE MATURATION OF ERYTHROID CELLS

By HENRY BORSOOK, JERRY B. LINGREL*, JOSE L. SCARO† and ROBERT L. MILLETTE

Division of Biology, California Institute of Technology, Pasadena

IT is generally believed[1] that it is in the nucleated erythroid cells in the marrow that nearly all synthesis of hæmoglobin occurs, that the rise and decline of hæmoglobin synthesis follow a course parallel to the maturation of the erythroid cell, and that the non-nucleated immature red cells, whether in the marrow or blood, carry out only a small, residual hæmoglobin synthesis. Fichsel[2] and Weicker *et al.*[3] dissent from this view ; they assign 2/3–4/5 of hæmoglobin synthesis (in rabbits) to the reticulocyte state. Lajtha and Oliver have cited the strong evidence against this opinion[4].

We have been led to a hypothesis (in animals with non-nucleated mature erythrocytes) which does not make hæmoglobin synthesis depend on the ontogeny of the erythroid cell. It is as follows. The hæmoglobin-synthesizing apparatus is nearly fully generated by the end of the basophilic erythroblast stage ; and there is little, if any, increase after this stage. Synthesis persists in some cells through all maturation stages ; and also stops in some cells in all stages ; when it stops it is not resumed, neither in the same cell nor in its progeny. The rate of synthesis, its persistence or cessation, are not governed by the amount of hæmoglobin in the cell. The longer synthesis persists through maturation the more hæmoglobin does the eventual erythrocyte have. Mitosis may occur both in cells in which hæmoglobin synthesis is in process and in those in which it has stopped.

The daughter cells after mitosis do not enlarge ; with the subdivision of mass there is a corresponding subdivision of the existing synthesizing activity or inactivity. Accordingly the activity per cell is halved. The basophilic erythroblast has the maximum rate of synthesis. In each successive intermitotic phase the rate per unit mass falls off slowly and the number of cells in which synthesis has stopped increases. Thus, on the average, the active orthochromatic erythroblasts are the slowest per unit mass, as well as per cell, among the active nucleated cells, and they have the largest fraction in which there is no synthesis. These features are exaggerated by the orthochromatic phase being of the longest duration. When the stimulus to the bone marrow is greater than normal many reticulocytes arise directly from the polychromatic cells, skipping the subdivision of mitosis. The size of such a reticulocyte is that of its parent minus the volume of the nucleus ; they do not constrict ; they give rise to erythrocytes of about the same size. Accordingly they are larger than orthochromatic erythroblasts and the erythrocytes to which the latter give rise. Some orthochromatic erythroblasts become small reticulocytes and some, as Lajtha and Oliver suggest, become erythrocytes directly ; by either route their eventual size is the same.

The data for the above hypothesis have come from experiments on protein incorporation with amino-acids labelled with tritium or carbon-14 by marrow cells and reticulocytes, fractionation of reticulocytes according to their synthesizing activity, cytological observations on and measurements of the cells in anæmic and normal marrow, and measurement of the hæmoglobin content and life-span of circulating erythrocytes after recovery from severe anæmia. (Publication of the details of these experiments is in preparation.) The observations which are correlated by this hypothesis are the findings in the foregoing experiments—some of these are inconsistent with present pictures of erythropoiesis, the variations observed in the size, hæmoglobin content and life-span of erythrocytes in the normal animal, in experimental and clinical hæmolytic anæmias, and after stimulation of the red cell marrow by erythropoietin.

Tables 1 and 2 are summaries of autoradiographic data from marrow cells of a severely anæmic and of a

normal rabbit. In the cells of the anæmic animal, Table 1 shows that the most active group was the basophilic erythroblast; the polychromatic were a little less than half, and the orthochromatic cells somewhat less than a quarter as active. The reticulocytes as a class were more active than the orthochromatic erythroblasts. Synthesis of hæmoglobin had stopped in cells at all stages; the fraction of cells showing no grains was larger in each successive maturation phase.

In the anæmic animal marrow the polychromatic, orthochromatic and reticulocytes were in about equal proportions; in the normal animal the orthochromatic was the largest fraction, and its increase was entirely at the expense of the reticulocytes. In the anæmic animal the synthesizing activity of the reticulocytes was more than twice that of the orthochromatic cells; in the normal the activity of the two groups was nearly the same. In the anæmic animal the reticulocytes contributed 25 per cent of the total activity, in the normal animal 6 per cent. The latter, but not the former, finding would have been expected from the view generally held.

The above hypothesis was tested by predictions regarding difference in sizes of marrow orthochromatic cells and reticulocytes in the normal on one hand and in the anæmic animal on the other. A summary of such measurements is given in Table 3. It is seen that the orthochromatic cells were the same size in the normal and anæmic marrows, as expected. Also as expected the reticulocytes were significantly larger in the anæmic marrow; $P < 0{\cdot}01$. In the normal marrow the reticulocytes were smaller than the orthochromatic cells; this difference we ascribe to the reduction in volume following the loss of the nucleus. The normal marrow reticulocytes were the same size as the circulating erythrocytes, which is evidence that reticulocytes do not constrict when they mature to erythrocytes. Brecher and Stohlman[5] had come to the same conclusion from other evidence. In the anæmic marrow the reticulocytes were significantly larger than the orthochromatic cells; $P < 0{\cdot}01$. When to this difference is added the shrinkage as a result of loss of the nucleus it is obvious that most of the reticulocytes in the anæmic marrow must have come from cells larger than the orthochromatic erythrocytes. Lajtha and Suit[6] noted that the more active reticulocytes in human marrow were larger than the nucleated orthochromatic cells. When there is a great reticulocytosis, as in our severely anæmic rabbits, Brecher and Stohlman found that the peak volume distribution of reticulocytes in the rat with an anæmia caused by phenylhydrazine was twice that of normal red cells. Double the volume corresponds to a diameter of about 4/3 normal, which, in turn, corresponds to the ratio of the diameters of the polychromatic and orthochromatic erythroblasts respectively[7]. Such abnormal cells could not have come directly from cells larger than the polychromatic erythroblasts. If they had come by skipped mitoses directly from stem cells or pronormoblasts, as Stohlman[8] proposed, their volume would have been about eight times normal, and if from the basophilic normoblasts, five times normal.

Table 3. DIAMETERS (ARBITRARY SCALE) OF MARROW ORTHOCHROMATIC CELLS AND RETICULOCYTES AND CIRCULATING ERYTHROCYTES IN ANÆMIC AND NORMAL RABBITS

	Orthochromatic cells	Reticulocytes in marrow	Circulating erythrocytes
Anæmic	16·0 ± 1·66	16·7 ± 0·98	—
Normal	16·0 ± 1·45	14·3 ± 1·41	14·3 ± 0 27

The following four tests of the above hypothesis were provided by fractionation of reticulocytes in the blood of a severely anæmic rabbit after they had been incubated with leucine labelled with carbon-14: (1) active (in hæmoglobin synthesis) and inactive reticulocytes should be found; (2) the active cells should contain more hæmoglobin because synthesis had persisted in them for a longer time; (3) the active should be larger than the inactive reticulocytes; (4) the hæmoglobin content of the most active reticulocytes should be greater than in normal erythrocytes even though they had not yet completed their synthesis of hæmoglobin. Predictions (2) and (4) are the reverse of the expected from the view that synthesis proceeds toward a final maximum hæmoglobin content per cell which is that found in the normal erythrocyte.

Some results are given in Table 4. The red cells (85 per cent reticulocytes) in the blood of severely anæmic rabbits were fractionated in a bovine serum albumin gradient[9] by a modification of the method of Vallee *et al.*[10]. The most active cells remained at the top; the cells in the pellet had almost no activity; there was a gradient of activity in the intermediate layers from the top down. The gradient of hæmoglobin content per cell was in the same direction: most at the top, least at the bottom. In a comparable experiment the cells were incubated with

Table 4. FRACTIONATION OF CIRCULATING RED CELLS OF A SEVERELY ANÆMIC RABBIT IN A BOVINE SERUM ALBUMIN GRADIENT

Position in centrifuge tube: layer number	9 (top)	5–8	3	Pellet
Per cent of total cells	1·7	45·7	19 2	33·2
Reticulocytes. per cent total red cells in the layer	100	100	100	13
Hæmoglobin per cell: (mg $\times 10^{9}$)	34·6	26·0	22·6	16·0
Hæmoglobin counts per cell: (c.p.m. $\times 10^{6}$)	35·4	12·3	4·3	0 06
Hæmoglobin (c.p.m. per mg)	1,020	470	190	3

tritium- instead of labelled leucine, similarly fractionated and then autoradiographed. Fifty per cent of the cells in top (most active) layer had no grains, which is practically the same fraction of inactive cells as was found in the autoradiography of non-nucleated erythroid cells in the marrow (Table 1); and as in the carbon-14 labelling, the number of grains per cell diminished sharply from the top down. Leif and Millette[11] had observed on fractionating rabbit reticulocytes which had been incubated with leucine labelled with carbon-14 that the specific activity of the hæmoglobin was highest in the cells of the top layer and lowest in the bottom; Miller[12] had observed by autoradiography that only 30–35 per cent of the cells had grains although 85 per cent of the cells stained like reticulocytes.) Hæmoglobin synthesis had stopped in the cells of all densities. Brecher and Stohlman showed that the hæmoglobin concentration determines the densities of these cells. As the cells at the top were the lightest and yet had the most hæmoglobin per cell they must have been the largest; conversely for the cells in the pellet; and correspondingly intermediate values for the cells between top and bottom.

Similar evidence was obtained by labelling the red cells in the blood of a rabbit recovering from severe phenylhydrazine anæmia. On the morning of the last phenylhydrazine injection a dose of valine labelled with carbon-14 was injected followed 4 h later by ten times as much unlabelled valine. On the following days the rabbit's blood was sampled and determinations made of the specific activity of the hæmoglobin (c.p.m./mg hæmoglobin) and the hæmoglobin per cell (mg hæmoglobin × 10^8/No. of cells). The findings are plotted in Fig. 1.

On day 4 all the marrow cells, which had been exposed to labelled valine for a short time, were in the blood. Declining specific activity in Fig. 1 denotes dilution of labelled hæmoglobin made in cells on day 0 by those made later. The correlation is clear between hæmoglobin content per cell and specific activity of the hæmoglobin. There was the same correlation on days 0–4 but these are omitted from Fig. 1 because the blood picture was complicated during this period by destruction of red cells with Heinz bodies caused by phenylhydrazine and by abnormally heavy labelling of circulating reticulocytes on day 0 exposed to the very high specific activity of the injected labelled valine.

In man, as in rabbits and rats, there is an increase in the average size and hæmoglobin content of erythrocytes in the peripheral blood in the response of increased erythropoiesis to hæmorrhage or hæmolysis[13].

Fig. 1 shows that on the 10th day of recovery the average hæmoglobin per cell was in the normal range, which testifies to the short life-span of the cells made during anæmia; the life-span of normal rabbit erythrocytes is 65–70 days[14]. We had made a similar observation in experiments in which polycythæmia was produced in normal adult rats by erythropoietin: the blood picture returned to normal in about three weeks after the erythropoietin administration had stopped[15]. This might have been explained on the basis of a normal life-span of rat erythrocytes of 100 days[16] and complete arrest of erythropoiesis in the marrow until the polycythæmia had subsided. But a shortened life-span of red cells produced in response to acute loss of blood had been observed by Berlin and Lotz[17] and after direct labelling of the cells by Stohlman[18]; in the latter's experiments the cells were the same which Brecher and Stohlman had shown to be larger than normal.

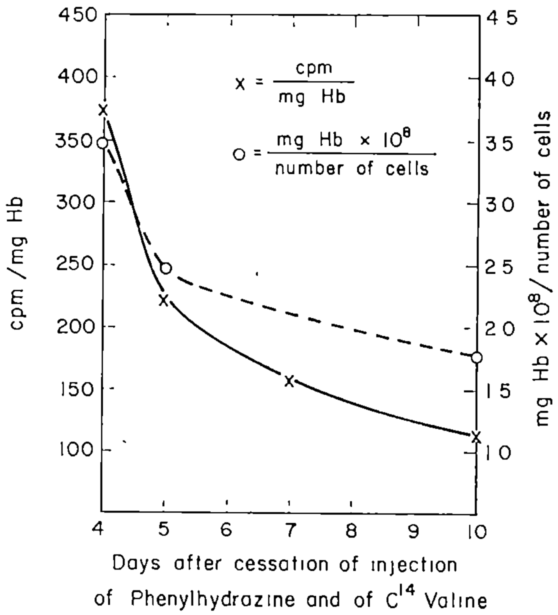

Fig. 1

It is a normal occurrence for some erythrocytes to arise directly from earlier erythroblasts than the orthochromatic; these are larger, have more hæmoglobin per cell and have a shorter life-span than normal erythrocytes. Ambs[19] gives the spread of diameters of normal human erythrocytes as 6·1–8·6μ, and of their hæmoglobin content as 15–48 × 10^{-9} mg per cell. Thorell's values for the diameters of the erythroblasts are 10, 8 and 6μ respectively for the basophilic, polychromatic and orthochromatic cells[7]. The diameter of the largest cells Ambs observed, 8·6μ, is that of the basophilic erythroblast minus the shrinkage due to loss of the nucleus; the diameter of the smallest cells, 6·1μ, is a little larger than the average of the orthochromatic erythroblasts, 6·0μ. The highest hæmoglobin content per cell Ambs found, 48 × 10^{-9} mg per cell, was higher than the average of the most active group in Table 4; in half the latter active hæmoglobin synthesis was still in progress. The lowest value, 15 × 10^{-9} mg per cell, is near to that of the pellet cells of Table 4. Ambs saw a tendency for the larger cells to have more hæmoglobin, though there was no rigorous ('gesetzmässiges') correlation. This is to be expected from findings such as those in Tables 1 and 2 that synthesis of hæmoglobin stopped in some cells at all maturation stages from the basophilic onwards. In the normal, as after severe blood loss, there is a fraction of the erythrocytes with a life span so much shorter that it constitutes a different population. London cites different pieces of evidence of an "infant mortality of the very youngest cells" and that the older erythrocytes tend to be smaller.

Analysis of hæmoglobin synthesis using incorporation of leucine labelled with carbon-14 in rabbit marrow cells and reticulocytes *in vitro* was in accord with the hæmoglobin synthesis aspect of the hypothesis here.

The reticulocytes in normal blood were about one-fifth as active as those in the blood of the severely anæmic animal. The explanation is that in the normal they came via the relatively inactive orthochromatic erythroblasts, in the anæmic a large fraction came directly from the much more active polychromatic erythroblasts and they were also larger than the normal reticulocytes.

The average activity per marrow cell was 3·1–5·2 times that of the circulating reticulocytes in the same animal. If one makes the likely assumption that the most active cells in the experiment of Table 4 were representative of the reticulocytes in the marrow then from the data in Tables 1 and 4 an expected value is obtained for:

$$\frac{\text{average activity per cell of marrow cells}}{\text{average activity per cell of marrow retics}} \times \frac{\text{average activity per cell of marrow retics}}{\text{average activity per cell of circulating retics}}$$

It is 1·07 × 5·3 = 5·6. The RNA per cell in marrow cells was about six times that in reticulocytes. The results in Tables 1 and 4 indicate that in the anæmic animal about half the activity in the basophilic erythroblast is lost by the time it becomes a reticulocyte; most of this loss is represented by the fraction of cells in which synthesis has stopped. The remainder of the original synthetic activity, about half, is lost in the maturation of the circulating reticulocyte.

New, structural ribosomal protein was synthesized by marrow erythroid cells *in vitro* at a rate that corresponded to 7·5 per cent in 24 h of the initial ribosomal protein. This small amount, which could be accounted for entirely by the pronormoblasts and young basophilic erythroblasts, supports the tenet that there is no significant increase of synthetic apparatus in the marrow erythroid cells after the basophilic stage.

The evidence is direct, and all of it concordant that abnormal demands on the red cell marrow such as acute hæmorrhage, severe hæmolysis or large doses of erythropoietin evoke cells which are larger, have more hæmoglobin per cell and are shorter-lived than normal erythrocytes. In the hypothesis we propose the polychromatic erythroblast has a dual capacity; it may subdivide and become an orthochromatic erythroblast or skip the mitosis and become a reticulocyte directly. Our evidence is insufficient to show whether the basophilic compartment may have such a dual capacity. If it has, its contribution to the reticulocytes of the quick response would be small because it is a small compartment. The orthochromatic compartment appears insensitive to stress, and in any event could not produce the abnormally large cells which are characteristic of the stress response. It is therefore only, or mainly, the polychromatic erythroblast which adapts directly to stress by changing its course of development. This explains the changed character of the red cells evoked by stress and also how, after administration of erythropoietin, the increased uptake of iron-59 in circulating cells is too quick for increased production of cells all the way from stem cells[20].

The question then arises whether it is necessary to invoke another or an additional site of action of erythropoietin. It is widely held that the sole action of erythropoietin is to stimulate the stem cell to proliferate[1,18,21]. All the development of the erythroid cell thereafter is considered to be normal. If that were the case one would expect the increased cells evoked by severe hæmorrhage or hæmolysis or erythropoietin to be normal in every respect. They are abnormal, and many of them appear too quickly to have come from stem cells in the normal way.

The stimulus to stem-cell proliferation could be a secondary effect of erythropoietin. There would then need to be another factor to carry the demand for increased cell production from the polychromatic to the stem cell compartment. An alternative hypothesis is that small doses of erythropoietin stimulate only stem-cell proliferation; large doses stimulate in addition skipping of mitoses by polychromatic cells. This would be in accord with the observation of Matoth and Kaufmann that erythropoietin stimulated mitotic activity of erythroblasts *in vitro*[22]. Either way we approach Stohlman's hypothesis[8,18] that red cell production is regulated by more than one mechanism, that erythropoietin is a stimulus evoked by 'panic' which promotes skipping of mitosis[5,8,18]. A difference between our hypothesis and Stohlman's is where the skipping of mitosis occurs. To have it occur at the stem cell offers no mechanism for the abnormal size and hæmoglobin content of the cells evoked by large doses of erythropoietin, for the speed of their appearance and the greater synthesizing activity of reticulocytes in severe anæmia than those in normal blood. Most of the abnormal cells are not large enough to have come via reticulocytes directly from cells larger than the polychromatic erythroblast. Neither our hypothesis nor Stohlman's offers a mechanism for the shorter life-span of the abnormal cells.

A little more detailed picture derived from our hypothesis would be that normal red cells come by the classical route of development through basophilic, polychromatic, orthochromatic erythroblasts and reticulocytes. A crisis evokes cells quickly by a shunt around the orthochromatic erythroblast; they are larger and contain more hæmoglobin than normal red cells, and are removed from the circulation relatively quickly after the crisis has passed. The crisis also stimulates (directly or indirectly) red cell production by the normal pathway, and after the crisis has passed, if a milder stimulus to red cell production persists stem-cell proliferation would continue to be stimulated; eventually there will be a polycythæmia mainly of normal cells. Under any given set of conditions there would be a mixture of normal and abnormal red cells in the blood, in a proportion which would vary according to the demands of the condition.

RESPIRATORY AND SWIMMING MOVEMENTS IN THE CEPHALOPOD *CRANCHIA SCABRA*

By MALCOLM R. CLARKE

National Institute of Oceanography, Wormley, Godalming

During a cruise on *Discovery II* in May–June 1962 observations were made on a living specimen of *Cranchia scabra*, a member of the œgopsid family Cranchiidae. Squids of this family differ from members of all other families in having a horizontal partition (Fig. 1, *H*) across the mantle cavity which is fused to the ventral midline of the enlarged cœlome (*C*) and to the mantle. This arrangement divides the mantle cavity into two dorsal (*DC*) and one ventral (*VC*) chamber. Each of the dorsal chambers is connected with the ventral chamber by an opening or spiracle (*S*) in the posterior end of the horizontal membrane and with the exterior by an inhalent opening at the side of the head (*I*). Each inhalent opening is limited by a thin membrane which is attached to the head along its anterior border and to the mantle wall along its dorsal and ventral borders (*V*). This is part of the nuchal collar and acts as a valve preventing water from leaving the dorsal chamber through the inhalent opening. A small funnel (*F*) allows water to pass from the ventral mantle chamber to the outside. Each gill (*G*) borders the posterior lip of a spiracle and lies on the ventral side of the horizontal membrane.

Cranchia scabra is a small, globular squid which has a very large cœlome which is divided into right and left halves anterior to the liver (*L*) by a thin membrane and has no sagittal partition behind the liver. This cavity, containing the body organs, is filled with a fluid which, if it is analogous to the fluid in the body cavities of other cranchids, makes the squid neutrally buoyant[1]. The cœlome extends the length of the mantle and is attached to it along the length of the pen and by the horizontal membranes, including their dorsally flexed, posterior ends (Fig. 1*B*, *HV*). The cœlome wall contains muscle cells and is capable of considerable contraction.

The living animal was neutrally buoyant, and changes of position and orientation (relative to light, gravity, etc.) were brought about by continual, rapid movements of the fins. Only once or twice, during its captive life of two or three hours, did the animal contract its mantle. Such contractions caused a rapid backward movement over a distance of three or four body-lengths. After the contraction the mantle remained deeply dented for several moments and only slowly regained its globular shape. This slow recovery of mantle shape and the infrequency of the movement in what appeared to be a healthy squid, suggests that such contractions are not used for continual movement but are probably only escape reactions. This conclusion is supported by observations on other small cranchids in which such movements have also proved infrequent.

Although mantle contractions are infrequent, water passes into the inhalent openings and out of the funnel continually, and it is interesting to find that the enlarged cœlome, besides imparting buoyancy, is also responsible for creating this water current. Such a current is necessary for respiration at the gills.

When the chromatophores are contracted the body is largely transparent so that the internal movements could be studied easily and the passage of fountain pen ink through the mantle cavity was observed from the side and from above with a binocular microscope. Contraction of the wall of the cœlome at its anterior end sucks in water through the inhalent openings at the same time as opening the valve (Fig. 2*A*). The contraction also stretches the horizontal membrane

Fig. 1. Diagram to show the arrangement of membranes in the mantle cavity of *Cranchia scabra*

For clarity, tubercles present on the outside of the squid have been omitted

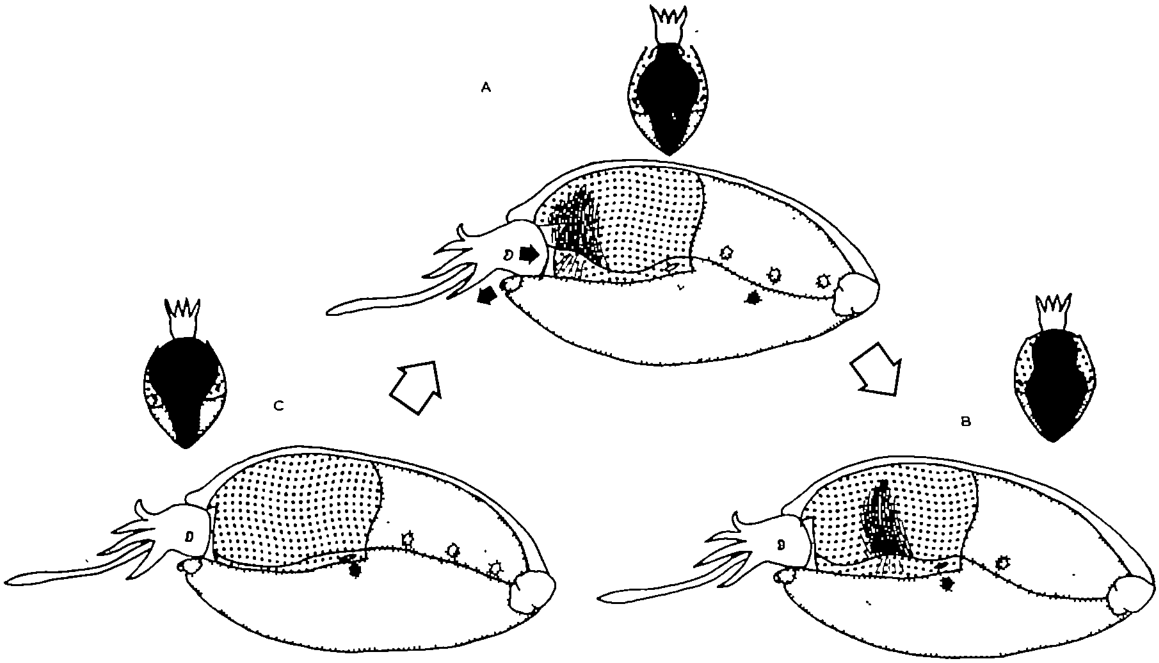

Fig. 2. Diagrams which show three stages in the respiratory movements of *Cranchia scabra*. The small diagrams show the movements from the dorsal aspect and the large ones show them from the left side. Solid arrows indicate water movements. Open arrows and shading indicate movements of the cœlome wall. Large and small dots indicate the extent of the left dorsal and ventral mantle chambers respectively

locally and so prevents it from moving upwards during the suction. Contraction at the front of the cœlome causes the posterior end to bulge and, as this lies in the ventral mantle chamber, water is forced out of the funnel. The gill, which forms a flap hanging below the spiracle (Fig. 1*B*), probably acts as a valve which prevents water from passing up through the spiracle at this stage. The area of contraction moves back along the cœlome and at the same time the region which was contracted at first, relaxes (Fig. 2*B*). The dual effect is to move water in the dorsal mantle chambers backwards and through the spiracle and also to shut the valves over the inhalent openings. The pressure necessary to close these valves may result from the expansion of the anterior end of the cœlome but, as water is being forced through the spiracle at this stage, the whole part of the cœlome adjacent to the dorsal mantle chambers must be expanding (presumably because the cœlome behind this is starting to contract) and this closes the valves by creating a positive pressure in the dorsal mantle chambers. The region of contraction increases in length when it reaches the partition at the posterior end of the dorsal mantle chambers so that the whole of the more posterior cœlome appears to contract simultaneously (Fig. 2*C*). Whether this is an active contraction or whether the cœlome wall is just changing shape by passive relaxation is difficult to decide but the wall of the posterior and anterior parts of the cœlome contain similar contractile elements. This complete movement, which is rather like a peristalsis having a large wave-length in comparison with the cœlome length, is repeated continuously.

During part of the cycle, water passes out of the funnel at the same time as water passes into the dorsal chambers and this, of course, is quite different from the timing of these currents in squids using the mantle muscle to draw water in and out.

Many cranchids, including *Cranchia scabra*, have no valve in the funnel and clearly there is no need for one with this water-circulatory system.

Similar movements of the cœlome wall have been observed in *Liocranchia* and *Megalocranchia*.

ELIMINATIVE RESPONSE IN THE ALBINO HAMSTER

By Prof. E. TOBACH and P. GOLD

Department of Psychiatry and Neurology, New York University
School of Medicine, New York 16

THE eliminative response as an indicator of individual differences in temperament was first systematically studied by Hall in the rat[1] and was afterwards studied by him[2] and others[3-6] in the mouse. Hall defined the 'emotional' defæcatory reaction as defæcation in an unfamiliar environment which ceases on repeated experiences in that environment[7]. The possibility of the occurrence of this phenomenon in various species of the rodent family is of theoretical and experimental interest. A relationship between this behavioural pattern and 'anxiety' has been suggested as generally applicable to mammals[7] on the basis of the autonomic involvement in the response. Easy measurement of the response has also added to its popularity. Delineation of the characteristics of the reaction in other rodent species may lay the basis for further inter-species comparisons. Accordingly, the following investigations of the responses of the albino hamster to the standard open-field situation were carried out.

12 albino hamsters from a mixed laboratory stock were used. All the animals were individually housed in wire mesh cages with food and water *ad libitum* except as indicated. The animals were exposed to the normal day–night cycle during the months of September and October 1961, in New York City. A standard rat diet pellet with a supplement of lettuce was fed the hamsters, except for seeds offered in the open-field situation. Animals were observed between the hours of 9 and 10.30 a.m. Each animal was placed individually in the centre of a circular arena 28 in. in diameter, with a wall 24 in. high. The arena was made of sheet metal covered by pastel green flat enamel paint. An overhead fluorescent fixture with two 40-W bulbs was suspended 100 in. above the floor. During the 4-min observation, incidence of defæcation and urination; locomotion; leaving and returning to the wall of the enclosure; feeding; and grooming were recorded. This procedure was followed once each day for 11 days. On days 12 and 13 the animals were not observed. The animals were again observed in the enclosure on days 14–16.

On days 17–19, an overhead buzzer and light on the perimeter of the enclosure were presented to the animal during the 4-min observation. The buzzer was an Edwards No. 15-0 mounted on a plastic arm 34 in. above the floor of the enclosure and measured at 77–78 db. when tested with a General Radio model 1551*A* sound-level meter on the centre of the floor of the arena. The added light stimulus was provided by a 200-W bulb 44 in. above the floor of the enclosure.

The animals were not deprived of food or water in their home cages until day 19. On that day, during the observations, all food was removed from the home cages. None of the animals had food stored in the pouches during the observation on day 19. On day 20, the animals were not observed. On days 21–23, 2 min after the hamster had been placed in the open-field, a plastic tray (2½ × 1½ × ½ in.) containing 6 seeds, of different variety, was placed in the centre of the enclosure. After 2 min of further observation, the animal was removed.

During days 21–23, each animal was assigned to one of two groups on the basis of their defæcatory response during days 1–11. Although exact matching was not possible, the ranges and distributions of scores in the two groups were such that there was no statistically significant difference between the two groups in regard to frequency of defæcation or micturition during the first 11 days of observation. Group I was observed in a glass fish tank (16 × 12 × 12 in.) which they had not previously experienced, although at one time they had lived in groups in cages similar to the observation apparatus. Group II was observed in the same enclosure used prior to this period.

Animals were removed from their home-cages by the use of a round plastic container measuring 4 in. in diameter and 3¾ in. in height. Air holes were punched in the lid of the cup. The cup and enclosures were swabbed with a 70 per cent alcohol solution before each observation. During days 21–23, approximately 1 h after observation, the animals were fed *ad libitum* for 1 h.

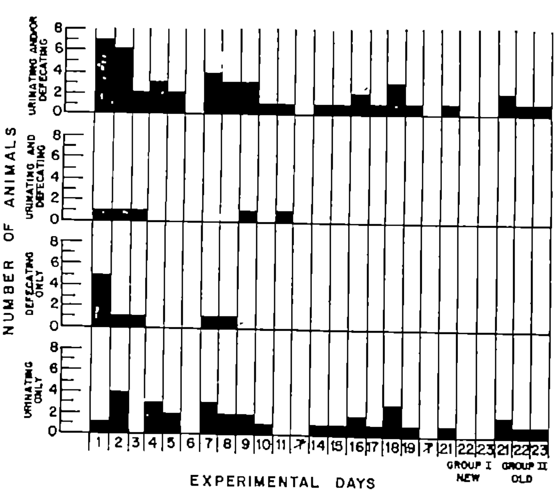

Fig. 1. During days 17–19, auditory and visual stimuli were introduced into the open-field situation. Group I animals were observed in an enclosure different from that in which they had been studied during days 1–19. Group II animals were observed in the same enclosure throughout the experiment. Crossed *T*, not tested

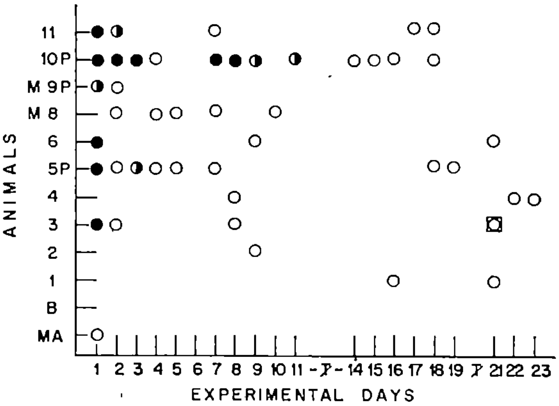

Fig. 2. Pattern of defæcation and urination of hamsters in open-field situation. See Fig. 1 for an explanation of treatment on different experimental days. ●, Defæcated; ○, urinated; ☐, newly introduced enclosure; *M*, male; *P*, pup; crossed *T*, not tested

Although the sample studied was not homogeneous as to age and sex, analyses of the dependent variables (for example, eliminative behaviour, grooming and activity parameters) showed no differences when males were compared with females, or pups were compared with adults. It should be noted, however, that some relationship between age and sex may exist in that the two female pups showed the highest frequency of eliminative behaviour. The sample was too small to warrant more precise analysis.

As can be seen in Fig. 1, the number of animals which only defæcated declined from day 1 to day 2 and except for days 7 and 8 no animal defæcated thereafter. This was not true of micturition: a low level was maintained throughout the experiment. Accordingly, the bar graph shows some decrease in number of animals defæcating or urinating, or both in the same session. There was a wide range of individual patterns of eliminative reaction as may be seen in Fig. 2. One animal stopped urinating after one day, but for the most part, individuals either persisted or showed sporadic patterns of elimination in the open-field. One animal never urinated or defæcated.

Defæcation and urination took place so infrequently before or after observation that no analysis was warranted.

Fig. 3 shows the mean, median and range of number of seconds between the animal's entry into the open-field at its centre and its arrival at the wall of the enclosure. There was a significant trend (Kendall concordance test, $P < 0\cdot05$) for this duration to decrease from trials 1–11. There was no significant difference between the group's latency on day 11 and on day 14 (Wilcoxon matched pairs test, $P > 0\cdot05$). From days 14 to 16 there was also no significant increase in latency ($P > 0\cdot05$). From days 17 to 19, the trend was significant in its tendency to decrease ($P < 0\cdot01$). The group in the newly introduced enclosure showed a downward trend on days 21–23 whereas the group in the customary enclosure did not. Both groups showed an increase in latency when days 19 to 21 were compared ($P = 0\cdot05$ for both groups). The animals in the newly introduced enclosure took about twice as long to reach the wall as did the animals in the customary enclosure ($P = 0\cdot05$), although the maximal distance in the fish tank was one-half that of the circular arena.

There was no relationship found between latency to wall and eliminative responses.

It was found that there was a significant decrease in the number of cross-overs during the first eleven days (Fig. 4) (Kendall concordance test, $P < 0\cdot001$). After two days without open-field observation there was a significant increase in the number of cross-overs when days 11 and 14 were compared ($P = 0\cdot05$). Days 15 and 16 were not different from day 11 ($P > 0\cdot05$). The trend was significantly in a downward direction when days 14, 15 and 16 were analysed ($P < 0\cdot02$). When auditory and visual stimuli were added on day 17, there was an increase in the number of cross-overs, but this was not significant ($P > 0\cdot05$). No pattern was discernible in either group on days 21–23.

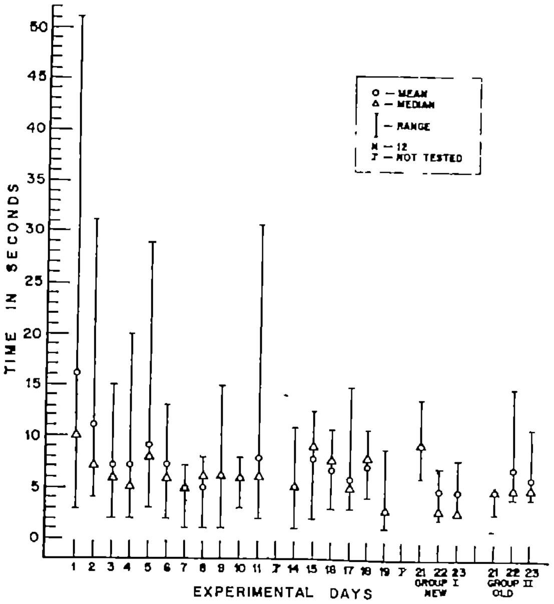

Fig. 3. Time to wall from centre of enclosure at start of observation (latency in sec)

See Fig. 1 for an explanation of treatment on different experimental days

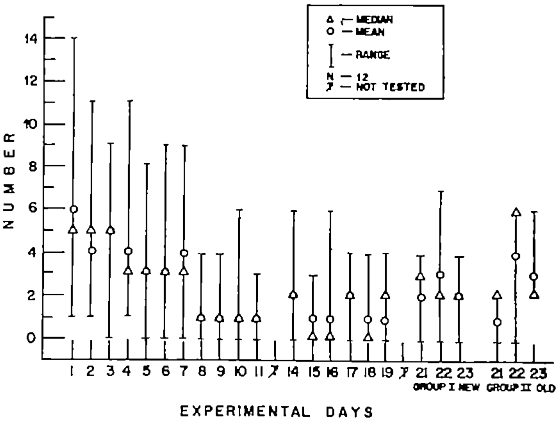

Fig. 4. No. of times animals left and returned to wall of enclosure (No. of cross-overs)

See Fig. 1. for an explanation of treatment on different experimental days

The only significant trend in grooming behaviour was evidenced in the group which was observed throughout in the same enclosure. This group showed a significant decrease in the amount of grooming during days 21–23 ($P < 0\cdot01$; Kendall concordance test).

There was no difference between the two groups in their latency measure on days 21, 22 or 23 (Mann-Whitney U test, $P > 0\cdot40$). There was no significant trend towards a decrease in the latency of this response in either group (Kendall concordance test, $P > 0\cdot05$). No behavioural measure correlated with the latencies of the combined groups.

When the animals were ranked as to eliminative responsiveness during days 1–11, it was found that the latencies of the animals in the newly introduced arena on day 21 were not related to their eliminative reaction ($RHO = 0\cdot086$; $P > 0\cdot05$). When the same analysis was made for the animals which were observed in the same arena throughout the study, it was found that there was a positive and significant correlation between latency to approach the food dish on day 21 and the eliminative reaction on days 1–11 ($RHO = 0\cdot94$; $P < 0\cdot02$).

None of the analyses of quantitative aspects of feeding activity proved to be statistically significant.

Certain aspects of the open-field behaviour of the albino hamster are noteworthy. In regard to eliminative reactions there was an unexpected persistence in micturition, accompanied by the expected decrease in the number of animals defæcating. This finding may be compared with the persistence of defæcation in the mouse[6], and the reported decrease in the rat[1].

The introduction of additional auditory and visual stimuli did not result in an increase in eliminative responsiveness, as might have been expected from the literature[5]. This may have been a function of the intensity of the stimuli used, although the buzzer increased the ambient noise-level from 66 db. to 77–78 db. It may also have been a reflexion of the level of adaptation of these animals to such stimuli because of previous experience. To our knowledge, the animals had not been presented with stimuli of this nature before. Further investigation of this variable is indicated.

In the early work of Hall[1], the relationship between the eliminative response and the feeding response was considered very important. For this reason, the observations on days 21–23 were made. On the basis of past work, it was anticipated that the animals in the new enclosure would not feed as readily as those in the customary arena. This was not found; all animals fed in both arenas. There was also no difference between the two groups with regard to the latency in responsiveness to the seed tray. It was found, however, that for the animals in the new enclosure, there was no relationship between the eliminative reaction during the first eleven days of observation and latency of response to the seed tray, while in the group in the familiar arena there was such a relationship. In other words, in the 'old' enclosure the animals which were previously high in eliminative reaction took the longest to approach the seed tray when it was presented to them under conditions of food deprivation and this did not maintain in the group in the new arena.

It was also expected from past studies that when the group was placed in the new environment, the number of animals defæcating and urinating would increase. This did not occur, possibly because they had lived in rectangular tanks of the type used in the experiment for approximately three months prior to the work recorded here. The change in enclosures was therefore possibly less significant than anticipated. It would still appear, however, that the eliminative response is particular to specific situations, in view of the fact that there was a relationship between elimination and latency of response to the seed tray in the customary observation arena, but not in the newly introduced observation arena. This finding is similar to that found in the study of open-field behaviour of the mouse[6].

We thank Amy Ziegler for help in the observation of the hamsters.

IMMUNE RESPONSE IN THE CALIFORNIA HAGFISH

By BEN W. PAPERMASTER*, RICHARD M. CONDIE† and PROF. ROBERT A. GOOD‡

Pediatric Research Laboratories, Variety Club Heart Hospital, and Department of Microbiology, University of Minnesota

THE hagfish, an agnathan cyclostome, is the most primitive of the true vertebrates. Since it is the first species in the phylogenetic scale with formed, circulating red blood cells and hæmocytopoietic tissue in the submucosa of the gut tract[1], definition of its immune response seemed particularly relevant to our investigation of the phylogeny of immune responsiveness. Our interest in these animals was stimulated by Jordan and Speidel's description[1] of blood cells of the Atlantic hagfish, *Myxine glutinosa*. Specimens of *Eptatretus stoutii*, the California hagfish, were obtained from Dr. David Jensen of the Scripps Institution of Oceanography, University of California, La Jolla, and were shipped in cold sea-water to our laboratories. The animals were kept at 10° C in well-aerated sea-water, except where specified, without feeding, for up to five months in good condition. In all, about 120 hagfish were used in these experiments.

Immunological responsiveness in mammals may be characterized by three parameters: the formation of circulating specific antibodies (γ_2-, β_2A- and β_2M-immunoglobulins) following antigenic stimulation, development of delayed sensitivity after appropriate sensitization, exemplified by the tuberculin reaction; and rejection of grafts from donors of differing genotype. A particularly important feature of these responses is anamnesis or immunological memory, which is reflected in the rapid increase in antibody concentration during the secondary response and by the second-set rejection of grafts.

Formation of Circulating Antibodies. Attempts to induce formation of circulating antibodies with diverse antigens were uniformly unsuccessful in the hagfish. Antigens used included killed *Brucella abortus*, typhoid–paratyphoid *A* and *B* vaccine, bovine serum albumin, hæmocyanin, and the bacterial viruses T_2 (*E. coli* phage) and *MSP*-8 (*Streptomyces griseus* actinophage). Although one, two, and, in some animals, several injections of antigens were given over periods of up to two months, and although a number of the antigens were incorporated in Freund's adjuvant at the time of injection, no agglutinating, complement-fixing, neutralizing antibodies, or antigen-combining globulin[2] were found. Up to 10 injections of T_2 phage by the intramuscular and intracœlomic routes, and under the skin into the subcutaneous lateral sinuses characteristic of the intermediate open-type circulation in this species, were given over a three-month period, without evidence of circulating neutralizing antibody at any time. Efforts to demonstrate such antibody included heat-inactivation of serum of injected hagfish for 30 min at 56° C and incubation with T_2 phage for as long as 72 h at 37° C and 0° C.

The persistence of antigen in the circulation of the hagfish was demonstrated with two of the antigens. Live infectious particles, in a concentration of 4,000 particles/ml., were found in the circulation 14 days after intramuscular injection of 10^{10} phage. Similarly, circulating hæmocyanin was detected in the serum

14 days after injection by capillary precipitin tests with rabbit antihæmocyanin antibody.

As a control on conditions of temperature and starvation, a fresh-water teleost fish, *Ameiurus melas*, the bullhead of the mid-western United States, was immunized with T_2 phage at 10° C. Phage were cleared from the circulation within four days, and circulating antibody was detected in a 14-day heat-inactivated sample (Fig. 1). Heterologous phage (PLT_{22}–*S. typhimurium*) were included in reaction tubes as a control on the specificity of the inactivation.

The thermal death point of the hagfish, which normally inhabits the deep waters at 4° C, is approximately 28° C. To evaluate the effect of temperature on ability to form circulating antibody, hagfish and bullheads were kept at 20° C for seven days. Stimulation with 10^{10} T_2 phage failed to elicit antibody production in the hagfish, and large numbers of circulating phage were present in serum samples taken both 4 and 7 days after injection. In the bullhead, on the contrary, a fourth-day serum sample showed no particles, and heat-inactivated serum showed neutralizing antibody (Fig. 1). Heterologous phage were again included in the reaction tubes as a control for specificity of inactivation.

Delayed Sensitivity. Attempts to elicit delayed sensitivity in hagfish were also unsuccessful. Complete Freund's adjuvant containing *BCG* was injected, in 0·5-ml. amounts, by the intramuscular or the intraperitoneal route. The fish were challenged at 14 and 30 days with *BCG* and old tuberculin. Regardless of the site of injection of the challenging dose, no evidence of either a local or systemic reaction was detected.

Homograft Immunity. Grafts of skin 1 cm² from the caudal regions were exchanged between pairs of hagfish, and a number of autografts were also done. The grafts did not remain in place, with the single exception of a homograft which was in place when the animal was killed 28 days after grafting. There was no gross evidence of rejection, and microscopic study of sections disclosed neither evidence of inflammation nor indications of healing of the graft bed or the suture areas. Although the skin of the hagfish is in direct contact with the subdermal lateral sinuses, it is avascular and does not adhere to the musculature on the sides of the animals.

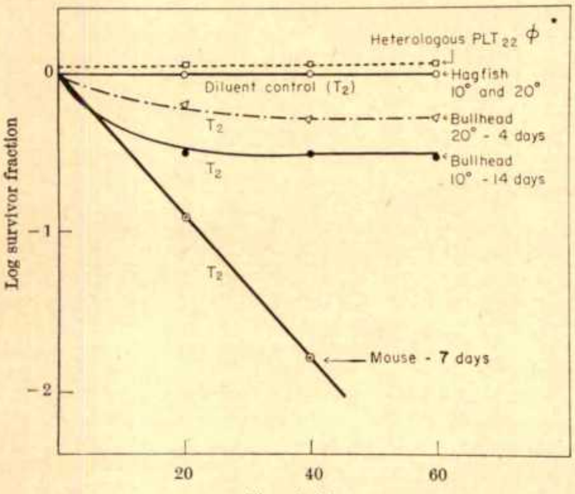

Fig. 1. Relative neutralization-rates of bacteriophage T_2 by antisera from the hagfish, bullhead and mouse. Antisera were collected after a single primary injection of 10^{10} particles on the days indicated (see text for hagfish). Dilutions of antisera were as follows : hagfish, undiluted ; bullhead, 1 : 2 ; mouse, 1 : 50

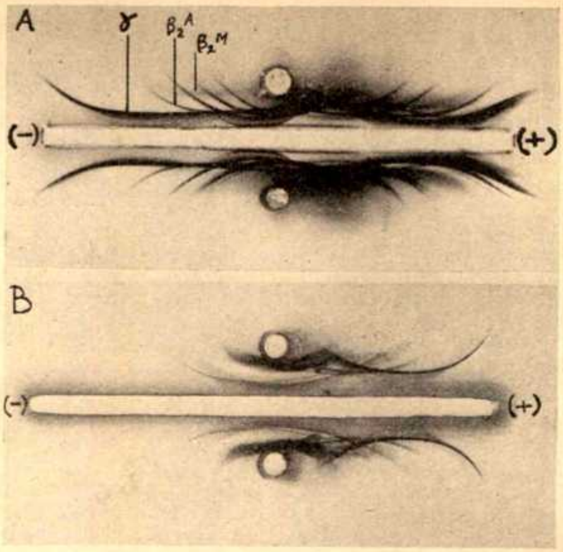

Fig. 2. Immunoelectrophoretic patterns of serum proteins from human (*A*) and hagfish (*B*). Patterns were prepared with rabbit antisera

Additional efforts to elicit homograft immunity included autografts and homografts of muscle (small sections of myotomes) and liver tissue (small implants and intrahepatic injections of liver cell suspensions). Twelve to 14 days after grafting, histiocytic infiltrations were found around all the myotome grafts, but in none of the liver implants. No morphological differences between autografts and homografts could be detected.

The poor healing in grafted animals led to death 7–14 days after the operation, and made a study of second-set reactions to grafts impossible. A similar failure to heal has been observed by Jensen[3] in the wound resulting from amputation of the tail of the hagfish.

Serum Proteins. Paper electrophoresis, starch-gel electrophoresis, and immunoelectrophoresis revealed an absence of proteins with the mobilities of albumins and γ-globulins in the hagfish. Immunoelectrophoretic analysis showed complete absence of bands corresponding to the albumin, cæruloplasmin, β_2A-, β_2M- and γ-globulins of higher animals (Fig. 2). The paper electrophoretic patterns were comparable with those of Rall *et al.*[4] on the lamprey. Further investigations concerning the chemistry of the serum proteins and electrophoretic analyses of concentrated serum samples are being completed.

Inflammatory Response. The response of the hagfish and the bullhead to an inflammatory stimulus was also examined, with the fish being maintained at temperatures of 10 and 20° C. Complete Freund's adjuvant, containing 30 mg/c.c. of *Mycobacterium butyricum*, and indian ink, was prepared, and 0·5 ml. amounts injected intramuscularly into hagfish and bullheads. By the fourth day, gross evidence of inflammation—swelling, erythema and induration—was noted in the bullhead at 20° C, and by the eighth day such changes were seen in animals kept at 10° C. There were no gross signs of inflammation in the hagfish after 7 days at 20° C or after 8 and 30 days at 10° C. The site of injection over the myotomes, marked with indian ink, was smooth and non-indurated. Microscopic sections of tissue from these sites showed infiltration of erythrocytic cells and of white cells best described as phagocytic histiocytes.

Hæmatology. Morphological studies of peripheral blood and imprints of liver and gut confirmed the original observations of Jordan and Speidel[1] that there are no apparent differences between peripheral circulating cells and cells of the presumed hæmocytopoietic centres. Our observations differed from theirs, however, in that we found no cells in the California hagfish which seemed identical with the lymphocytes of higher fishes, birds or mammals. Cells classifiable as lymphoblasts, medium-sized or large lymphocytes, or plasma cells were completely lacking in our material. A cell type resembling the small lymphocyte of higher animals, with a rim of dark basophilic cytoplasm, was observed and interpreted as a possible primitive precursor of the erythrocytic series. The cells we observed in the California hagfish did not differ significantly from those described by Jordan and Speidel, and we consider that our differences are largely differences in terminology regarding lymphoid cells. In contrast, well-developed, easily recognized lymphocytes of all stages of development and occasional plasma cells were found in the bullheads.

Examination of serum bactericidal substances and complement were not attempted. This form of immunity, often included in descriptions of natural resistance[5], has been found in invertebrates[6], and may account for protection from invasive parasites and organisms in the hagfish. Our investigations were concerned exclusively with adaptive immunological responses. In the hagfish, apparent inability to form circulating antibody, to develop delayed sensitivity, and to reject homografts was correlated with the lack of lymphoid cells commonly associated with the immune response. Additional findings in the hagfish and higher species, correlating the evolution of the immune response and lymphoid tissue, will be presented elsewhere.

We thank Dr. David Jensen of the Scripps Institution of Oceanography, La Jolla, California, for obtaining the specimens used in this work and for many helpful suggestions and discussions. We also thank Dr. Robert A. Bridges for preparation of the electrophoretic patterns, and Dr. S. G. Bradley for supplies of actinophage *MSP*-8 and its host *Streptomyces griseus*, strain 113.

This work was supported by grants from the U.S. Public Health Service, American Heart Association, Minnesota Heart Association and the National Foundation.

EFFECT OF PARASITISM ON GRAM-POSITIVE BACTERIA, WITH REFERENCE TO THE ORIGIN OF CERTAIN TYPES OF VIRUS

By Dr. PHYLLIS PEASE and Dr. K. A. BISSET
Department of Bacteriology, University of Birmingham

IN a previous communication[1], one of us proposed the hypothesis that Gram-positive bacteria, under the influence of a parasitic mode of life, evolved in a parallel manner in different groups, with the progressive loss of such organs as spores and flagella, of Gram-positivity, catalase and other enzyme systems, with the effect that, from a morphologically complex saprophyte is thus derived an anaerobic, Gram-negative, nutritionally exacting parasite (for example, *Veillonella* or *Fusobacterium*). It is not suggested that all Gram-negative bacteria are derived from Gram-positive forebears; but it seems to be true of most oral and similar mucous-membrane parasites (cf. also ref. 2).

One group of such bacteria, parasitic on mucous membranes, not discussed previously, in which a comparable series appears to occur, is *Corynebacterium–Haemophilus*, and here the degenerative series can be observed to proceed even further, in a dramatic manner, in the production of members of the group of parasitic micro-organisms known as mycoplasma or pleuropneumonia-like organisms.

It seems certain that neither *Haemophilus* nor *Corynebacterium*, as at present defined, is a natural genus; both are assemblages of morphologically similar bacteria of diverse origin. However, there may be considered to exist a group of *Corynebacteria*, characteristically parasitic on mammalian mucous membranes, and including several well-known species, *C. diphtheriae*, *C. cervicis*, etc., and a group of *Hæmophilus*, of similar habitat, and including *H. influenzae*, as well as numerous, less-well-defined species.

Considerable evidence has recently accumulated to show that many strains of pleuropneumonia-like organisms are derived from bacteria of these two genera, to which they bear the same relationship as do *L*-forms to *Proteus* and similar Gram-negative bacteria[3–8]. The differences, usually quoted, between pleuropneumonia-like organisms and *L*-forms[9], are not so great as between *Corynebacterium* and *Proteus*, the *L*-forms of which latter provide the basis for most such comparisons (cf. refs. 3, 8). Descriptions of these and similar strains of *Haemophilus* provide reason for concluding that they are, in fact, structurally and nutritionally degenerate *Corynebacteria*[10–12], and we have ourselves observed the dissociation of *Haemophilus*-like organisms from *Corynebacteria*, and vice versa. Another superficially Gram-negative parasite of the mammalian nasopharynx that has been proved, by dissociation studies and immunological reactions, to be derived from *Corynebacterium*, is *Streptobacillus monilformis*[8]; its well-known *L*-form is antigenically related to the pleuropneumonia-like organisms described as *Mycoplasma hominis* Type 1 (ref. 8), and thus provides further conclusive evidence that pleuropneumonia-like organisms are of bacterial origin. This has previously been suggested (ref. 13 and others) but not proved.

The transformation of bacteria into pleuropneumonia-like organisms or *L*-forms occurs in a series of stages, of which the first is little more than the loss of the cell wall, leaving a naked, sometimes flagellated protoplast[14,15]. Subsequent stages may be so reduced in size and synthetic ability as to resemble viruses by ordinarily accepted definitions.

These transformations are influenced by the presence of antibiotics, notably penicillin, in artificial media or in the body fluids of the host. It is probable that the cell-wall free stage is induced, or at least selected, by the action of penicillin, which is mainly on the cell envelopes[14,16].

Apart from the pathogenic pleuropneumonia-like organisms originally described as such, notably the actual organism of bovine pleuropneumonia, a pleuropneumonia-like organism derivea from a *Corynebacterium* has been implicated in neonatal pneumonia[3] and the so-called Eaton agent, one of the causes of virus pneumonia, has been shown to be a pleuropneumonia-like organism[17]. Patients recovering from this type of infection frequently develop serum agglutinins reacting with a bacterium which has been isolated from cases of virus pneumonia at post-mortem, although it is not regarded as the primary infective agent. This micro-organism is usually described as a *Streptococcus* (*Streptococcus M.G.*), but it is not a typical member of this genus, and somewhat resembles the coccal stages observed in the transformation of other bacteria to and from pleuropneumonia-like organisms[3,4]. In this it is strangely analogous with *Streptobacillus moniliformis*, which presents the appearance of a semi-stabilized, intermediate *L*-form stage of a *Corynebacterium*[8], and which is responsible for a variety of rather obscure infections that have, at various times, been suspected of a virus origin.

Association of a virus with a bacterium in infective conditions, especially of the respiratory organs, is by no means exceptional. The classical example is a *Haemophilus* (*H. influenzae*), and the relationship between the bacillus and the virus has been the subject of considerable speculation, especially in the early days of the knowledge of the association; but comparable conditions are known to exist as swine influenza and fowl coryza, and the bacterial member of the infective complex is in every case referable to the *Corynebacterium–Haemophilus* degenerative series.

The actual nature of viruses is now reasonably clear, since the results of the research work of the past ten years, in this field and in that of nuclear biochemistry, have become understood. In its essentials, a virus is a system of nucleic acids, capable of genetic but not physiological expression, that is enabled to invade the nuclear processes of a host cell and to divert its metabolic activities to the production of the virus. Such a system of nucleic acid (with or without a variable amount of associated, non-genetically active material) may be derived from rogue genes of the host type of cell itself, or it may have an extrinsic origin. Plant viruses and bacteriophage are widely believed to be intrinsic in origin, and this may be true of some animal viruses. The suggestion we wish to make, however, is that the viruses of the type we have been discussing are derived, not from the host itself, but from a parasite already adapted to the host, in this case a bacterium, and that these viruses originate as pleuropneumonia-like organisms or *L*-forms, being the final stages in a generative process that affects bacteria of the *Corynebacterium–Haemophilus* series. This process is itself a manifestation of a comparable degenerative phenomenon that affects several other groups of parasitic, Gram-positive bacteria.

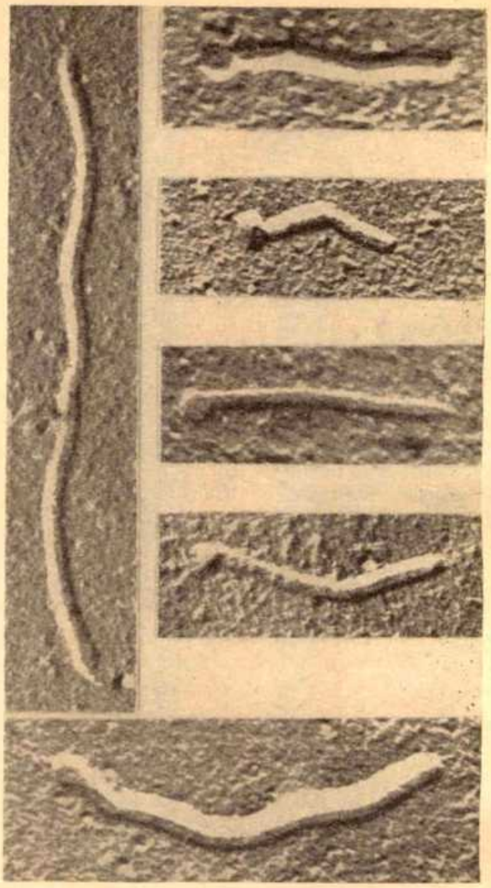

Fig. 1. Filamentous particles exactly resembling those of the influenza virus, observed in preparations of the *L*-form of *Haemophilus influenzae* induced by the action of penicillin. Note the enlarged terminal granule and obtuse-angled breaks. (Electron micrograph, gold–palladium shadowed, × 30,000)

Such a suggestion is not entirely original. Apart from the speculations, already referred to, on the nature of the association between the influenza bacillus and the influenza virus, a general theory of virus evolution from bacteria, by such a degenerative process has been suggested by Burnet[18] and others. There can also be observed the separate process of evolution of an almost virus-like condition in rickettsiæ, that appear to be, in origin, bacterial symbiotes of blood-sucking arthropods, adapted by this habitat to an existence in mammalian tissues. Such originality as we can claim is in the suggestion of a dynamic mechanism for the development of viruses and near-viruses of one type.

Experimental verification is not entirely lacking. Some strains of *Haemophilus*, and *L*-forms derived from other strains exhibit the hæmagglutination phenomenon characteristic of the influenza virus[7,19,20], and freshly isolated influenza viruses have been shown to include relatively large bodies, almost identical with the 'large bodies' of bacterial *L*-forms[21]. Lastly, one of us (P. E. P.) has succeeded in demonstrating the regular occurrence, in *L*-forms (or pleuropneumonia-like organisms) derived by exposure of *H. influenzae* to penicillin, of small filamentous particles that exactly resemble the filamentous particles of the influenza virus (Fig. 1). They are of similar dimensions, and most filaments have the regular, obtuse-angled breaks, one or more according to length, and the enlarged body at one pole (described as the 'warhead' by Burnet[18]), that characterize the authentic myxoviruses[22,23].

In the light of these observations, it is reasonable to speculate whether the greatest danger arising from indiscriminate use of antibiotics may not lie in the adaptation and selection of resistant strains of bacteria but in the artificial creation of new viruses.

GENETIC CONTROL OF TOLERANCE TO TETRA- AND PENTA-CHLORONITROBENZENE IN *HYPOMYCES SOLANI* F. *CUCURBITAE*

By S. G. GEORGOPOULOS

Department of Plant Pathology, University of California, Berkeley

COLONIES of *Hypomyces solani* f. *cucurbitae* Snyd. and Hans. inhibited by tetrachloronitrobenzene (TCNB) and pentachloronitrobenzene (PCNB) often give rise to sectors which show relative insensitiveness to the presence of the inhibitor. (In the work reported in this article the 2,3,5,6 (also designated as 1,2,4,5) isomer of TCNB was used.) Regardless of the first appearance of the sector in the presence of the one or the other of the two fungistats, its subsequent growth shows tolerance to both, and such tolerance is not lost even after many transfers to inhibitor-free medium. TCNB is much more inhibitory to the wild-type *H. solani* f. *cucurbitae* than PCNB, while strains obtained from sectors are only slightly less tolerant to the first than to the latter compound. Therefore, scoring for tolerant versus sensitive is more clear cut when TCNB containing medium is used. Work reported previously[1] has shown that this tolerance is inherited in a Mendelian manner and that all the tolerant strains from sectors that were tested contain one gene for tolerance. This last conclusion, originally based on testing random ascospores, has since been confirmed by analysing the progeny of single asci: whenever a tolerant strain obtained from a sector was mated with a sensitive one of the opposite mating type and single asci were dissected, 4 of the ascospores of each ascus gave tolerant and 4 gave sensitive isolates.

Though considerable differences with respect to tolerance to TCNB were not observed among these tolerant strains, it was considered desirable to investigate whether or not they all contain the same gene for tolerance. In preliminary tests different tolerant strains were mated with other tolerants and random ascospores were tested. Though from many such crosses only tolerant ascospores were obtained, a considerable percentage of those obtained from some other crosses were sensitive. In the case of this latter category of crosses, sensitive ascospores were obtained from every one of a number of the resultant perithecia chosen at random. Therefore, the appearance of sensitiveness in the progeny of parents which are both tolerant could not have been due to an occasional protoperithecium or fertilizing conidium having lost its tolerant gene. It suggested that one of the parents contains a gene for tolerance which is non-allelic to the tolerant gene of the other parent.

A better understanding of this phenomenon was achieved by single ascus dissection. The spores of 45 asci taken from different perithecia which resulted when protoperithecia of the tolerant strain 12*a* were fertilized with conidia of the also tolerant strain 4*b* were analysed for tolerance to TCNB. Three kinds of asci were thus recognized (Fig. 1). In the first kind all the 8 ascospores from one ascus gave tolerant isolates. Only 6 of the 45 asci belonged to this category. Each of the 11 asci of the second kind found contained 4 tolerant and 4 sensitive ascospores. The remaining 28 asci were of the third kind, which gave 6 tolerant and 2 sensitive spores. Likewise, 4 of the 20 asci from the cross 5*a* × 4*b*, which were dissected, were of the first, 4 of the second, and 12 of the third kind. All the 3 kinds of asci can be found in the same perithecium. These results are in agreement with the hypothesis that the two parents, in each of the two crosses here, contain genes for tolerance at different loci. In such a case, the 4 tolerant ascospores of any ascus from such a cross segregating 4*T*:4*S* (as well as 2 of the 6 tolerant ones of any one segregating 6*T*:2*S*), though not more tolerant than each of the parents, should contain both genes.

To test this hypothesis further, the 4 tolerant ascospore isolates from ascus 21 of the cross 12*a* × 4*b*,

Table 1. SEGREGATION OF PROGENY FROM CROSSES BETWEEN TCNB-SENSITIVE STRAINS OF *Hypomyces solani* f. *cucurbitae* AND THE ASCOSPORE ISOLATES A_{43} AND A_{44}

Cross	Asci analysed	Non-segregating (8*T* : 0*S*)	Segregating 4*T* : 4*S*	Segregating 6*T* : 2*S*	Ratio *T*:*S*
9 × A_{43}	27	5	2	20	3·50
10 × A_{43}	8	2	1	5	3·57
9 × A_{44}	32	6	3	23	3·42
40 × A_{44}	7	2	1	4	3·66
	74	15	7	52	

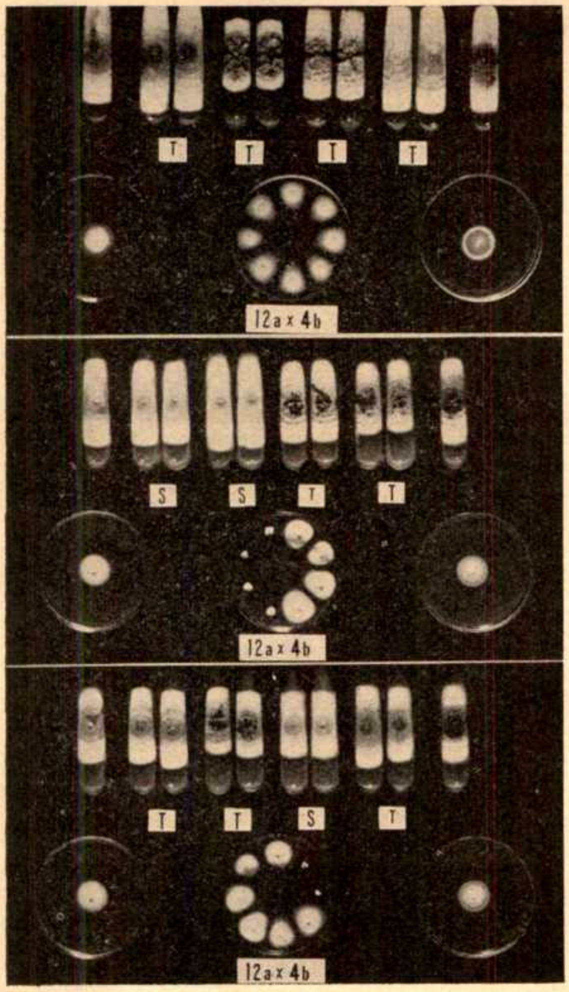

Fig. 1. The 3 kinds of asci produced from the cross $12a \times 4b$. Parents and progeny on PDA slants and TCNB agar plates. In each set of cultures on the left is strain $12a$, on the right strain $4b$, and between the two parents 4 pairs of isolates—the progeny of a single ascus. Top, $8T : 0S$; centre, $4T : 4S$; bottom, $6T : 2S$; T, TCNB-tolerant ; S, TCNB-sensitive

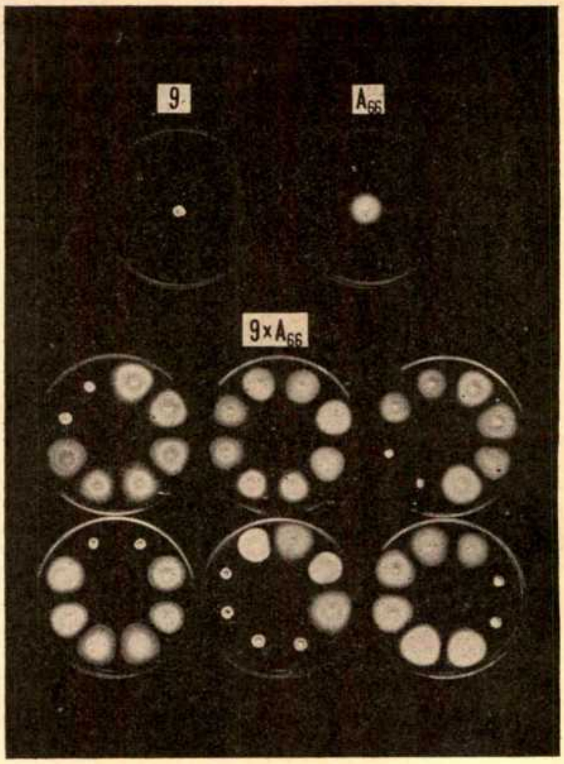

Fig. 2. Colonies on TCNB-agar of sensitive strain 9, tolerant ascospore isolate A_{66}, and the progeny of 6 asci from cross $9 \times A_{66}$. The colonies of 9 and A_{66} were started with single conidia. In each of the bottom 6 plates the 8 ascospores of one ascus were transferred

the progeny of which is shown in Fig. 1 (centre), namely A_{65}, A_{66}, A_{67}, and A_{68}, were chosen and attempts were made to mate them with different sensitive strains. Of these 4, the 2 sister ascospore isolates A_{67} and A_{68} were found to be neuters. Since strain $12a$ is a female and strain $4b$ a male, the appearance of neuters among the progeny is in agreement with previous findings[2,3]. The genetic results of crosses of isolates A_{65} and A_{66}, both of which are males and belong to compatibility group A, with sensitive strains are shown in Table 1. An illustration of the kind of segregation for tolerance to TCNB which such crosses give is given in Fig. 2. These results, together with those obtained from the cross $12a \times 4b$, show that each of the isolates A_{65} and A_{66} contain two genes for tolerance to TCNB and prove beyond any doubt that tolerance to this compound in *H. solani* f. *cucurbitae* is controlled by at least two different genes which operate independently of each other. The relative position of the two genes has not yet been determined. However, from both crosses, tolerant × tolerant and sensitive × double tolerant, the non-parental ditype ascus was produced quite frequently. This suggests that the two genes are probably on different chromosomes or different arms of the same chromosome.

I thank W. C. Snyder and P. St. Lawrence for advice.

SUBJECTIVE VALUE OF A 'BIT' OF INFORMATION

By PROF. JOHN COHEN and PETER COOPER

Department of Psychology, University of Manchester

INFORMATION theory has had its chief impact on psychology in relation to studies of channel capacity and analysis. In this article we consider another psychological aspect of information theory, namely, the determination of the subjective value of a 'bit'.

(1) Subjects were given a page on which was printed a number of small circles. They were told the

number, and that the experimenter was thinking of a particular circle. Their task was to say how many questions they would have to ask in order to identify the circle for certain. Only questions which could be answered by 'Yes' or 'No' were allowed. Ten such pages were presented to each individual, the number of circles on any given page ranging from 2^1, by successive powers of 2, to 2^{10}. Half the subjects had pages with circles arranged regularly, and half with circles arranged irregularly, and there were four age-groups, namely, 9-year-old ($N = 79$); 12-year-old ($N = 61$); 15-year-old ($N = 93$); and 22-year-old ($N = 267$). The three younger groups were chosen from the brighter streams at school; the members of the oldest group were students at teachers' training colleges.

Theoretically, the number of questions which must be asked in order to locate any particular circle for certain is given by $\log_2 n$ (where n is the number of circles), that is, the number of 'bits' of information on the page. Actually the number of questions which our subjects believe to be necessary is in excess of this, and it increases logarithmically in all four age-groups, as the number of 'bits' increases. For example, at 8 'bits' of information (256 circles) the 9-year-old children require 70 questions; at 9 'bits' they require 89 questions; and at 10 'bits' they require no less than 450 questions. Fig. 1 shows the median number of questions plotted against the number of 'bits', for each age-group.

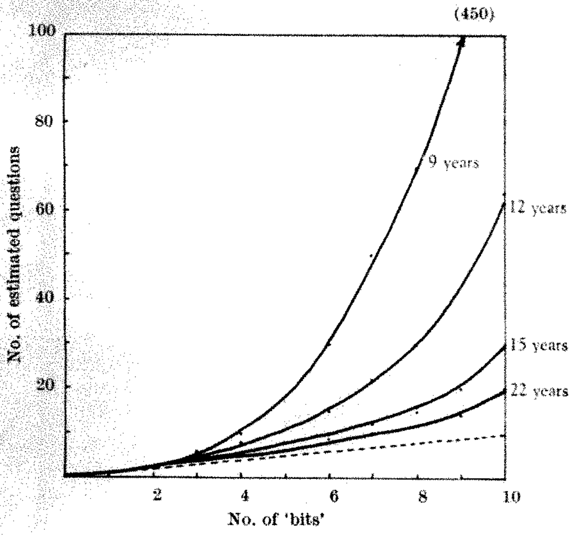

Fig. 1. Median number of estimated questions in relation to number of 'bits'

Over the entire range of 10 'bits', the mean number of questions per unit 'bit', at each age-level, indicates the extent to which the discrepancy between 'subjective' and 'objective' information steadily declines with age. This number may be regarded as a measure of subjective 'information' or, alternatively, of subjective 'uncertainty': at 9 years it is 13; at 12 years 4; at 15 years and thereafter it is approximately 2.

So far as responses to regular and irregular arrangements are concerned, the youngest group require about three times as many questions for the latter as for the former patterns. This difference is blurred in the older groups.

Every subject was also asked to say (*a*) what his first question would be, and (*b*) to mark the particular circle he thought the experimenter had in mind. In respect to (*a*) we found that 15 per cent of the 9-year-old children asked whether the given circle was located in one or other half of the page; in other words, they adopted a binary principle. The corresponding proportions in the other age-groups were 25, 65 and 54 per cent. Having regard to the fact that only one in two of the 22-year-old group realized the correct procedure, it is rather surprising that as many as one in six or seven of the 9-year-old children did so. In respect to (*b*) it might be supposed that every circle had the same 'chance' of being chosen. In fact, we find that 50 per cent of the subjects choose a circle from the 20 per cent of the circles clustered near the middle of the page.

(2) The foregoing results were obtained from group experiments. In addition, we examined 90 subjects individually on a more restricted range of 'bits', 30 aged 9, 24 aged 12, and 36 aged 15 years. Each individual was required to locate the particular circle by asking the experimenter appropriate questions. We are now in a position to make a comparison between the group and individual situations respectively, as in Table 1.

Table 1. MEDIAN NUMBER OF ESTIMATED (E) AND ACTUAL (A) QUESTIONS IN RELATION TO NUMBER OF 'BITS'

	No. of 'bits'							
	4		6		8		10	
Age	E	A	E	A	E	A	E	A
9	10	6	30	8	70	13	450	17
12	8	5	15	9	30	13	64	15
15	5	5	10	8	15	10	30	13

The main outcome is that the median number of questions actually asked is considerably less, at each age, than the corresponding number of estimated questions to be asked, obtained in the group experiments. This suggests that performance in a task such as this cannot be invariably judged from an estimate in advance.

At all three age-levels a small, but significantly larger, number of questions was required for the irregular as compared with the regular arrangements.

Over the range of 4–10 'bits', the mean number of actual questions per unit 'bit' is 1·6 at age 9; 1·5 at age 12; and 1·3 at age 15. The reciprocals of these values represent the mean proportions of a 'bit' eliminated at each question.

Inspection of the results, together with observation of the subjects at their task, shows that any given strategy which they adopt is not necessarily sustained unchanged from beginning to end. Furthermore, the strategy for a residual number of 'bits' is not necessarily equivalent to the strategy for the same number of 'bits' facing the subject *ab initio*. For example, the final 16 circles, when n initially is 1,024, are not invariably searched in the same manner as when n is initially 16. A random search may become systematic or vice versa.

These experiments raise a number of further problems for research; for example, the determination of the subjective value of a 'bit' at much larger values of n, the rate of work, the effect of presenting information in other forms and modalities, and a more detailed scrutiny of strategies at different ages in tasks of varying complexity, and at different stages of the same task.

LETTERS TO THE EDITOR

COSMOLOGY

Finite Universe and Mach's Principle

RECENTLY, Ozsváth and Schücking found an exact solution of Einstein's field equations of gravitation, which represents an instructive new model of a universe (finite rotating universe)[1]: Although in the entire cosmos matter is at rest relative to a suitably chosen co-ordinate system, nevertheless everywhere Coriolis forces do exist. This property of the Ozsváth–Schücking model is common to a solution already found by K. Gödel in 1949[2]; whereas Gödel's solution represents a universe of infinite space extension and, besides, closed time-like world lines exist, the Ozsváth–Schücking model represents a spatially finite universe in which time-like world lines cut the closed space like hypersurfaces only once. Therefore, no reasons exist for excluding this model as physically meaningless.

Ozsváth and Schücking call their world model explicitly an 'anti-Mach solution', because the inertial compass and the light compass do not coincide. They have constructed their model with the intention of disproving the 'creed', that in a finite closed universe Mach's principle is necessarily being fulfilled (*BFH* version of Mach's principle).

According to the interpretation of the O.–S. model given by us in Freiburg/Br., this solution deals with a generalization of the static Einstein cosmos, to which a circulating gravitational wave is superimposed. Since the gravitational wave is transporting energy and momentum, it gives rise to a Coriolis field (similar to the momentum density of matter), although matter is at rest everywhere.

This physical meaning follows immediately, if one writes the line element $\mathrm{d}s^2 = g_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu$ of the given solution in the following way ($x^4 = ct$):

$$g_{\mu\nu} = \left(\frac{R}{2}\right)^2 (\overset{0}{g}_{\mu\nu} + k\overset{1}{g}_{\mu\nu} + k^2\overset{2}{g}_{\mu\nu})$$

whereby

$$\overset{0}{g}_{\mu\nu} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & -1 & -\cos x^1 & 0 \\ 0 & -\cos x^1 & -1 & 0 \\ 0 & 0 & 0 & \left(\frac{2}{R}\right)^2 \end{pmatrix}$$

$$\overset{1}{g}_{\mu\nu} = \begin{pmatrix} -\cos\Phi & \sin x^1 \sin\Phi & 0 & 0 \\ \sin x^1 \sin\Phi & \sin^2 x^1 \cos\Phi & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

$$\overset{2}{g}_{\mu\nu} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -2\cos^2 x^1 & -2\cos x^1 & 2\alpha\cos x^1 \\ 0 & -2\cos x^1 & -2 & 2\alpha \\ 0 & 2\alpha\cos x^1 & 2\alpha & 0 \end{pmatrix}$$

The following abbreviations have been used:

$$\Phi = \alpha ct - 2x^3,\ \alpha = \frac{2}{R}\sqrt{\frac{2}{1-4k^2}}$$

(Φ phase, k means a parameter with $|k| < \frac{1}{2}$; $k = 0$ corresponds to the Einstein cosmos, R is the curvature radius of the universe). Regarding k as a small quantity ($|k| \ll 1$), the gravitational wave $k\overset{1}{g}_{\mu\nu}$ represents a first order disturbance of the Einstein cosmos, the time average of which being equal to zero. First in the second approximation according to $k^2\overset{2}{g}_{\mu\nu}$ we get a time-independent deformation of the Einstein cosmos. This interpretation is still valid if $|k|$ is no longer small against one.

As the calculation shows the momentum components of the gravitational field t^1_4 and t^2_4 are equal to zero. Since the 'basic metric' $\overset{0}{g}_{\mu\nu}$ makes no contribution to t^i_4 ($i = 1,2,3$), energy propagation of the gravitational wave is therefore determined, and that is in accordance with phase propagation:

$$\mathrm{d}x^1 = \mathrm{d}x^2 = 0,\ \mathrm{d}x^3 = \frac{\alpha c}{2}\,\mathrm{d}t$$

Thus the 4-velocity of energy-momentum propagation becomes:

$$u^\mu = \frac{\mathrm{d}x^\mu}{\mathrm{d}s} = \sqrt{\frac{2(1-4k^2)}{1-2k^2}}\left\{0, 0, \frac{\alpha}{2}, 1\right\} \quad (u_\mu u^\mu = 1)$$

The wave-length of the gravitational wave is equal to 1/4 of the circumference of the universe.

The 4-velocity of energy and phase is time-like, and therefore it is possible to introduce a co-ordinate system, in which the $g_{\mu\nu}$'s become independent of t. For that reason one may call this model 'stationary' (similar to the fact that an electromagnetic wave passing a dispersive medium with a velocity $< c$ may be transformed to a stationary condition). u^μ is a time-like and geodesic killing-vector. Corresponding to this, the $g_{\mu\nu}$ have constant values along the stream-lines of energy.

According to the field equations of gravitation, the Coriolis forces are uniquely determined by the energy-momentum components of the gravitational wave (boundary conditions do not exist). The field intensity ω of the Coriolis force is constant in the whole cosmos:

$$\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} = 2\cdot\vec{v} \times \vec{\omega},\quad \omega = \alpha c\,\frac{k^2}{\sqrt{1-k^2}}$$

Surely ω is so small (in the order of the circulation frequency of the light around the universe, $R/c \simeq 10^{10}$ years) that one cannot think of an experimental proof even under extreme conditions.

We are of the opinion that Ozsváth and Schücking's interesting world model does not contradict Mach's principle, and especially not the idea that a finite and closed world model is in accordance with Mach's principle. Certainly it will not be possible to uphold the dogmatic form of Mach's principle containing the exact accordance of kinematics and dynamics since each gravitational wave (like all other disturbances of a homogeneous and isotropic metric field) shows a tendency to become self-consistent. In interpreting Mach's principle as a selectional principle for world models the accordance of kinematics and dynamics has to be postulated only on a large scale, which might be satisfied by all finite closed world models[3].

A detailed paper on this subject will appear in the *Zeitschrift für Physik*.

IN our previous communication to *Nature* we gave an exact solution of Einstein's field equations contradicting a certain well-defined version of Mach's principle (*BFH* principle). Dehnen and Hönl now state "that a finite and closed world model is in accordance with Mach's principle (*BFH* principle)".

But our example showed that a finite and closed world model may not be in accordance with *BFH*.

Dehnen and Hönl write in their following sentence: "Certainly, it will not be possible to uphold the dogmatic form of Mach's principle". The 'dogmatic form' is the *BFH* version, which postulates "the exact accordance of kinematics and dynamics". Therefore, this would seem to contradict their first statement.

It may be that Dehnen and Hönl now put their faith in another version of Mach's principle. But so far we have not seen a precise mathematical statement of such a new form of this evasive principle. We do not agree with Dehnen and Hönl's interpretation of our solution. Their arguments depend completely on the co-ordinate system used, are not invariant and therefore inconclusive.

GEOPHYSICS

An All-Sky Photometer

DURING the period of the International Quiet Sun Year, better opportunities may be found for the examination of airglow in the middle latitudes at a time when little or no auroral contamination is expected. With the view of measuring the intensities of the night airglow radiations emitted from the whole dome of the sky, a simple photoelectric type of photometer has been designed and built, in the Upper Atmosphere Research Section of the National Research Council, Ottawa, Canada.

The basic objective is to provide a kind of index of the airglow intensity at specific wave-lengths. The instrument will be operated on all clear moonless nights to obtain the hourly or half-hourly 'airglow index' for the station. The all-sky photometer basically differs from the conventional airglow photometer in that the former measures the intensities up to 80° zenith angle and at all azimuths (about 10° from the horizon are cut due to the tree tops on the site), while the latter usually covers a narrow angle and hence has to scan the sky to obtain complete information. It is agreed that the scanning type of photometer, subtending narrow angle, can reveal a great deal of information regarding the finer and detailed structure of the airglow. With the present apparatus, however, it is felt that a measure of the integrated intensity over the whole dome of the sky will be a useful factor in understanding some processes in the upper atmosphere.

The basic assembly of the electric clock, the convex mirror and the stand which holds the camera unit, is that of the all-sky auroral camera[1]. The camera unit is replaced by a cylindrical housing containing an end-on type (EMI 9528*B*) photomultiplier tube, a filter disk with three filters and a blank in the four quadrants of the disk, a 6 r.p.m. motor to rotate the filter disk and a cam-microswitch assembly to position the filters over the cathode of the photomultiplier.

The clock-timer mechanism is located in the base of the instrument. Every 5 min it supplies a pulse to the filter-disk motor which rotates the disk 90° in 2·5 sec. The photometer is turned on and off automatically by the clock at preset times. When the photomultiplier tube is turned off, the motor continues to operate until the blank segment is in front of the photocathode. Furthermore, a phototransistor circuit is included that can be adjusted to turn the photomultiplier off when the ambient illumination exceeds a given value.

The filters used in the present apparatus are shown in Table 1.

Table 1

Filter centred at (Å):	Half-width (approx., Å)	Peak transmission (per cent)
6300	40	73
5577	48	55
5400	46	55

The filters turn in the following sequence, 6300 Å, 5577 Å, 5400 Å and 'blank'.

The intensity of the airglow is recorded on a paper chart for 5 min in each wave-length band. The blank space in the disk permits recording of the zero intensity. A complete cycle is repeated every 20 min. In order to accommodate a wide range of intensity, say due to an aurora, the output of the photomultiplier tube is recorded as the logarithm of intensity of the incident light falling on the photocathode. At present, the full-scale recording covers a range of 10^5 in intensity, which may be reduced to 10^2 or 10^3 for convenience.

Fig. 1 gives a sample record obtained with the all-sky photometer on the night of June 27/28. Time shown on the record is E.S.T. Radiation intensity is recorded from sunset to shortly before sunrise. It

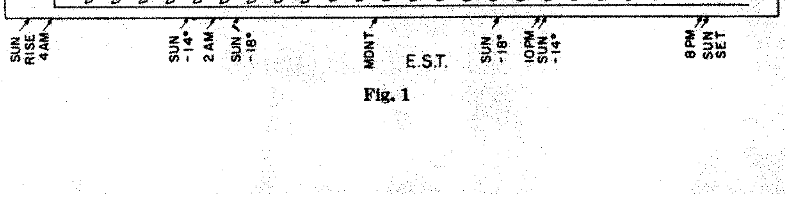

Fig. 1

may be assumed that the night conditions are almost reached at 0957 p.m. when the Sun is 14° below the horizon and the night prevails until the Sun is in the similar position on the morning side.

Although no absolute calibration is given, it is quite striking to note that the relative intensities in the three wave-lengths show a wide variation with time. Independent variation of the individual radiations can also be observed. Throughout the night 5400 Å radiation shows random and small fluctuations. 6300 Å radiation shows higher intensities at the beginning and end of the night, with a minimum around 0020 E.S.T. The 5577 Å radiation shows some decrease in intensity in the early part of the night with a distinct maximum at about 0045 E.S.T. and falling off again towards dawn. The ratio of maximum to minimum intensity of 5577 Å radiation during the night is 2·3 : 1. Photometers subtending narrow angles have also shown maxima of intensity around midnight, both at the middle latitudes[2] and in the tropics[3].

Table 2

	Beginning of night	When I_{5577} is maximum	End of night
$\frac{I_{5577}}{I_{6300}}$	4·5	8·9	4·75
$\frac{I_{5577}}{I_{5400}}$	4·3	8·4	5·3

Table 2 gives the ratios of intensities of I_{5577}/I_{6300} and I_{5577}/I_{5400} for the three epochs of the night; (1) at the beginning of the night; (2) at the time when 5577 Å radiation had maximum intensity; (3) at the end of the night.

Fitting the Continents

THE discussion[1] by Dr. C. H. Barnett and Sir Harold Jeffreys calls for comment. First, the original suggestion that the Earth might be expanding, on the basis of experimental fit of the 200-m depth contours of the continental shelves, was made by O. C. Hilgenberg in 1933[2]. Further, Sir Harold Jeffreys's objection that there is too much implied distortion can be met. The pseudo-viscosity of the crust[3,4] and observed distortion by shear[5,6] would lead one to expect continental distortion in any event; and the outline of the continental margins may have changed in geological time, by accretion of the continents[7,8], by loss of continental crust[9], or both.

These points must be borne in mind when seeking evidence for or against Earth expansion and continental drift.

GEOLOGY

Kenya Ignimbrites

IN a recent communication[1], Dr. G. J. H. McCall gave his views on some ignimbrite-like rocks found in the Kenya rift valley. The full details of these rocks, particularly those in the Menengai area, are awaited with great interest as they should prove to be a valuable contribution to the subject of ignimbrites and ignimbrite-like rocks. Some comments are called for in the light of an investigation[2–4] made on similar rocks in the area immediately to the east of that studied by Dr. McCall.

The hypothesis that the lenticles (or lithophysæ) are due to a drawing out by flow of formerly continuous laminæ cannot be accepted for two reasons. The first is that the lenticles would show a preferred direction of elongation when viewed in the foliation plane if they were due to a drawing out by flow; in the same way that gas vesicles drawn out by flow in a normal lava show elongation in both horizontal and vertical sections. Such an elongation has not been noticed in any of the several hundred specimens of Kenya ignimbrites examined. The second reason for rejecting Dr. McCall's explanation of the origin of the lenticles is that it fails to account for the vertical transition of the lenticles from lens-shaped vesicle-free blebs near the base of a flow unit, to equidimensional pumiceous blocks near the top; all transitions between these two extremes being present in a single unit. This transition is particularly well seen in the ignimbrite which forms the bank of the Melawa River 5 miles south-east of Ol Kalou. This ignimbrite also shows a thick development of incoherent unwelded ash as its upper member, which is indistinguishable from normal vulcanian ash. Such a deposit could not have been produced by the collapse of a lava froth. It is noteworthy that the vertical zonation of the ignimbrites in this region can be matched with those described by Marshall[5] and more recently by Martin[6] from the type locality for ignimbrites in North Island, New Zealand.

The xenoliths, which Dr. McCall attributes to the break-up of a brittle solidified lava, are common features of Kenya ignimbrites. However, in any one flow, many different kinds of lava may occur as xenoliths and they can sometimes be matched with underlying lavas. In the case of the Gorge flow of the Lower Oramutia volcanics[4] it is possible to relate the distance of the ignimbrite from its presumed source to the increase in xenolithic debris. Besides lava fragments, clods of earth and weathered lava have been found in many Kenya ignimbrites. There is obviously no reason for abandoning the orthodox view that the xenoliths are fragments of country rock torn off during the eruption or during transport above ground-level.

One of the Pleistocene 'ravine flow' occurrences mentioned by Dr. McCall is the subject of a recent paper[4]. Dr. McCall describes these as 'watery'. Does 'watery' in this context mean a high water content or an exceptionally low viscosity? It is important to realize that these 'ravine flows' are of two different kinds: ignimbrites with a texture suggestive of coalesced liquid blebs and true froth lavas. The latter are of low density and closely resemble pumice tuffs.[4]

Composite flows showing eutaxitic structure and normal lava in one unit are apparently restricted to Menengai crater. Most of the ignimbrites occur in the main body of the Kinangop tuffs. However, the phonolite and phonolitic trachyte flows in the Ol Kalou–Ol Joro Orok region sometimes show local development of ignimbrite-like structure on their upper surfaces. This would seem to be due to fluidized systems breaking out on the surface of volatile rich lavas. Some process akin to the second order *nuée ardentes* described by Cotton may be responsible[7]. Recently, Molloy and Kerr[8] described reconstituted flows of apparently normal lava derived from air-fall material. Has Dr. McCall fully considered this possibility for the Menengai occurrence ?

Dr. McCall's dissatisfaction with the term 'welding' is shared by me, although for rather different reasons. Welding implies a softening of solid bodies by heat, causing them to stick together. Many of the more massive Kenya ignimbrites show relict shard structure only in the upper and lowermost parts of the flow unit. The central part is composed of an extreme kind of eutaxitic structure (parataxitic) or by a kind of 'blobby' structure in which no definite outlines can be discerned. It is thought that the shards in these rocks were liquid at the time of deposition and that they coalesced as the gas cushion leaked away. Near-solid or plastic shards produced the zones with typical eutaxitic structure. In some cases the eutaxitic mass appears to have been invaded by the molten glass derived from the coalesced molten shards, so producing a two-phase system of shard glass in matrix glass. The operative process in these rocks is coalescence and not welding. The presence of two glasses was wrongly attributed to liquid immiscibility by Steiner[9,10].

It may be concluded from the foregoing remarks that there is no reason for giving the Kenya ignimbrites a totally different origin to the ignimbrites elsewhere. A form of Marshall's[5] original *nuée ardente* theory modified along the lines suggested by Fitch[11,12] and others is adequate to explain all the textures and structures seen in these rocks.

Mr. C. M. Bristow's pertinent comments on my communication dealing with froth-flows in Kenya underline a fundamental difference in interpretation of these rocks between me and geologists of the Ministry of Works, Kenya. The latter have attempted to fit the evidence from this field into a framework based on the orthodox concepts of ignimbrite genesis—following Fenner[1], Marshall[2], Mansfield and Ross[3], and Gilbert[4]. I have come to the conclusion that certain features of the flows in question are incompatible with these concepts: and that some departure from the concept of ignimbrites (as clearly defined by Marshall[2]—products of deposition from immense clouds or showers of intensely heated but generally minute fragments of volcanic magma) is necessary, in this case. Grange[5], working in the same field as Marshall, remained unconvinced that the process suggested by Marshall had been responsible for the unusual rock types, and preferred to invoke an origin in effusive processes, and Steiner[6] has lately invoked such processes to explain anomalous features in certain rocks of this field. Even the foremost, active exponents of welding and compaction (lithostatic load) processes, Ross and Smith[7,8], have come a long way from Marshall's original concept. The description of an eruption of Cotopaxi quoted by them[7] as possibly a typical 'ash flow' eruption suggests effusion rather than the process envisaged by Marshall. This eruption could equally well have represented vesiculation, expansion and partial or complete rupturing in a rising magma column and effusive flow, quite independent of welding processes —a froth-flow eruption as envisaged by Kennedy[9] and Boyd[10].

I have suggested that, in the Kenya field, there is evidence that processes other than welding of sticky, hot fragments can produce a rock characterized by *fiamme*, and that it is even possible that the evidence from this field indicates a need for the complete reappraisal of the concept of welding and compaction—a concept already questioned (either directly or by implication) by Kennedy[9], Hausen[11], Steiner[6] and Boyd[10].

The idea of welding seems to have stemmed from the assumption that coherent, indurated and fragmental volcanic rocks, resembling lavas and in which glass shards were conspicuous, must of necessity have been derived from tephraitic products—fragments which had undergone air-travel in a dispersed state—by redeposition and reconstitution in a coherent mass. Nowadays, it is becoming apparent that pyroclastic material derived from magma ruptured by extreme vesiculation and autoclasis can flow, both before extrusion, and over the surface in the form of overland avalanches. Further, Steiner[6] has logically concluded that shards can stem from processes of autoclasis within partly cooled magma. The basis for considering shards and other fragments within a tabular, coherent body, resembling a lava flow, as of necessity deposited from clouds or showers may thus be questioned. The advocates of ash-flow, while retaining the idea of welding related to compaction, have moved towards the idea of overland flows. I go a stage further and question whether there is any real need to invoke welding at all ? The alternative froth-flow hypothesis allows for gradations, within the limits of single flows, from well-crystallized lava, to banded glassy lava, to mottled eutaxitic and partly fragmental lava, and even to incoherent, pulvurulent material. The welding hypothesis invokes a reverse process, fragmental material derived from rupturing processes in a gas-exsolving magma being restored to a cohesive state. There are cogent objections to this hypothesis on physical grounds, and it involves a more complex sequence of events than the froth-flow hypothesis.

Bristow accepts the fact that there are, in this field, structurally composite flows—part well-crystallized or glassy lava, part eutaxitic material indistinguishable from his 'ignimbrites'. He suggests an origin in *nuée ardente* activity. I differ in believing that these phenomena have nothing to do with *nuées ardentes*, and in believing that they provide the key to the problem of genesis of these eutaxitic rocks. Though they have been examined in especial detail in Menengai, such structurally composite flows are widespread, occurring particularly where phonolitic-trachyte rather than quartz-trachyte has been erupted—though also present to a limited extent in the latter setting. The recorded transitions from flow-banded lavas characterized by vesicular swells or lithophysæ within the laminæ to discontinuous, eutaxitic patterns in which the lithophysæ appear as shreds or *fiamme* (transitions recognized within the limits of single hand specimens) seem difficult to relate to observed *nuée ardente* eruptions, low-temperature phenomena, which have given rise to unsorted avalanche deposits never yet observed to be welded. There is strong reason to believe that the mechanism of *nuées ardentes* primarily involves entrapped air, not gas exsolution[12], and the latter process is clearly evidenced in the eutaxitic portions of the composite flows. There is no reason for believing that the material forming the fragmental, eutaxitic layers in structurally composite flows ever passed through a stage of air-travel in a dispersed state, or that it was ever completely incoherent.

The zonation seen throughout the thickness of these flows is not, in my view, as regularly progressive as in the example cited by Bristow. It is true that obsidian blebs or *fiamme*, devoid of vesiculation cavities, tend to occur at the base of flows, but I interpret this as a chilling phenomenon, the volatiles in the lava having congregated, but vesiculation prior to solidification having been negligible. Such *fiamme* also occur, however, near the upper surface of flows. Transition from coherent to incoherent material is not only seen at the tops of the flows—bands of incoherent, pulvurulent material have been observed near the base of some flows. The ash referred to by Bristow may not be a vulcanian shower deposit: it is my contention that the bulk of the so-called pumice tuffs in this field are pumice avalanche deposits, products of extreme vesiculation and rupturing—collapsed bubble-froth flows—and such material may well be found in continuity with the so-called ignimbrite within a single flow. The most convincing evidence that the flattening of the *fiamme* is not connected with compaction (lithostatic load) effects is to be found in the fact that such flattened *fiamme* are to be found at the top surface of flows, and also in very attenuated flows, in both cases where nothing has ever been superincumbent.

In connexion with these *fiamme*, Bristow's point of criticism concerning flow-lineations is interesting. It is true that no regular lineation appears on the upper surface of cubes cut from hand-specimens (with upper and basal surfaces parallel to the foliation plane). What is apparent is a swirling pattern, a distinct arrangement of sinuous linear trains of *fiamme*, other fragments, and felspar phenocrysts. This flow structure (if such it be) seems to be primarily a flow-foliation, the flow having been strongly laminar, but the fragments, *fiamme* and phenocrysts moved turbulently in the lamination planes without any strongly preferred direction. Usually side-faces of these cubes show a greater elongation of the *fiamme* on one face than on the other. It is not unknown for vesicles in lavas to reflect a similar combination of primary foliation and lineation: a specimen of nephelinite in my own possession shows strongly aligned amygdales—the structure expected by Bristow—but on the side faces of the cube it is seen that these are both elongated and flattened; that is, they are drawn out in both horizontal directions.

That some of the well-crystallized material present as angular 'xenoliths' in these flows is accidentally accrued is accepted by me. It is also agreed that all these enclaves appear as if more weathered than the host, but this does not mean, necessarily, that they were weathered before incorporation in the flow. The consistent presence of numerous, abruptly defined enclaves of crystalline material in the eutaxitic rocks would, however, seem to require an explanation involving the essential process of genesis of these rocks—particularly as these inclusions show some degree of sorting as to size, and frequently are more evident in the higher levels than the lower levels of the flow. Petrographic evidence indicates that the majority of these are nothing more than sharply defined areas of complete crystallization in the flow, either *in situ* or to some extent moved within the flow in the manner of rafts. In any event, it is agreed that these are not the fragments of the cloud or shower that is progenitor to the ignimbrite: Where then are those fragments?—if the *fiamme* are actual or embryonic vesiculation areas showing considerable uniformity with their neighbours, as I believe, and not pyroclastic fragments.

Reconstitution and processes involving 'liquid shards' have been invoked to explain relationships such as I have described. I regard these hypotheses as involving excessive 'stretching' of the original welding hypothesis to fit the evidence. Certainly, reconstitution is difficult to accept in the case of the almost holocrystalline, intersertal/intergranular textured parts of the Menengai composite flows. I consider that their similarity of texture with many nearby lavas, and the temperature required for such a crystallization, strongly support an origin in direct crystallization from a cooling silicate melt.

I have had no experience of rhyolite ignimbrite fields: while I accept the fact that there is, in these fields, a wealth of indirect evidence which has led geologists to formulate ideas of welding related to compaction, and of reconstitution, I know of no criterion which distinguishes, unequivocably, whether a particular rock is the product of partial fragmentation or of complete fragmentation followed by partial reconstitution. But while this has led me to question the concept of welding, I consider it to be a mistake, perhaps, in the present state of knowledge, to be too dogmatic, and to conclude that any worker in this or any other field is completely in the wrong. It is clear that the term ignimbrite will continue to be preferred by those who, like Bristow, adhere to welding concepts, but equally, I consider that Marshall's definition of the term makes it impossible for me to apply it to any of the rocks which I have studied in this field. The term 'ash-flow' would be acceptable allowing for the fact that in this case it would be applied to effusive rocks in which no welding is believed to have taken place, and which may never have passed through a fully incoherent stage.

The occurrence of rocks of 'ignimbrite' aspect as repeated intercalations in sequences of marine sediments is not unknown and such relationships present a problem, since it is difficult to believe the 'ignimbrite' mechanism could operate under water. Repeated emergence coinciding with volcanic outbursts or some other such unlikely process has to be invoked. The froth-flow hypothesis is one which incorporates a process equally compatible with terrestrial or submarine eruption.

PHYSICS

Radiation Enhancement following Johnston Island Thermonuclear Explosion

We wish to report the observation, made at Hobart, Tasmania, of an enhancement in the counting-rate of a balloon-borne Geiger counter at the time of the high-altitude thermonuclear explosion above Johnston Island on July 9, 1962.

The counter, designed for operation at the temperatures encountered in night flights of balloons (down to − 60° C), was 10 cm long and 4 cm in diameter. Thicknesses of the glass wall and internal nickel cathode were 1 mm and 0·1 mm respectively. At the time of the explosion, 0900 U.T., the balloon carrying this counter (mounted horizontally) and associated circuitry had reached an atmospheric depth of 80 g cm^{-2} and was rising in altitude at the rate of 2·5 g cm^{-2} min^{-1}. The balloon burst prematurely at 0927 U.T.

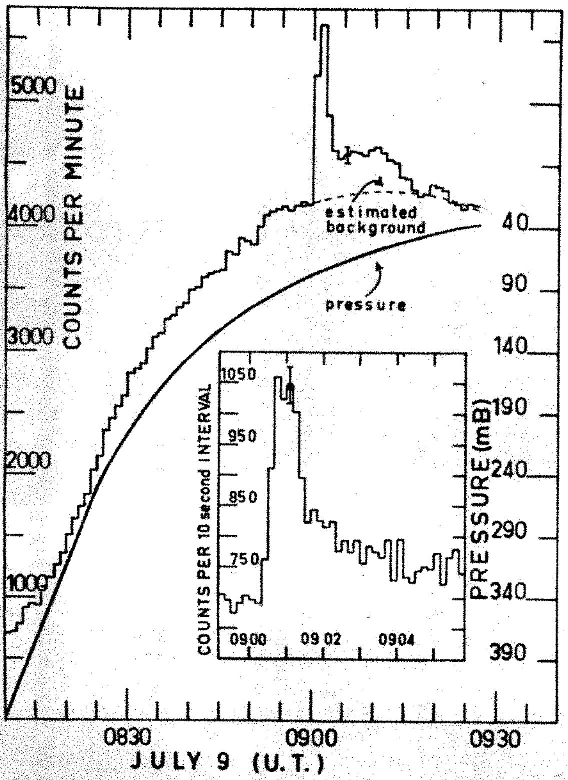

Fig. 1. Main diagram, 1 min count totals from balloon-borne Geiger counter and atmospheric pressure level versus time; inset, variation of 10-sec count totals through time of Johnston Island explosion (0900 U.T.)

Fig. 1 summarizes the observations. The maximum error in timing is estimated at ± 2 sec.

Significant features of the event are the considerable atmospheric depth at which it was observed, the delay of between 20 and 30 sec between the instant of the explosion and commencement of the enhancement, and the peak intensity (averaged over 10-sec intervals) of about 50 per cent above the normal background-level near the Pfotzer maximum of the cosmic ray transition curve. There seems little doubt that recovery to the normal background intensity was not complete until at least 0915 U.T. No effect was observed by cosmic ray neutron monitors and meson telescopes at ground-level in and near Hobart.

It is clear that if the enhancement were due to protons incident vertically at the top of the atmosphere their minimum energy was 350 MeV. However, the line of force through Hobart (geographic coordinates 43° S., 147° E., geomagnetic latitude 51° S.) crosses the equatorial plane at 2·5 Earth radii, and thus passes outside the region in which protons of energy exceeding 70 MeV were observed by *Explorer VI*[1]. The possibility that other types of radiation were responsible for the enhancement must be examined, but we consider that an attempt at this time to interpret the observations from the information available to us would be premature.

We wish to acknowledge the assistance of Mr. H. E. G. Dyer, who manned a duplicate radio telemetry station.

Laboratory Test of the Finlay-Freundlich Red Shift Hypothesis

A new round of discussion and experiment has been set off by a recent suggestion made by A. Ward[1]. He points out that recent developments in physics make possible a laboratory test of a proposal by E. Finlay-Freundlich[2] for an alternative interpretation of the galactic red shift. The Finlay-Freundlich hypothesis was based on anomalies in various stellar red shifts and suggested that these, as well as the Hubble–Humason red shift in galactic spectra, commonly interpreted as Doppler shifts in an expanding universe, are in fact the result of loss of energy by observed photons traversing a radiation field. No generally accepted physical mechanism has been proposed for this loss. It may be noted that an as yet unknown photon–photon interaction has been suggested in which the energy lost somehow reappears as lower frequency radiation, or alternatively, it has been proposed that the energy lost reappears as neutrino pairs resulting from the exchange of a graviton between two photons[3]. The empirical relation first offered by Finlay-Freundlich may be written as:

$$\frac{\Delta\lambda}{\lambda} \cong 0{\cdot}26 \times 10^{-14} \int \rho_{\text{rad}}\, dl \qquad (1)$$

where ρ_{rad} is the energy density in ergs/c.c. of the radiation field traversed by the red-shifted photon, and l is the path length from source to observer. The Finlay-Freundlich hypothesis was attacked strongly when it was made. M. A. Melvin[4] and others have emphasized the seemingly serious astronomical counter-evidence, particularly binary star data assembled by H. L. Helfer[5]. While holding no brief for the relation, Melvin nevertheless revaluated the numerical constant in equation (1) to obtain a better representation of the various data on which Finlay-Freundlich based his relation. The improved version of equation (1) due to Melvin is smaller by 10^{-3}:

$$\frac{\Delta\lambda}{\lambda} \cong 0{\cdot}26 \times 10^{-17} \int \rho_{\text{rad}}\, dl \qquad (2)$$

The proposal made by Ward was to verify or disprove equation (2) by an experiment combining the high sensitivity for resonant absorption associated with the Mössbauer effect with the high-radiation fields in a laboratory device for thermonuclear fusion studies.

Recently two types of experiments have been reported by R. Weiss and L. Grodzins[6] in which the 14·4-keV γ-radiation from a cobalt-57 Mössbauer source was passed through a radiation field. In one the field was that of an x-band RF cavity 1 m long, with a radiation density of 7×10^{-2} ergs/c.c., while in the other γ-rays traversed a 1 m long oven containing helium at 1,300° C, with a radiation density of $2{\cdot}1 \times 10^{-2}$ erg/c.c. In the x-band experiment it was found that the wave-length shift, if any, could not be larger than $-(0{\cdot}4 \pm 5{\cdot}6) \times 10^{-16}$, while in the oven experiment the upper limit was determined to be $+(1{\cdot}5 \pm 5) \times 10^{-16}$.

Weiss and Grodzins point out that these upper limits are substantially less than the original Finlay-Freundlich hypothesis, equation (1), as indeed they are. Thus, equation (1) would predict $\Delta\lambda/\lambda \cong 1{\cdot}8 \times 10^{-14}$ and $\cong 0{\cdot}55 \times 10^{-14}$, in the two cases, and the original hypothesis is certainly disproved. However, equation 2 would give $\Delta\lambda/\lambda \cong 0{\cdot}18 \times 10^{-16}$ and $\cong 0{\cdot}055 \times 10^{-16}$, shifts the values of which lie within the experimental error of the upper limits obtained by Weiss and Grodzins. Since one might better use equation 2 to test this effect, if one is going to make a laboratory test at all, then one is led to the unfortunate conclusion that the otherwise excellent Weiss–Grodzins experiments are not definitive after all.

It is the further purpose of this communication to suggest the possibility of using an optical maser to provide the radiation field through which to pass the photons the wave-lengths of which are to be observed. Line-widths for the 14·4 keV γ-ray from iron-57 have been found experimentally to be $\sim 1{\cdot}8 \times 10^{-8}$ eV (equivalent to a Doppler shift of 0·04 cm/sec or a $\Delta\lambda/\lambda = 1{\cdot}3 \times 10^{-12}$). The radiation field which the optical maser must provide is given by

$$\rho_{\text{rad}} = \frac{1{\cdot}3 \times 10^{-12}}{0{\cdot}26 \times 10^{-17}} f = 5 \times 10^{5}\, f \text{ ergs/cm}^3 \qquad (3)$$

where f is the experimentally desired fractional shift of the γ-ray line-width.

Consider now a light pulse (assume it to emerge uniformly) from a 1/4-in. diameter ruby laser with a power-level of 10 MW, duration 10 mμsec (a commercially available arrangement). The radiant energy is then contained approximately in a cylindrical region of 0·3 cm² area, 300 cm long, with a resultant energy density of $\sim 10^4$ ergs/cm³ (equivalent to $3{\cdot}5 \times 10^4$ °K for black-body radiation). If one settles for observing a shift equal to 1 per cent of the line-width, then path-lengths for the γ-ray through the radiation field of the order of 0·5 cm suffice. If a geometry could be arranged so that the laser pulse and the γ-ray propagation directions were essentially parallel, then shifts of the order of 6 line widths should be observed. Two comments should be made at this point. First, one can envisage a lasor-iron-57 experiment in a hard vacuum, which would minimize extraneous effects of matter. Second, the brevity of the laser pulse may require a very strong γ-ray source or a large number of repetitions of the experiment if one is to achieve a statistically significant result. Thus, let R be the γ-ray counting-rate established without the laser pulses, and suppose that the wave-length shift of the γ-rays passing through the laser field is such as to reduce the counting-rate by a factor F. Suppose further that a repetition-rate of P pulses per sec, each 10^{-8} sec long, is achieved for the optical maser so that the radiation field is on for $10^{-8}\, P$ sec/sec. With the optical maser pulsing, one has after a time T a total count of:

$$(R - FPR \times 10^{-8})\, T \pm \sqrt{RT}\, \sqrt{1 - FP \times 10^{-8}}$$

To achieve a statistically significant change in the count from that obtaining when the optical maser is not used, one requires:

$$10^{-8} \times FP\, \sqrt{RT} \gg 1$$

Thus, if $R = 3{\cdot}7 \times 10^{9}$ counts per second, $F = 1/2$, $P = 10$ pulses per second, one requires:

$$T \gg 9 \times 10^{4} \text{ sec}$$

which in turn involves 9×10^5 operations of the optical maser. Could such experiments be carried out successfully, one would then have a nearly definitive proof or disproof, 'nearly' because one could regard equation 2 as implying an equilibrium radiation field, which the optical maser radiation certainly is not.

Elastic Deformation and the Wear of Electrographite

IT has recently been shown that when electrographite slides repeatedly over a copper surface, the worn surfaces eventually become extremely smooth[1]; the mean angles of inclination of the irregularities on both surfaces are of the order of 2–5°. The maximum slope of an irregularity which can be deformed elastically into the general plane of a surface is inversely proportional to the modulus of elasticity of the material and may be calculated from criteria given by Halliday[2]. For metals the slopes required are usually less than 1°; for carbon and graphitic materials, however, the moduli of elasticity are much lower and the maximum permissible slopes range from about 7° to about 15°. Thus, with carbons, the stresses produced by deformation of the surface irregularities during sliding are likely to be well below the elastic limit, as recently pointed out by Clark, Connolly and Hirst[3]. In these circumstances, it has been suggested that wear might occur by a 'micro-fatigue' process, resulting from repeated applications of elastic stress over the localized regions of real contact[1]. This possibility is directly supported by the experiments described here.

Two polished cylinders of electrographite, 0·25 in. in diameter and 6 in. long, were loaded together at right angles to give nominal point contact at a stress below the elastic limit. The material, supplied by Morganite Carbon, Ltd., was *EG*11 for which the elastic limit in compression is about 25 kg/mm² and Young's modulus of elasticity is about 2×10^{10} dyn/cm². One of the cylinders was then reciprocated at 45° with respect to the other at a speed of 10 cm/s; the apparatus has been described in detail elsewhere[4]. During the first few traversals, the width of the track became constant and polished in appearance, and on changing the load the track width then varied approximately as the one-third power of the load. It may, therefore, be concluded that the deformation of run-in carbon cylinders is predominantly elastic.

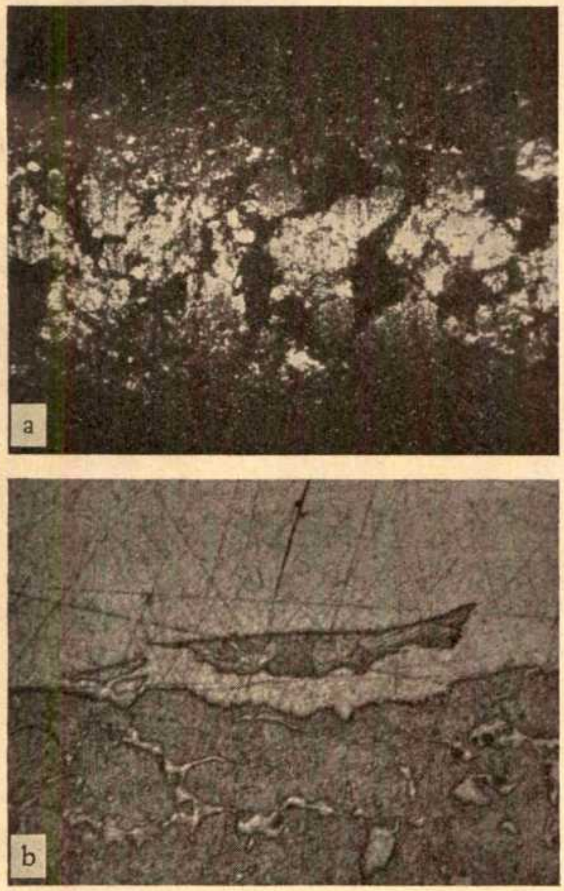

Fig. 1. Surface failure of *EG*11 cylinders after repeated elastic stresses. *a*, Pits on an *EG*11 cylinder after 6 cycles at 18 kg/mm² stress (× *c*. 22); *b*, normal section of a pit produced after 4,500 cycles at 5 kg/mm² stress (× *c*. 450)

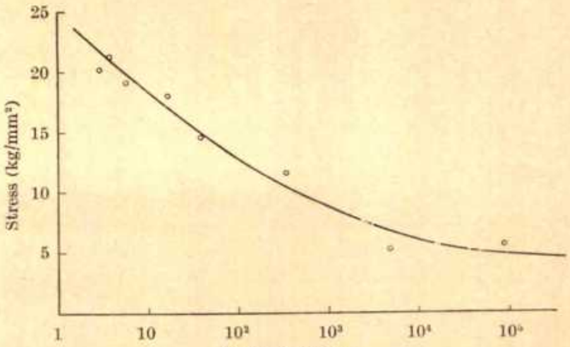

Fig. 2. Variation of the number of cycles to failure with stress for *EG*11 crossed cylinders

After a critical number of traversals of the cylinders at any one load, the surfaces within the band of contact began to break-up, leaving a number of shallow pits. An example obtained at the relatively high stress of 18 kg/mm² is shown in Fig. 1*a*, and a section through a typical pit obtained at a lower stress, 5 kg/mm², is shown in Fig. 1*b*. It may be noted that the fragment detached is in the form of a flake, and the size of the flakes decreased slightly with decreasing stress. The relationship between the mean Hertzian stress and the number of traversals required to initiate surface damage is shown in Fig. 2. The critical number of traversals increases very markedly as the stress decreases and the relationship is very similar to one characteristic of a fatigue failure.

When a carbon brush slides continuously on a metal slip-spring, the magnitude of the elastic stresses at the localized regions of real contact will depend on the number, size and shape of the irregularities supporting the load. The mean radius of curvature of the irregularities present on the surfaces of an *EG*11 brush and a copper slip-ring, after several hours of sliding at a load of 1 kg and a speed of 1,800 cm/s, has been estimated from Talysurf profiles to be of the order of 0·7 cm. The surface of the ring was largely covered by a transferred film of carbon and the wear debris was in the form of flakes, varying in size from a few hundred Angstroms upwards. If the whole of the load is assumed to be supported on a single pair of hemispherical contacts of carbon, the mean Hertzian surface stress will be about 4 kg/mm². At these low stresses, Fig. 2 shows that the critical number of contacts required to produce a wear particle will be very large, of the order of 10^6, and also depend very markedly on the magnitude of the stress. The fact that the rate of wear is proportional to the load[1] suggests that the main effect of an increase in load must therefore be to increase the number of regions of contact rather than their size. Measurements of the variation with load of the electrical constriction resistance between run-in surfaces of carbon have confirmed this conclusion.

The formation of wear particles after a critical number of repeated contacts between surface irregularities is also known to be a feature of the severe wear process of metals, for example, 60/40 brass on hardened steel[5]. The rates of severe metallic wear, however, $\simeq 10^{-7}$ cm³/cm/kg for brass on steel, are usually several orders of magnitude greater than those of carbons in the same conditions of sliding, $\simeq 10^{-10}$ cm³/cm/kg for *EG*11 on copper. The slopes of the irregularities generated on metal surfaces during severe wear are of the order of 1°, and the localized stresses must therefore be near to, or even greater than, the elastic limit. This suggests that the relatively high rates of wear of metals are a direct consequence of the greater stress on the surface irregularities. At stresses near to the elastic limit, or when the deformation is plastic, the number of cycles required to cause failure will be very much less than when the stresses are well below the elastic limit. Wear caused by micro-fatigue of the surface irregularities during repeated contacts is therefore not necessarily restricted to carbons alone; it may be equally important for metals.

Path Integral Formulation of Relativistic Quantum Mechanics

FEYNMAN[1] has given a path integral formulation of non-relativistic quantum theory which he showed to be completely equivalent to that given by Schrödinger's equation. Although the same can be done for the existing relativistic theory[2], it cannot be unique because the latter is not consistent. The fundamental dilemma is[3]: either one adopts unitarity and all the divergences that go with it, or else admits non-Hermitian interactions and thus the non-conservation of probability.

Previously I gave a group-theoretical argument[4] in favour of the latter. Since the group in question, the exceptional Lie group F_4, is quite complicated and its infinite representations have not yet been investigated, the path integral approach is an important step toward finding not only a physical interpretation but also a representation theory of F_4.

Consider paths $z(\tau)$ in a relativistic phase space E_8 in which a geodesic corresponds to a classical relativistic oscillator. The quantum version of this problem gives, according to Huygens–Feynman principle, for the wave amplitude:

$$\psi(z/z') = \sum_{\omega} e^{i \int_{z}^{z'} z_\omega^2(\tau)\, \mathrm{d}_\tau} \qquad (1)$$

where paths ω are dense in some measure space Ω.

Such an oscillator is a model of a particle in the sense that it has a relativistic invariant which can be associated with a proper mass. But this, let us call it $k_0^2 s$, has the curious property that it depends on the space-time interval s so that if taken on the light cone it is nothing or alternatively if taken as an expectation value inside the cone it is infinite. An unambiguous result can only be obtained if one admits a metric or Lagrangian function $\mathscr{L}$, with a non-Hermitian interaction, say of the form $\mathscr{L} = (1 + i\sigma/2)z^2$, then the expectation value:

$$< k_0^2 s > = \int_0^\infty k_0^2 s e^{-\sigma k_0^2 s^2} \mathrm{d}s \Big/ \int_0^\infty e^{-\sigma k_0^2 s^2} \mathrm{d}s = k_0/(\pi\sigma)^{\frac{1}{2}} \qquad (2)$$

while the expectation value of the Laplacian of probability density is a small but non-vanishing quantity $\approx k_0^2$.

Thus σ is a very small number (the reciprocal of the cosmological constant), and to interpret it consider the following generalization of equation (1). Let $\mathscr{L} = (z_a - iz_\omega)^2$, where α is from a measure space $A \neq \Omega$. This makes it possible that the correlation $< x_a x_\omega >$ exists and equation (1) becomes the condition that it shall have the minimum value σ. If $A = \Omega$ we have essentially a phase space version of the Wiener–Siegal[5] α-representation of existing theory.

Conditions which determine A, Ω (or their generalizations) now depend on the structure of F_4. The basic fact is the principle of triality, namely F_4 acts on a vector space $M_{24} = E_8 + S_8 + S_8{}^*$ leaving invariant a trilinear form $f(z, \psi, \psi^*)$ which is also invariant under cyclic permutation P of the sub-spaces. In view of this I adopt the parametrization:

$$z_\mu = \theta_\mu^2\ (M\tau; u) \qquad (3)$$

where θ_μ runs over the 8 hyperelliptic theta functions[6] of genus three and zero characteristic. Then $u = (u_1, u_2, u_3)$ are local co-ordinates on a three-dimensional generalized Kummer surface K_3 in E_8 which, in certain neighbourhoods of u, will be equivalent to the light cone. Take $P = ST$, the operation of the modular group given by $S\tau = \tau + 1$, $T\tau = -1/\tau$.

Now suppose:

$$u = u_\gamma\ (\tau) = u_a\ (\tau) + iu_\omega(\tau) \qquad (4)$$

is a complex Wiener process in which, however, the real and imaginary parts, as above, are not independent, so that the equation for the diffusion of the probability $Pr(u/\tau)$ is not self-adjoint. If the matrix M in equation (3) is such that the θ's satisfy the same equation, then $(M; A, \Omega)$ can be considered a consistent representation in a physical sense.

To determine $(M; A, \Omega)$ uniquely requires consideration, among other things, of the cohomology structure of F_4. The essential result[7] here is that the degrees of the invariant operators (commuting with all others) are of the form $(g_i + 1)$, where g_i are the primes modulo 12. It thus appears that the determination depends on a special relation which exists between algebraic number fields, having g_i as singular divisors, and the construction of A, Ω which involves an infinite subdivision of the range of τ.

Isotropic Exchange Integral for Cupric Acetate Monohydrate Crystals

MOOKHERJI[1] from his magnetic studies on cupric acetate monohydrate crystal predicted that there is some sort of exchange interaction between adjacent copper atoms. But in the absence of either crystallographic data or diamagnetic dilution data he could not say whether the interaction forces were of Kramers' super-exchange type acting through intermediate oxygen atoms, or whether direct spin interaction occurred. Later, from an examination of anomalous behaviour of cupric acetate monohydrate towards magnetic susceptibility and paramagnetic resonance absorption, Bleaney and Bowers[2] concluded that there is some form of strong coupling between unpaired electrons on adjacent copper atoms through exchange forces. Van Niekerk and Schoening[3] from X-ray analysis showed that cupric acetate monohydrate is a new type of complex having the formula $Cu_2(CH_3COO)_4.2H_2O$. The Cu–Cu distance is 2·64 Å, showing that there is direct interaction between the copper ions, because the distance for super exchange of Kramers type (Cu–Cu distance) should be of the order of 4 Å. Figgis and Martin[4] have shown that exchange integral $J = 1 \cdot 6\ kT_c$, where T_c is critical temperature at which $\Delta\chi/\Delta T = 0$ (χ being the gram molecular susceptibility).

We have measured the principal magnetic susceptibilities of single crystals of cupric acetate monohydrate from 300° K to 90° K. Room temperature values for the principal anisotropies were obtained by the method of Krishnan and Banerji[5] and the principal susceptibility in a convenient direction by a micro-balance as devised by Neogy and Lal[6]. Temperature variation of the susceptibilities was studied by using a cryostatic device as devised by Bose[7].

Our mean molar susceptibility values are in good agreement with those of Figgis and Martin[4], but below 200° K these values deviate considerably from those of Guha[8] and Foex *et al.*[9]. Our measurements show that the critical temperature T_c for the three principal magnetic axes of the crystal is the same and is equal to 271° K. This brings out the interesting point that the exchange integral is isotropic and equal to -299 cm^{-1}.

The value of J as given by Bleaney and Bowers (*loc. cit.*) from paramagnetic resonance data varies from -315 cm^{-1} at room temperature to -255 cm^{-1} at 90° K, while Abe and Shimada[10] suggest a constant J value. In the absence of any specific thermal expansion data or X-ray data at a low temperature it is rather difficult to say anything definite about the variation of J with temperature. Bose *et al.*[11] from their work on several cupric salts came to the conclusion that thermal variation in the crystal field makes the g values depend on temperature. We also find that the angle between the two paramagnetic units in the unit cell of the crystal changes with temperature, indicating a change of crystal field. However, theoretical susceptibility values, from the expression due to Bleaney and Bowers[2], on the assumption of a constant value of J but different values of g at different temperatures, agree well with our experimental values.

CHEMISTRY

Vibrational Spectra and Structure of the Tricyanomethanide Ion $C(CN)_3^-$

THE tricyanomethanide ion $C(CN)_3^-$ has been known for some time[1], but its chemistry has only recently been investigated[2], and its vibrational spectra and structure have not been previously reported. We give here a summary of our recent investigation of the infra-red and Raman spectra of the potassium salt of this ion.

The infra-red spectrum was investigated both in solution and in the solid state over the range 375–2,500 cm^{-1}. For the solution spectra the following solvents were used: *cyclo*hexane (375–600 cm^{-1}), benzene and carbon disulphide (500–600 cm^{-1}), water (800–2,500 cm^{-1}), ethanol (900–2,150 cm^{-1}) and methanol (2,100–2,250 cm^{-1}). The solid-state spectra were obtained in 'Nujol' (500–2,250 cm^{-1}) and in potassium bromide disks (375–2,500 cm^{-1}). The Raman spectra were obtained from aqueous solutions. The solution spectra were very simple, but in the spectra of the solid many of the bands were split. For structural analysis the infra-red and Raman spectra based so far as possible on solution work only are given in Table 1.

Table 1

Infra-red	—	2,175 *vs sh*	1,250 *s sh*	967 *w br*	—	610*	567*	—		cm^{-1}
Raman	2,225 *vvs sh* *pol*	2.175 *vvs br* *dp*	1,242 *vvw diff* *dp*	967 *vvw* *wpol*	658 *s sh* *pol*	610 *vw* *dp*	—	478 *vvw* ?	162 *s vdiff* *dp*	cm^{-1}

* Solid state

Two structures are possible for the ion, a planar one (D_{3h}) or a pyramidal one (C_{3v}). The selection rules for the two structures are:

D_{3h} : in-plane : $2a_1'$ ($R.p$), $1a_2'$ (inact.), $4e'$ ($R.dp.$ i.r.)
out-of-plane : $1e''$ ($R.dp$), $2a_2''$ (i.r.)

C_{3v} : $4a_1$, ($R.p.$ i.r.), $1a_2$ (inact.), $5e$ ($R.dp.$ i.r.)

As D_{3h} requires seven Raman active fundamentals and six infra-red active fundamentals with only four coincidences, whereas C_{3v} requires nine infra-red and Raman active fundamentals all coincident, the vibrational spectra should enable the two possibilities to be distinguished.

The spectra quoted here support the D_{3h} configuration. Three Raman lines (2,225, 658 and 478 cm^{-1}) have no counterpart in the infra-red. As two of these are strong, sharp and polarized they are the a_1' frequencies and the third is the e'' frequency. One infra-red band has no Raman counterpart and is thus class a_2''. The other non-coincident infra-red band would be expected to lie below 375 cm^{-1}, the limit of the present investigation. There is, however, a third, weakly polarized Raman line at 967 cm^{-1} which has a coincident infra-red band. If the D_{3h} structure is accepted this cannot be a fundamental, but it can be satisfactorily explained as the first overtone of the e'' fundamental (2 × 478 = 956) which will be both infra-red and Raman active ($(e'')^2 = a_1' + e'$). This leaves three coincidences between the Raman and infra-red spectra above 375 cm^{-1}, namely 2,175, 1,250 and 610 cm^{-1}, and these are three of the e' fundamentals. The fourth e' fundamental is the Raman frequency 162 cm^{-1}, which is outside the infra-red region studied. In addition to this satisfactory correlation of the spectra it should be noted that although —C≡N vibrations are always intense the infra-red spectrum most certainly contains only one —C≡N frequency (2,175 cm^{-1}) whereas the Raman spectrum contains two (2,225 and 2,175 cm^{-1}), and that the infra-red band is coincident with the depolarized Raman line. This pattern of —C≡N frequencies is, in itself, strong evidence for the planar structure.

We thank Dr. W. O. George and Dr. D. Steele for help in obtaining infra-red spectra. One of us (R. A. G. C.) acknowledges leave of absence from Shell Research, Thornton, to work at Swansea.

Reactions of Sulphoxides with Phosphorus Compounds and Reactive Organic Halides

Dimethyl sulphoxide is known as an oxidizing agent for organic halogen derivatives[1] and certain aromatic methyl compounds[2]. Reactions of sulphoxides with acid anhydrides give carboxylic acids and acyl derivatives of sulphides[3]. Organic sulphoxides have attracted attention as ligands in co-ordination compounds; but silicon halides and diphenyl sulphoxide give halogenated diphenyl sulphides and silicon oxychlorides and/or silica[4]. Lappert and Smith[5] investigated addition compounds of sulphoxides with boron, silicon, and tin halides, and reaction with boron trichloride or silicon tetrachloride gave a boron oxychloride-chloromethyl methyl sulphide addition compound, or silica and chloro-substituted sulphides.

Our work with phosphorus compounds and organic halides is summarized in equations (1–6).

$$Ph_3P + Me_2SO \rightarrow Ph_3PO + Me_2S \quad (1)$$

$$Ph_2PCl + 2Me_2SO \rightarrow Ph_2PO_2H + Me_2S + MeSCH_2Cl \quad (2)$$

$$PhPCl_2 + 3Me_2SO \rightarrow PhPO(OH)_2 + Me_2S + 2MeSCH_2Cl \quad (3)$$

$$N_3P_3Cl_6 + 6Me_2SO \rightarrow N_3P_3O_6H_6, MeSCH_2Cl + 5MeSCH_2Cl \quad (4)$$

$$N_3C_3Cl_3 + 3Me_2SO \rightarrow N_3C_3O_3H_3 + 3MeSCH_2Cl \quad (5)$$

$$PhCOCl + Me_2SO \rightarrow PhCO_2H + MeSCH_2Cl \quad (6)$$

Dimethyl sulphoxide oxidizes certain tervalent phosphorus compounds to the quinquevalent state, when the by-product is dimethyl sulphide (1), or causes replacement of chlorine by hydroxyl in quinquevalent compounds, when chloromethyl methyl sulphide is formed (4). A combination of these processes is observed with diphenylchlorophosphine (2) and phenyldichlorophosphine (3). Hexachloro*cyclo*triphosphazatriene gives a moisture-sensitive chloromethyl methyl sulphide addition compound of the hydroxyoxophosphazane (4), and the product of a similar reaction with octachloro*cyclo*tetraphosphazatetraene gives the dihydrate of tetrakis(hydroxyoxo)*cyclo*tetraphosphazane[6] on mild treatment with water.

Cyanuric chloride (5) and benzoyl chloride (6) are converted to cyanuric acid and benzoic acid respectively. It seems likely that this reaction will have wide applications to inorganic and organic compounds containing reactive halogen atoms.

Diphenyl sulphoxide is less reactive than dimethyl sulphoxide but the same pattern of behaviour is observed.

We thank the Agricultural Research Service of the U.S. Department of Agriculture for financial support under Public Law 480.

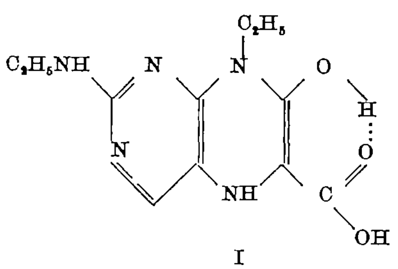
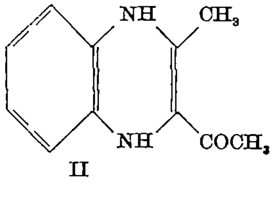
Structures of Sepiapterin and Isosepiapterin

Sepiapterin and isosepiapterin are yellow, yellow-fluorescent compounds which occur in *Drosophila melanogaster* and accumulate in the sepia mutant. They are believed to be closely related 2-amino-4-oxo-6-acyltetrahydropteridines, the acyl group in isosepiapterin being propionyl and in sepiapterin, lactyl. However, there has been some controversy concerning the location of the hydrogen atoms on the pyrazine part of the molecule. Forrest[1] favoured a distribution of the hydrogens on the 5 and 8 positions largely by analogy with the yellow 5,8-dihydro compounds (for example, I) synthesized by Pfleiderer and Taylor[2], and with the 5,8-dihydro structure assigned to the red dihydroquinoxaline (II) on the basis of its nuclear magnetic resonance spectrum by Barltrop, Richards and Russell[3].

Nawa[4], on the other hand, considered the 7,8-dihydro structure more probable because of his



I



II

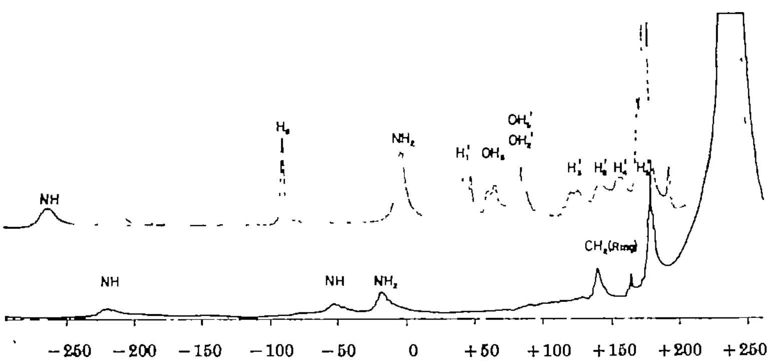


Fig. 1. The nuclear magnetic resonance spectra of isosepiapterin (——) and guanosine (ref. 6) (– – –) measured in dimethylsulphoxide, with toluene as an internal standard. Chemical shifts (c.p.s.) are converted to the figures quoted in the text by dividing by 60 and subtracting 6·86

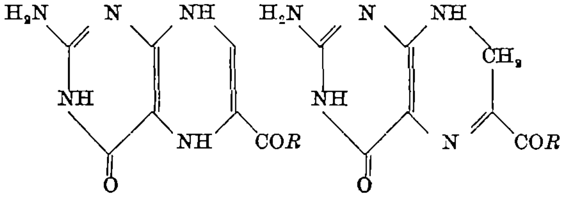
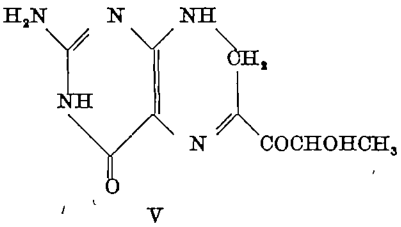
isolation of 7,8-dihydroxanthropterin as a degradation product from sepiapterin.

A direct test of these alternatives has now become possible using nuclear magnetic resonance spectroscopy. By inspection of the two possible formulæ (III and IV) it can be seen that III has one amino-group and three imino-groups, whereas IV has one amino-group and two imino-groups.



III IV

The nuclear magnetic resonance spectrum of isosepiapterin dissolved in dimethylsulphoxide (approx. 0·5 M; solution is supersaturated (Fig. 1)) reveals the presence of 3 peaks which can be ascribed to protons attached to nitrogen. These can be further resolved by comparison with the spectrum of guanosine[5,6], in which the pyrimidine ring is chemically identical with that of isosepiapterin. Thus, the peak at − 7·16 p.p.m. from tetramethylsilane (calc.) corresponds to the amino-group and that at − 10·56 p.p.m. from tetramethylsilane corresponds to the imino-group in the pyrimidine portion of the molecule. The third peak, which occurs at − 7·76 p.p.m. from tetramethylsilane (calc.), must then correspond to the imino-group or groups in the pyrazine ring. Since the area underneath this peak is approximately half the area below the amino-peak and about equal to that below the imino-peak assigned to the pyrimidine ring, the conclusion is inescapable that there is only one imino-group in the pyrazine ring. Hence, the structure of isosepiapterin must be IV (R = CH_2CH_3). In addition, the peak at − 4·53 p.p.m. from tetramethylsilane (calc.) may be ascribed to the ring methylene group present in the 7,8-dihydro formulation but absent from the 5,8-dihydro structure.



V

Although the peaks in these spectra are broad, presumably due to solvent interaction with the protons attached to nitrogen, and their height is not great due to solubility limitations, the observations are quite unambiguous. An advantage of this technique is that no chemical reactions are performed on the material under investigation; therefore, any possibility of isomerization is eliminated.

Since isosepiapterin and sepiapterin have very similar chemical properties and superimposable absorption spectra, the structure of sepiapterin, by analogy, must be 2-amino-4-oxo-6-lactyl-3,4,7,8-tetrahydropteridine (V).

We thank Mrs. Lila Gatlin and Dr. J. C. Davis for the nuclear magnetic resonance spectra and for advice on their interpretation.

Ionization Potential of NO_2

THE ionization potential of NO_2 has been the subject of controversy for some time, and a satisfactory answer has not yet been given.

The spectroscopic and photo-ionization results lead to the following possible values: 9·78 eV[1], 11·3 eV[2], 12·3 eV[3]. Recently, Tanaka and Irsa proposed another higher value at 18·87 eV[4]. These different results probably correspond to different excited states of the ion.

On the other hand, electron impact results show a great disparity, varying from 9·91 eV to 13·98 eV (refs. 5–7), and a recent direct determination by Kiser[8] leads to 11·27 eV. I had previously[7] suggested that the indirect electron impact value 9·91 eV deduced from the appearance potential of NO_2^+ from nitromethane[5,7] corresponded to the ground ionic state of NO_2^+, which is linear, whereas the directly determined high value, 13·98 eV, would refer to the bent excited state, in accordance with the Franck–Condon nature of the ionization process.

If such is the case, one would expect the indirect value to be always the same, whatever the parent molecule. We therefore determined the appearance potential of NO_2^+ from ethyl-nitrate $C_2H_5ONO_2$. The mean result of three measurements, to which three different methods of estimating ionization potentials were applied (vanishing current, modified Warren's method, semilog method), was AP (NO_2^+) = 11·40 ± 0·12 eV.

Using $\Delta H_f(NO_2)_g$ = 8·03 kcal/m[9], $\Delta H_f(C_2H_5O)_g$ = − 8·5 kcal/m[10], and ΔH_f $(C_2H_5ONO_2)_g$ = − 36·8 kcal/m[11], one calculates D $(C_2H_5O - NO_2)_g$ = 36·33 kcal/m. This result may be combined with the appearance potential of NO_2^+ according to the usual way:

$$AP(NO_2^+) \geqslant D(C_2H_5O - NO_2) + IP\,(NO_2)$$

and leads to the result $IP(NO_2) \leqslant 9{\cdot}93$ eV.

This is exactly the same value as obtained from nitromethane. Although the perfect agreement probably is fortuitous, it may be considered as a further confirmation of the value of the lowest ionization potential of NO_2, in agreement with the lowest photoionization result, as well as with our previous interpretation.

BIOCHEMISTRY

Purification of Streptolysin O

Among the numerous extracellular enzymes and toxins elaborated by the different strains of groups *A*, *C* and *G Streptococci*, streptolysin *O* has been investigated very extensively. A number of reports[1–3] have suggested the close relation existing between streptolysin *O* and the damage occasioned by *Streptococcus* in several infections especially in rheumatic fever. The different stages of discovery and study of biological and physico-chemical properties of streptolysin *O* have been reviewed thoroughly by Rammelkamp and Dingle[4], Herbert and Todd[5] and Bernheimer[6].

In the past two decades, many attempts have been made to purify streptolysin *O*, and more or less partially purified preparations were obtained[7–12]. In this communication a new method of purification is outlined. The details will be published elsewhere[13]. A preparation of very high specific activity has been obtained showing a main single diffusion line against anti-streptolysin *O* sera and an apparently homogeneous behaviour in the ultracentrifuge.

The crude streptolysin *O* is obtained after 24-h culture of the strain *A* 78 (Lancefield group *A* Griffith type 3, Institut Pasteur Collection) grown on the medium described by Wahl and Meyer[14]. The titre obtained was 80–160 minimum hæmolytic dose per ml., or 5–10 combining units per ml. The crude streptolysin *O* is concentrated ten times either by ultra-filtration through a parlodion membrane, as described by van Ramshorst[15], or by successive freezing and thawing. The concentrated dark-coloured fractions of streptolysin *O* which thaw before water show a very high toxic titre.

We add solid sodium chloride (20 g/100 ml. to the concentrated streptolysin *O*) and the toxin is cooled overnight at −10° C. Cooled trichloroacetic acid 2 M is added slowly at −10°. When *p*H 4 is reached, a dark and sticky precipitate is obtained. 2 h later the suspension is centrifuged at 0° C, the supernatant is discarded and the precipitate dissolved in the minimal volume of 0·01 M KH_2PO_4–K_2HPO_4 buffer (*p*H = 6·4) and dialysed two days against the same buffer. The solution obtained (fraction P_1) is precipitated by solid ammonium sulphate up to 68 per cent saturation at 0° C. The supernatant is discarded, the precipitate is dissolved in the buffer and after dialysis the solution (P_2) obtained is adsorbed on DEAE – cellulose DEAE – cellulose 5 per cent + cellulose 10 per cent in 0·02 M phosphate buffer). The brown pigments are firmly adsorbed and after centrifugation and several washings with the buffer and recentrifugations the pooled clear-yellow supernatant (P_3) is precipitated by solid ammonium sulphate up to 68 per cent saturation at 0° C. The precipitate is dissolved in 0·01 M buffer and dialysed two days. The solution P_4 obtained is passed through a DEAE – cellulose column (2 cm × 30 cm) and eluted by solutions of KH_2PO_4/K_2HPO_4 ranging from 0·003 to 0·1 M.

Table 1

Fraction	Specific activity (combining units/mg N)	Yield (per cent)	No. of antigenic constituents*
Crude toxin	8·3	100	9
Concentrated toxin	5·0	99	9
P_1	123	84	8
P_2	411	55	6
P_3	—	40	—
P_4	784	30	5
P_5	3,300	15	2 (+1)
P_6	—	6	1 (+1)†
P_7	6,400	3	1 (+1)†

* Estimated by immunodiffusion against a serum prepared by immunization of horses with crude formol detoxified streptococcal toxin.

† The two last preparations P_6 and P_7 contain one major antigenic constituent and a minor one (+1), only visible when a very large excess of antigen is used in the immunodiffusion test.

— Not done.

The purest fraction obtained (P_5) is eluted at 0·01 M and is precipitated by solid ammonium sulphate (55 per cent saturation). The precipitate is dissolved in a 0·02 M phosphate buffer and the solution (P_6) is refractioned by ammonium sulphate. The 'purest' fraction, P_7, is obtained by precipitation between 45 and 55 per cent ammonium sulphate (see Table 1 for the purification method). The P_7 preparation is a colourless limpid solution with a specific

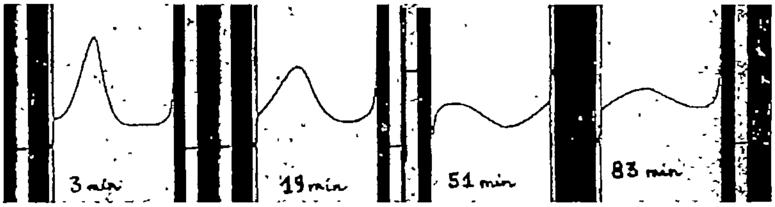

Fig. 1. Ultracentrifugation of streptolysin *O* (preparation P_7). 59,780 r.p.m. 'Spinco' analytical centrifuge photographs taken after 3, 19, 51 and 83 min (synthetic boundary cell)

activity (when expressed in combining units/mg nitrogen) 2,130 times higher than the crude streptolysin *O*. The ultra-violet absorption spectrum presents a maximum at 2750 Å and a minimum at 2550 Å. The ratio of optical densities at these wave-lengths is low (1·17). The fraction of P_7 has not yet been ultracentrifuged for the determination of its sedimentation characteristics. However, the sedimentation in phosphate buffer at 20° of fraction P_8 (1,000 times purified, showing two major lines in gel precipitation) presents an almost single symmetrical peak in the ultracentrifuge (synthetic boundary cell). Fig. 1 illustrates the sedimentation pattern, which shows a very strong diffusion of the preparation and a sedimentation coefficient lower than 1. This result implies a molecular weight of streptolysin O certainly lower than 10,000. More precise experiments are now being undertaken to determine with more accuracy the molecular weight of purified fraction P_7.

Quantitative Extraction of Acid-soluble Human Skin Collagen with Age

It has been shown that the acid-extractable collagen from the skin decreases with age (see review by Harkness[1]), but no quantitative data are available in man or animals which permit correlation of extractable collagen with growth, development, and age over the entire life-span. This communication presents and discusses such findings in man.

Specimens of skin were obtained at autopsy within 8 h of death from accident cases or from patients suffering from non-debilitating diseases. Total body skin was removed from fœtuses and new-borns. In the remainder, strips were excised from the abdomen. In no specimen was gross or microscopic evidence of decomposition present. Each specimen was treated individually and extraction was carried out immediately. The epidermis and subcutaneous fat were removed by scraping with a sharp blade and the wet weight determined. The weight of the dermis was never less than 3 g, usually 10–80 g. The extraction method was that used by Gallop[2] and Boedtker and Doty[3] on ichthyocol, but the citric acid extract was dialysed against water instead of dibasic sodium phosphate. All extractions were limited to a 48-h time-interval as such solutions have been shown by several investigators to contain a homogeneous molecular species[2–4]. After Kjeldahl digestion, the concentration of soluble collagen nitrogen was determined by the Conway diffusion technique[5]. To calculate the dry weight of collagen, a value of 18·2 per cent nitrogen previously obtained from the amino-acid data of human skin fœtal collagen[4] was used. Reproducibility on duplicate determinations by the Conway procedure was ± 2 per cent. Results were expressed as milligrams of soluble collagen per gram of wet dermis. It has been shown[6] that the percentage of water in the skin of human infants of age 3–6 months is similar to that of adults. During the preparations, the solutions were never exposed to temperatures above 5° C.

The extracted molecule has been characterized previously for the human fœtus and new-born[4]. Similar values for the sedimentation coefficient, 3·10*S*, limiting viscosity number (1,350) and temperature of denaturation, 36° C, established for the new-born were also found in representative samples in the older age-group.

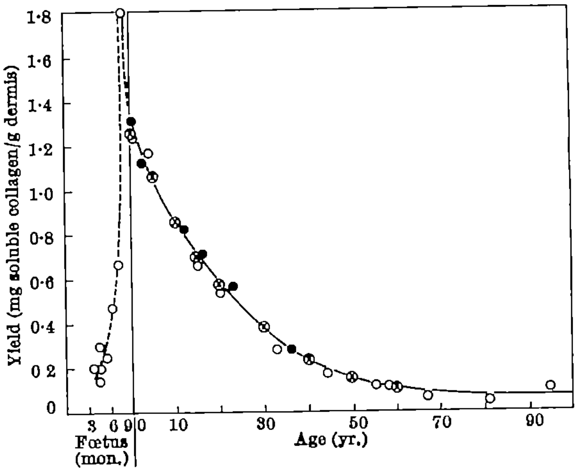

Fig. 1. Yield of citric acid-soluble human skin collagen with age. ●, Specimens obtained from accident cases; ○, specimens obtained from patients with non-debilitating diseases; ⊗, calculated values using equation 1

Fig. 1 shows the yield of citric acid-soluble human skin collagen with age. The yield is very low in the young fœtuses. This may only be relative, reflecting the increased cellularity of the dermis, which contains more fibroblasts and relatively less collagen in the young fœtuses than in the older specimens. As the cellularity decreases during fœtal development, the yield increases and reaches a maximum several weeks prior to birth and then falls precipitously. The extractable collagen decreases during successive decades to the age of 60, and thereafter is essentially constant. The following relationships of age and extractable collagen are apparent: puberty (age 13) slightly more than one-half that of the new-born; menopause (age 45), approximately one-seventh; age 60 and over, approximately one-fifteenth.

The dependence of extractable collagen on age was found to follow a two-parameter relationship in the interval 0–60 years:

$$N = N_0 e^{-A/k} \qquad (1)$$

where N is the extractable collagen (mg) per gram of wet dermis; N_0 is a constant of 1·3 mg per gram of wet dermis which is the extractable collagen at zero age; A is the age of the patient in years; k is a constant equal to 23·5 years. The value of N at age k is N_0e^{-1}, where e is the base of the natural logarithm.

Equation (1) expresses N as a function of A. By use of the inverse function, age may be estimated by measuring N. In Fig. 1, the theoretical curve is superimposed on the curve drawn from the experimental data and the deviation of the theoretical from the experimental curve does not exceed 5 per cent.

Equation (1) describes the course of a process analogous to typical first-order reactions of chemical physics, and this equation may be derived statistically. The *in vivo* transition of citrate soluble collagen to the insoluble form through the formation of intermolecular cross-links follows a similar exponential course in the interval between 0 and 60 years, and may be a statistical process independent of known rate-regulating mechanism.

The relationship (equation 1) is probably characteristic of all collagen regardless of source, and the inherent 'ageing' parameters are embodied in the constants N_0 and k. Exceptions to this exponential law have been observed in patients with chronic liver disease and other prolonged debilitating disorders and also in patients treated with steroids. These exceptions are now being investigated. The physiological implications of this first-order process during growth, development and ageing are unknown. Further quantitative studies of collagen are necessary to find out if different physiological characteristics of collagen follow this exponential relationship as a function of age.

Ultra-violet)Absorption Spectra of Simple Aliphatic Guanidines

ACCORDING to Gillam and Stern[1], light absorption of the azomethin bond (=C=N—) possessing a nitrogen chromophore has so far not been examined adequately in the aliphatic series. In the case of amino-acids, the significance of the region below wave-length 220 mμ, which had been neglected, was pointed out by Saidel *et al.*[2].

Recently, on examining the infra-red and ultra-violet spectra of primycin[3], an antituberculotic antibiotic of Sakaguchi-positive nature, the presence of the azomethine group was shown by the ultra-violet maxima at 205–210 mμ of the basic chromogenes. We pointed out also the effect of the applied solvent systems on absorption values. The guanidine derivatives of biologically important effect (arginine, creatine, glycocyamine, etc.) are known to possess at most only an end absorption. Therefore, it seemed interesting to develop further the experimental conditions on the basis of which aliphatic guanidines can directly be determined at their absorption maxima (Fig. 1). The pre-requisites of this determination are as follows. (1) No changes should occur in the wave-lengths position of the maxima (λ_{max}) established in three different concentrations of the tested compounds. (2) The relative error (± Δ per cent) of the 'E-values' of the dilution series measured at the constant maxima should range within defined error limits, that is, these values should obey Beer's law. On choosing the solvent system in a satisfactory way, these conditions could be fulfilled in each case.

The data of absorption were established with a Beckman *DU* spectrophotometer (model 2400), by the method described earlier[3]. The absorption spectra were plotted as logarithmic values of the molecular extinction coefficient, $\log \varepsilon = \log\left(E\times\frac{M}{c\times l}\right)$, where $E = \log I_0/I$; c = g/l.; and l = 1 cm/silica cuvette.

External factors, such as solvents, errors due to dilution, stray radiation of the region of wave-length below 205 mμ, and further certain inner factors such as the molecular state of strongly dissociated guanidine bases and of their derivatives of amphoteric nature, respectively, interfere with and affect, respectively, the determinations to a marked extent. Arginine, in an aqueous alcoholic solution (*BEW*) with λ_{max} at 201 mμ, did not obey Beer's law. Therefore, our further investigations were adjusted to a so-called 'arginine test'. In the development of the absorption maximum of arginine, the H⁺ ion concentration of the solvent played an appreciable part. In our measurements, standard aqueous buffer solutions of *p*H values controlled by a *p*H-meter (up to ± 0·05 *p*H) or preferably aqueous alcoholic buffer solutions (prepared from BuOH : EtOH : H_2O in a ratio of 1 : 1 : 2) denoted briefly as *BEW*-buffer were used[3]. The maximum values and the absorption intensity values of both arginine and other guanidines

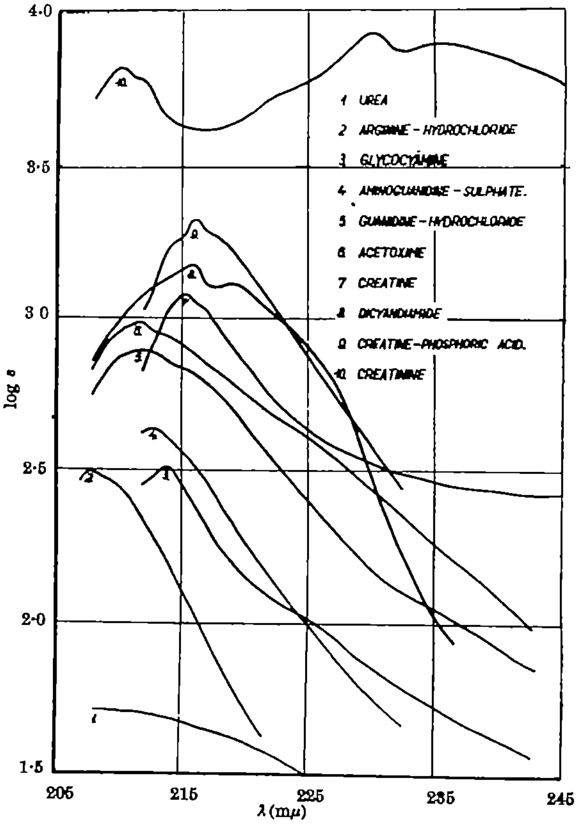

Fig. 1

proved to vary rather sensitively with *p*H values. In aqueous buffer solvents, arginine showed only at the *p*H values 7·0 and 10·5 maxima of high intensity but over 10 per cent error limit, at wave-lengths below 205 mμ. A similar case was also observed with the system's alcoholic *BEW*-buffer, however, with the difference that at *p*H value 8·05 it was possible to observe the highest position of constant maximum of arginine experienced, at 208 mμ as well. The values of the relative error of dilution sequences measured at 208 mμ ranged within 1–3 per cent, in a fairly reproducible way.

On examining the buffer capacity of the solvents, it was found that, similarly to the observations made at the amino-acids[3] : "the choice of a suitable concentration of a particular buffer was important". The spectrum of arginine (208 mμ) established in a *BEW*-buffer (*p*H 8·05; 0·025 M) served as a basis for comparison. On applying the solutions of the same buffer substance of gradually increasing concentration (0·003–0·3 M) as solvents, the spectra and the dilution series were repeatedly established. On raising the concentration of buffer solution, the wave-length values of the maxima 204–208 mμ disclosed a 'bathochromic', while those of absorption intensity after an initial rise a 'hypochromic', shift. Also the relative error of the dilution series diminished. On taking the necessary precautions, the absorption spectra (Fig. 1) of 8 aliphatic guanidine derivatives were established by us at three different dilutions (c = 0·01–0·1). In a 0·025-M *BEW*-buffer (of *p*H 8·05), the following constant selective maxima were observed, λ_{max} (ε_{max}) : arginine, hydrochloride 208 mμ (331); guanidine, hydrochloride 212 mμ (790); dicyandiamide 216 mμ (1,495); creatinine 210 and 230 mμ (6,330 and 8,020). At the same time, urea showed an end absorption, while acetoxime disclosed at 212 mμ (950) values characteristic of its azomethine group. In a 0·1-M *BEW*-buffer, in turn (of *p*H 8·05), the following measurable constant maxima appeared: aminoguanidine, sulphate 213 mμ (289); glycocyamine 214 mμ (310); creatine 215 mμ (1,192); creatine phosphate 216 mμ (2,065). The dilution series of the above-mentioned compounds obeyed Beer's law within an error limit of 2–5 per cent.

We thank Dr. L. J. Saidel (Chicago, Illinois) for the samples of guanidines.

Isolation of Aspartic Acid Activating Enzyme from Bakers' Yeast

IN the investigation of amino-acid activating enzymes in various tissues, aspartic acid activating enzyme has been found[1,2]. Although several other activating enzymes have been purified[3-5], the aspartic enzyme has not so far been isolated. This communication describes a simple procedure for isolating the enzyme from bakers' yeast.

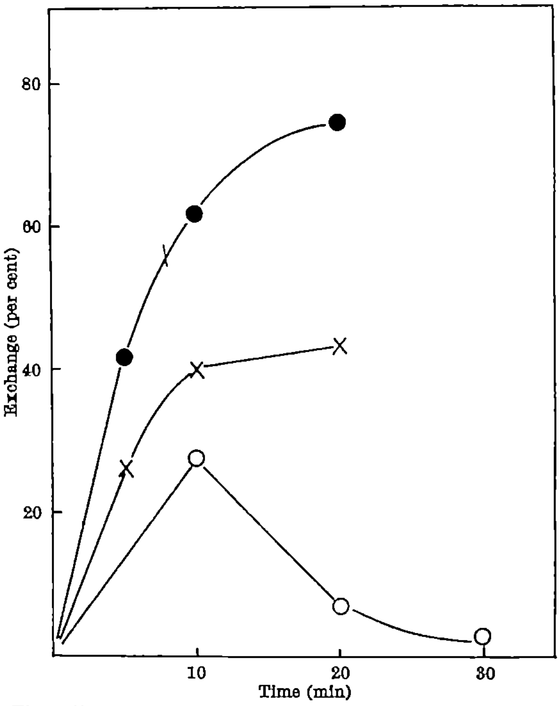

Fig. 1. ^{32}P ATP-PP exchange catalysed by aspartic acid activating enzyme from bakers' yeast. ○, 4 8–5·1 *p*H fraction (2 mg enzyme/ml. reaction mixture), ×, 4·8–5·1 *p*H fraction (2 mg enzyme/ml. reaction mixture) + 10 μmole/ml. *l*-threonine; ●, 60–70 per cent saturation ammonium sulphate fraction (1·2 mg enzyme/ml. reaction mixture)

The enzyme activity was determined by phosphorus-32 PP–adenosine triphosphate exchange[3]. The reaction mixture contained (per ml.) 100 μmole *tris* *p*H 7·1, 10 μmole magnesium chloride, 4·5 μmole adenosine triphosphate, 4·5 μmole ^{32}P-sodium pyrophosphate (80,000 c.p.m.), 8 μmole amino-acid, 10 μmole sodium fluoride and the enzyme. The mixture was incubated with and without amino-acid at 37° and the results are expressed as per cent phosphate exchange[3].

An extract was prepared from bakers' yeast according to Van de Ven *et al.*[6]. This extract was fractionated by drop-wise addition of 0·2 M acetic acid at 3° and the fraction precipitated between *p*H 4·8 and 5·1 was collected, washed briefly with cold 0·01 M acetate buffer *p*H 4·8 containing 0·15 M potassium chloride, and then stirred for 1 h in sucrose buffer as used by Zamecnik *et al.*[7]. This fraction, on testing by pyrophosphate exchange in the presence of a complete range of amino-acids, showed slight activity in the presence of alanine and tryptophan, and a marked exchange in the presence of aspartic acid. However, the rapid exchange in the first 5 min was followed by a decline in AT^{32}P concentration (Fig. 1). The fall in the rate of phosphate exchange appeared to be due to the effect of the enzyme aspartokinase[8], which in the presence of aspartic acid and adenosine triphosphate catalysed the formation of adenosine diphosphate and aspartyl phosphate. When *l*-threonine, which inhibits the enzyme aspartokinase[9], was added to the reaction mixture there was no decline in the phosphate exchange (Fig. 1).

If the enzyme fraction was subjected to further purification by ammonium sulphate fractionation, the fraction precipitated between 60 and 70 per cent saturation was found to be free from the residual alanine and tryptophan activating enzymes, and also free from aspartokinase. In the presence of aspartic acid normal phosphate exchange took place even in the absence of *l*-threonine (Fig. 1). There was no exchange caused by *l*-threonine alone in either of the two fractions. The reaction is dependent on the concentration of aspartic acid, and the Michaelis constant is of the order of $3\cdot1 \times 10^{-4}$ M. The *p*H optimum is 6·8–7·1.

The activating enzyme prepared in this work is free from a proteinase which was found in the crude yeast extract and which caused difficulty in determining enzyme activity as it caused high blank reading.

PHYSIOLOGY

Repetitive Activation of Motor Nerve Endings

It has been suggested that after repetitive activation motor nerve endings become hyperpolarized and that consequently the spike potential in the endings is larger in amplitude and more effective in transmission[1]. An alternative suggestion is that activation causes a mobilization of transmitter in the terminals so that more is available for release[2]. If the spike potential could be recorded in the terminals, it would give information about the relative importance of these two hypotheses. Hitherto this has been impossible in a mammalian preparation because there was no reliable method of locating the microscopically small endings. This difficulty can, however, be overcome by using as a criterion the ability to record extracellular miniature end-plate potentials, for it is generally accepted that this is only possible within a few micra of junctional regions[3].

4 M sodium chloride filled glass microelectrodes with a tip diameter of 1·5–3μ and a resistance of 1–3 MΩ were used to record extracellular miniature end-plate potentials in the rat diaphragm–phrenic nerve preparation *in vitro*. The mounting of the preparation, the recording technique and the bathing solutions have been previously described[4]. Neuromuscular transmission was blocked in all experiments by raising the magnesium chloride concentration of the bathing solution to between 11–13 m.moles/l.

When recorded by a microelectrode located as described the extracellular end-plate potentials were always preceded by a diphasic (positive–negative) spike potential (Fig. 1*A*), which is shown at higher amplification and on a faster time base in Fig. 1*B*. As this spike potential was all or nothing in character and had the same threshold as the following end-plate potential, we assume that it was recorded from the nervous element of the junction at which the miniature end-plate potentials and extracellular end plate potentials were generated. The effect of repetitive phrenic nerve stimulation on spike and end-plate potential was examined by photographically superposing 30–60 faint traces. End-plate potential and spike were recorded simultaneously at two gains, the lower gain (*A*) being used for later measurement of end-plate potentials and the higher gain (*B*) for measurement of spikes. The graph in Fig. 1*C* of end-plate potential and spike amplitudes at frequencies of 1–320/sec, and the sample records of end-plate potentials (*A*) and spikes (*B*) show that, as the frequency of stimulation was increased above 10/sec, there was a parallel increase in the amplitudes of end-plate potentials and spikes (measured between positive and negative peaks). After stimulation ceased the end-plate potential and spike amplitudes returned to the control size with a similar time course. The logarithm of the increased end-plate potential amplitudes was found in a large series of experiments, to be linearly proportional to the increased spike amplitudes.

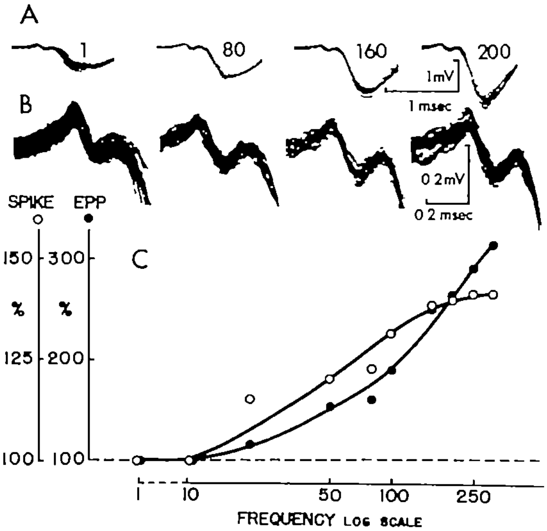

Fig. 1. Extracellular records of end-plate potentials and spike potentials at a neuromuscular junction during repetitive stimulation. *A*, Extracellular end-plate potentials at stated frequencies. Records were produced by superposition of many faint traces. *B*, as *A* but at a higher gain to show the presynaptic spike potential. *C*, End-plate potential and spike potential amplitudes during repetitive stimulation at frequencies of 1–320/sec. The amplitudes were measured from the records shown in *A* and *B* and similar records at other frequencies. The spike and end-plate potential amplitudes found during 1/sec stimulation were taken as 100 per cent

Further experiments showed that the end-plate potential potentiation which can be detected after a single impulse or a few impulses at high frequency was not accompanied by an increase in spike amplitude. In these experiments paired stimuli 4 msec apart were delivered to the phrenic nerve at 2-sec intervals for about 200 trials. The average second end-plate potential response was, as expected at such a close interval[5], larger than the first by some 20–30 per cent. The second spike potential, however, was on the average always smaller than the first, as would be predicted if it was generated when the terminals were depolarized by the negative after-potential following the first spike[6]. It must be concluded, therefore, that the potentiation after a single impulse is of a different character from that during and following prolonged tetanic stimulation, and could well be due to mobilization of transmitter. This conclusion has recently been supported by the finding that hyperpolarizing currents which are thought to mobilize transmitter can increase the potentiation found after a single impulse or a few impulses at high frequency[7].

Thus impulses in nerve terminals appear to increase transmitter release by at least two mechanisms. The first—mobilization—is the primary mechanism since it is produced by a single impulse. It is thought to be a spatial reorganization of transmitter so that there is an increased amount in close relationship to sites of release[2]. The second mechanism—an increase in spike amplitude—needs repetitive stimulation for its development because it is produced by the cumulative hyperpolarization of nerve terminals which follows such stimulation[6].

Essential Absence of Glucose in the Fœtal Fluids of the Sheep

Barklay, Haas, Huggett, King and Rowley[1] estimated the fœtal fluids of the sheep between the 49–140th day of gestation for total reducing substances by copper reduction and for fructose by resorcinol. The glucose concentration was taken as the difference between these two values. The mean values were 61 mg and 150 mg/100 ml. for the amniotic and allantoic fluids respectively; for fructose both allantoic and amniotic fluids had mean values of 195 mg/100 ml. Re-examination of the fœtal fluids using the specific glucose oxidase method of Huggett and Nixon[2] has revealed that, in fact, the concentration of glucose is extremely small and in some cases absent.

Determinations were made on Welsh mountain sheep of known gestational age over the age-range 90–145 days; in this breed term is at 148 days. Under procaine spinal anæsthesia the uterus was exposed and samples of the amniotic and allantoic fluids withdrawn by syringe from the respective fluid compartments. The samples were deproteinized with sodium hydroxide–zinc sulphate. In addition to glucose, the concentrations of total reducing substances and fructose were also measured using the methods of Somogyi[3] and Chinard *et al.*[4] respectively. The mean and range of the values obtained are shown in Table 1. No correlation of concentrations of the substances with fœtal age was discernible.

Table 1. MEAN AND RANGE OF GLUCOSE, FRUCTOSE AND TOTAL REDUCING SUBSTANCES IN SHEEP FŒTAL FLUIDS (MG/100 ML.)

	Amniotic fluid		Allantoic fluid	
Glucose	2·8	(0–11) *26*	3·1	(0–11) *26*
Fructose	252	(45–625) *26*	172	(50–630) *26*
Total reducing substances	380	(170–725) *18*	338	(135–720) *26*

No. of observations in italics.

These results indicate that both fluids contain appreciable concentrations of reducing substances other than glucose and fructose.

It is suggested that the essential absence of glucose in the fœtal fluids is in part due to the entry of urine low in glucose into the fœtal fluid compartments and reflects the active renal tubular reabsorption of glucose. This conclusion is supported by plasma clearance studies on the sheep fœtal kidney (Alexander and Nixon, submitted for publication).

Importance of Calcium for Acetylcholine-evoked Salivary Secretion

ONE of the functions of the chemical transmitter acetylcholine is to evoke secretion. How it does this is unknown; but recent evidence[1] indicates that, at one of its sites of action, the adrenal medulla, acetylcholine stimulates secretion through some calcium-dependent process. Thus, the stimulant effect of acetylcholine on catecholamine release was found to vary with the extracellular calcium concentration over a wide range, and calcium itself in certain circumstances proved an adequate stimulus for secretion. These observations considered along with the known ability of acetylcholine to increase membrane permeability at various sites led to the suggestion that acetylcholine evokes catecholamine secretion by promoting the influx of calcium into the chromaffin cells[1]. This idea gains support from experiments showing that acetylcholine increases the uptake of calcium-45 by the adrenal medulla[2].

The adrenal medulla is unique among the organs secreting in response to acetylcholine: first, the chromaffin cells are developmentally related to neurones; second, the acetylcholine receptors at this 'nicotinic' site are readily distinguishable pharmacologically from those at the other, 'muscarinic', sites of secretion, the exocrine glands; and finally, the secretory products of the chromaffin cells, the catecholamines, are chemically unrelated to the principal constituents of exocrine secretions, water, electrolytes and protein. Nevertheless, certain morphological features of exocrine secretion are similar to those of catecholamine secretion: protein appears to be released from exocrine gland cells in much the same way as catecholamines are released from the chromaffin cells of the adrenal medulla, that is, by the process that has been described as 'vesiculation and membrane flow'[3,4]. The question therefore arises whether calcium may also be involved in the secretory response to acetylcholine at muscarinic sites. The present experiments have revealed that calcium has an important role at one such site, the submaxillary salivary gland.

Our experiments have been carried out on the submaxillary glands of cats perfused *in situ* with Locke's solution at about 25° C. Under such conditions the

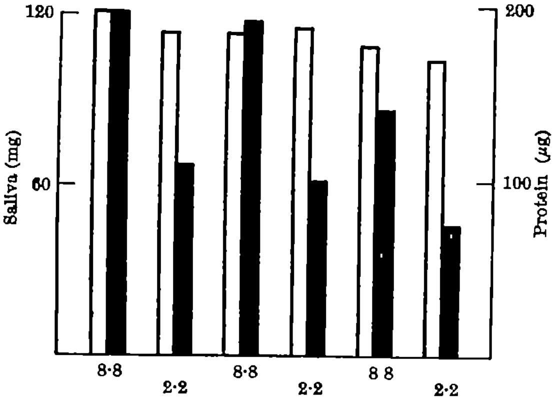

Fig. 1. Effect of excess calcium on secretion from the submaxillary gland in response to acetylcholine (10^{-4} g/ml. for 30 sec). The responses were obtained at 20 min intervals and each represents collection over 5 min. White, total weight of saliva (mg); black, protein content of saliva (μg)

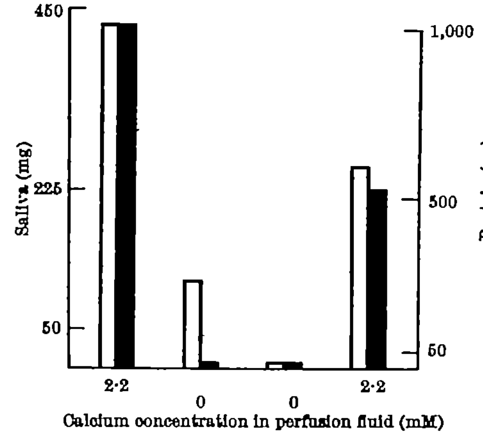

Fig. 2. Effect of calcium deprivation on secretion from the submaxillary gland in response to acetylcholine (10^{-5} g/ml. for 2 min). The responses were obtained at 20-min intervals and each represents collection over 5 min. White, total weight of saliva (mg); black, protein content of saliva (μg)

output of water and electrolytes (sodium, potassium and chloride) in response to acetylcholine (10^{-5} g/ml.), given for 30 sec–2 min, was reproducible for 2 h or more when repeated at 20-min intervals: the output of protein declined in successive tests but this decline was regular and did not obscure experimentally induced changes of the magnitude that we observed.

In a first group of experiments it was found that the amount of protein secreted in response to acetylcholine was increased when the calcium content of the perfusion fluid was raised fourfold. This effect is illustrated in Fig. 1, which shows that the increase in protein output was not accompanied by any change in the total amount of saliva. The high calcium medium was also without effect on the amount of sodium, potassium or chloride secreted in response to acetylcholine. A second group of experiments showed that the secretory response to acetylcholine was profoundly reduced when calcium was absent from the perfusion fluid (Fig. 2). In such experiments, however, the effect was not confined to the protein: the secretion of water and electrolytes was also depressed.

It is clear from these experiments that calcium has some important part to play in the secretory response to acetylcholine at a typical muscarinic site of action, the submaxillary salivary gland. The profound effect of calcium deprivation on the acetylcholine-evoked secretion of water and electrolytes is reminiscent of existing evidence that in the absence of calcium there is a severe reduction in sodium and water transport in the rat intestine[5,6]. The variation in protein output with calcium concentrations above as well as below the normal is paralleled by the similar effect of calcium on catecholamine secretion[1]. In view of this—and because of the similarities in the morphological aspects of protein and catecholamine secretion—the possibility arises that acetylcholine effects the release of protein in the same way as it seems to effect the release of catecholamines, that is, by causing an influx of calcium ions into the secretory cells. Calcium indeed may be involved generally in secretory processes associated with vesiculation and membrane flow.

Effect of Tri-iodothyronine on Ethanol Metabolism in the Dog

Kalant, Sereny and Charlebois[1] have recently reviewed the literature pertaining to the effectiveness of tri-iodothyronine in the treatment of acute alcoholic intoxication. Contrary to several earlier studies by other investigators, Kalant *et al.* observed no effect in patients in either the rate of disappearance of blood alcohol or in percentage improvement in the performance of a letter-marking test following treatment with tri-iodothyronine. Since these investigations on man yielded results similar to those which we had obtained in dogs it seemed of interest to report our findings in intact dogs and in rat liver homogenates.

Mongrel male dogs, 15·8–19·6 kg fasted overnight, were injected intravenously with 20 per cent ethanol in physiological saline in volume sufficient to give 4 g/kg of ethanol. All injections were completed by 10 a.m. The animals were divided into control and experimental groups. Blood samples were obtained at 12, 1, 2, 3, 4.30, 6 and 8 p.m. Immediately following venepuncture at 1 p.m., experimental animals were injected intravenously with 0·333 mg/kg of 1-tri-iodothyronine, dissolved in 0·01 N sodium hydroxide, and control dogs were similarly injected with the equivalent volume of 0·01 N sodium hydroxide alone. The concentration of blood ethanol was determined in each blood sample. In order that the potency of tri-iodothyronine might be proved, sodium hydroxide solutions of this substance were injected intraperitoneally into fasted rats. In every case increased oxygen consumption was demonstrated. Control rats, receiving sodium hydroxide alone, failed to exhibit increases in oxygen consumption.

Additional experiments were designed to determine the effect of tri-iodothyronine on hepatic alcohol dehydrogenase activity. Buffer solution containing glycine, sodium hydroxide, semicarbazide and ethylenediamine tetraacetate was adjusted to *p*H 9·54. In

Table 1. RATE OF DECLINE IN BLOOD ETHANOL IN DOGS

	1.00–2.00	2.00–3.00	3.00–4.30	4.30–6.00	6.00–8.00 p.m

	†23 ± 3·7	23 ± 2·9	17 ± 2·0	19 ± 1·8	20 ± 2·2
Exp. (10 dogs)	*451–427	427–410	410–382	382–352	352–308
	†24 ± 3·9	17 ± 2·7	19 ± 1·8	20 ± 1·7	22 ± 2·1

* Range in blood levels, mg/100 ml.

† Mean rate of decline, mg/100 ml./h.

Statistical evaluation: no significant difference between the various groups even at the 0·05-level.

a portion of this buffer, tri-iodothyronine, 0·333 mg/l· was dissolved. Specimens of rat liver were homogenized in either: (*a*) buffer alone, or (*b*) buffer-tri-iodothyronine. In each case the homogenate was diluted 1 : 400 with (*a*) or (*b*). Diphosphopyridine nucleotide (DPN) was added to a portion of the liver homogenate–buffer mixture, incubated for 20 min at room temperature, and set at 100 per cent transmission in a Beckman *DU* spectrophotometer at wavelength 340. DPN was added to cuvettes containing homogenate and buffer or homogenate–buffer–tri-iodothyronine and incubated 20 min. Ethanol was then added to each cuvette, except the one set at 100 per cent transmission, and changes in optical density were determined at 2-min intervals for 12 min. Statistical evaluation of the results: the 6·2 per cent lower activity when tri-iodothyronine is present is significant at the 0·05-level but not at the 0·01-level.

The results may be summarized as follows:

(1) Tri-iodothyronine failed to accelerate the rate of ethanol metabolism in intact dogs.

(2) Alcohol dehydrogenase activity in liver homogenate of rats was to some extent depressed when tri-iodothyronine was present in the homogenate. Increased activity did not occur.

This investigation was supported by grant *B*–2465 from the National Institutes of Health, U.S. Public Health Service.

Variability of Twitch Potentiation in Frog Skeletal Muscle

TWITCH responses of frog skeletal muscle can be potentiated without any increase in peak tetanus responses, by many agents, for example, lyotropic anions[1-3]. The magnitude of twitch potentiation in these investigations varied considerably; but according to Hill and Macpherson (ref. 3, p. 88) "this cannot be avoided since the effect varies from muscle to muscle". Recently, zinc also has been shown to act as a potentiator[4-6]. In these experiments, the potentiation (increment of twitch tension expressed as a percentage of the initial twitch tension) varied from 60 to 490 per cent. A major source of this variability is herein identified, and a control procedure is presented that should aid future potentiation studies.

Isometric contractions of frog (*Rana pipiens*) sartorius muscles were recorded at room temperature (average 23° C, range 21°–25° C) using an *RCA* 5734 transducer tube. After excision, with the pelvic bone attached, the muscles were equilibrated for at least 1 h in 100 ml. of normal frog Ringer's solution, and then mounted by firmly clamping the pelvic bone. A metal chain[7] was attached to the tibial tendon either by tying with waxed cotton thread directly to the tendon, or by engaging a hook at the end of the chain to a loop of cotton thread tied on to the tibial tendon. The chain was then hooked to an isometric lever contacting the plate pin of the transducer. Muscles were routinely mounted under a constant resting tension of approximately 2 g. Slightly supramaximal stimuli of 0·3 msec were used. Fused tetanus responses were obtained using a train duration of 200 msec and a stimulation frequency of approximately 120 shocks/sec.

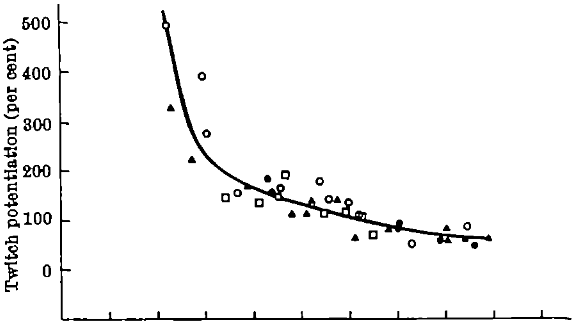

Fig. 1. Percentage of twitch potentiation obtained in 38 muscles treated with 0·05, 0·1 or 1 mM zinc plotted against the corresponding normal values of $(P/P_0)_t$. Concentration of zinc (mM/l.): ▲, 1; ○, 0·1; ●, 0·05; □, 0·1 (final concentration)

Analysis of the experiments shows zinc potentiation varies inversely with the ratio, $(P/P_0)_t$, of the normal tension of the twitch, P, to that of the tetanus, P_0. Fig. 1 shows the maximal potentiation obtained in 38 muscles, treated with 0·05, 0·1, or 1 mM zinc, plotted against the corresponding normal values of $(P/P_0)_t$. All these zinc concentrations produce the full potentiation effect of zinc[6]. Similar results have been obtained by Ramsey and Street[8] for post-tetanic potentiation and by A. Sandow (personal communication) with nitrate and quinine potentiation. These results, in general and particularly those presented in Fig. 1, clearly demonstrate that the degree of potentiation is an inverse function of the value of $(P/P_0)_t$, and thus they especially suggest that abnormally high degrees of potentiation may not be owing to an intrinsic property of the agent causing the potentiation, but to the presence of an abnormally low value of $(P/P_0)_t$.

Therefore, one can deduce from Fig. 1 how important it is to use muscles with similar value of $(P/P_0)_t$ in determining how twitch tension varies with, for example, the concentration of a potentiator. Alternatively, one may prefer to examine the concentration dependence by exposing a single muscle to successively increasing concentrations of the potentiator[5,6]. Perhaps Hill and Macpherson's (ref. 3, p. 88) conclusion "there is no 'threshold' to the nitrate or iodide effect—it increases continually with concentration" would be modified by consideration of the effect of $(P/P_0)_t$ on potentiation.

Variation in $(P/P_0)_t$ may be in part an intrinsic property of muscle, perhaps reflecting a range of zinc content in normal muscle. But another and much greater source for variation in $(P/P_0)_t$ appears to arise from the compliance added in a series when a muscle is mounted for isometric recording. The variability of $(P/P_0)_t$ decreased as we more uniformly connected a muscle's tibial tendon to the recording-lever. The variations in added compliance that occur with some common linkages have been emphasized recently by Jewell and Wilkie[9]. They note that the total series compliance of isometrically mounted muscles has varied widely in different investigations from 10 per cent muscle length/tetanus tension to 2 per cent muscle length/tetanus tension. From Hill's[10] experiments in which springs of known compliance were added in series with an isometrically mounted muscle one can infer that $(P/P_0)_t$ should vary inversely with added series compliance.

Several investigators[11,12] have reported the related observation that the degree of apparent potentiation can be increased by deliberately adding extra compliance in series with a muscle. We simply wish to emphasize that unintentional variations in added compliance can largely determine the magnitude of potentiation and suggest that the use of muscles with similar values of $(P/P_0)_t$ will help minimize the variability of potentiation data.

PHARMACOLOGY

Pharmacologically Active Extracts from Oak Gall

FELDBERG *et al.*[1,2] have shown that guinea pigs are protected to some degree against a lethal histamine aerosol by injection of extracts of Hungarian oak gall. As well as confirming these results, we have shown that the extracts exert some protection against other agonists. However, the work reported raises the question of the mode of action of these extracts.

Dried alcoholic extracts of Hungarian oak galls (*Andricus quercus-tozas*, Bose) were obtained by the method of Feldberg and Kovacs[1] and solutions were prepared in 0·9 per cent saline for injection. Guinea pigs were randomly divided into two equal groups. One group, normally six animals, received saline intraperitoneally and the other group received 40–50 mg powdered oak gall extract in 2 ml. saline by the same route. After 1 h, the pigs were exposed to an aerosol of the agonist and the time of exposure before convulsions and/or collapse was recorded. Table 1 gives typical results obtained.

Table 1. PROTECTION OF GUINEA PIGS AGAINST AEROSOLS OF VARIOUS AGONISTS

Aerosol	Percentage concentration of agonist (w/v in water)	Mean time to convulsions and/or collapse (sec) Treated	Controls	Statistical significance
Histamine acid phosphate	0·8	450	125	$0·01 > P > 0·005$
Acetylcholine bromide	8·0	173	107	Not significant
5-hydroxytryptamine creatinine sulphate	0·6	266	58	$0·01 > P > 0·005$

A further investigation was made using the technique of Konzett and Rössler[3] as modified by Holgate and Warner[4] to measure the pulmonary resistance in guinea pigs exposed to intravenous injections of histamine, acetylcholine or 5-hydroxytryptamine before and after intraperitoneal or intravenous injection of extract. Intraperitoneal injection of doses of extract which protected animals exposed to histamine aerosol failed to change significantly the responses to any of the foregoing bronchoconstrictors.

The maximum tolerated dose of extract by the intravenous route was ~ 10 mg/kg. In one experiment with this dose of extract, the weight of histamine had to be increased four times to maintain its response. No evidence of antagonism to histamine was obtained with an intravenous dose of 5 mg/kg extract. Neither acetylcholine nor 5-hydroxytryptamine could be antagonized.

The results confirm Feldberg and Kovacs's findings that the extracts confer some degree of protection against a histamine aerosol[1]. Furthermore, they show that a similar protection is afforded against 5-hydroxytryptamine; the less obvious effect against acetylcholine is not statistically significant.

Standard antagonists lead to a reduction in the degree of bronchial resistance as measured by the Konzett–Rössler technique in addition to protecting against an aerosol. In contrast, while affording protection against aerosols, the oak gall extract shows only a slight effect on the degree of bronchial resistance. Although limitations are imposed by the crude nature of the extracts used, it appears possible that the protection afforded may not be achieved by blockade at the drug receptors in the bronchioles, but by some other mechanism.

Effects of Thiols on Oxytocin and Vasopressin Receptors

IT was shown by van Dyke *et al.*[1] that thioglycollate inactivates oxytocin and vasopressin presumably by reducing the S–S bond in these polypeptides. This effect has been widely used to detect the presence of posterior pituitary hormones in tissue extracts by incubating them with thioglycollate and testing whether their pharmacological activity is afterwards abolished. We have confirmed that thioglycollate inactivates oxytocin and vasopressin, but find that this is a slow process and that the lack of activity of S–S polypeptides in the presence of thioglycollate is largely due to a pharmacological antagonism at the receptor level. Another thiol, α-thioglycerol, also exhibits this antagonism, although its ability to destroy S–S polypeptides is negligible.

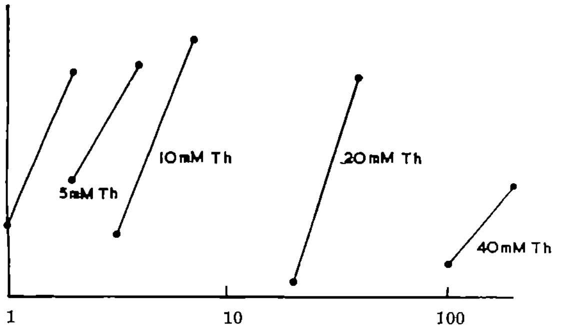

Fig. 1. Displacement of log dose-response curve of oxytocin by thioglycollate. Rat uterus in de Jalon solution at 30°

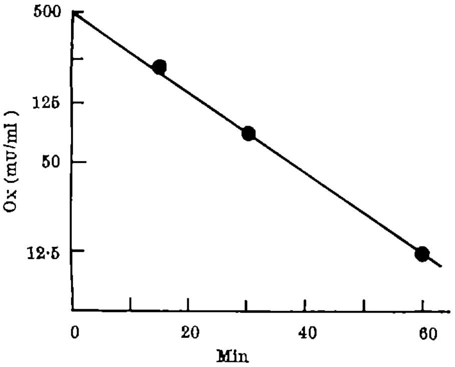

Fig. 2. Rate of destruction of oxytocin when incubated with 20 mM thioglycollate at 20° and pH 7·6

Fig. 1 shows the antagonism of oxytocin by neutralized thioglycollate on the rat uterus. The antagonistic effect can be overcome by increasing the dose of oxytocin; the dose ratio[2] varies from 1·6 for 5 mM to 125 for 40 mM thioglycollate. This antagonism is reversible. Similar effects were obtained on the guinea pig and rabbit uterus. Since in these experiments oxytocin was injected into a bath containing thioglycollate, the question arises whether the antagonism could be due to its rapid destruction as soon as it is added to the bath. To decide this point we tried to measure the destruction-rate of oxytocin incubated with thioglycollate *in vitro*, but this was complicated by interference of thioglycollate contained in the incubation mixtures with the assays. It was found eventually that the destruction-rate is exponential (Fig. 2) so that a valid estimate of the rate constant can be obtained from incubation experiments with relatively high concentrations of oxytocin which can be sufficiently diluted for assay to eliminate interference by thioglycollate.

Fig. 2 shows that the half-life of oxytocin in 20 mM thioglycollate at 20° is 10 min, which is too slow to account for the observed antagonism. At this temperature the dose ratio is 12; assuming that at 20° the uterus takes 4 min to reach its maximum response after adding oxytocin. the calculated destruction in the bath is only about 25 per cent, which gives a dose ratio of 1·3 and not 12. Lys^8-vasopressin is less active on the uterus than oxytocin, but when used in equi-active amounts it is equally antagonized by thioglycollate. This antagonism likewise cannot be due to chemical destruction since the rate of destruction of vasopressin by thioglycollate *in vitro* is similar to that of oxytocin. The uterus contracting effect of bradykinin—a polypeptide which contains no S–S bonds—is not appreciably antagonized by thioglycollate. Further evidence that thiols antagonize independently of destruction is provided by the effects of α-thioglycerol, which antagonizes oxytocin and vasopressin on the uterus, but does not inactivate them appreciably even in 50 mM concentration; α-thioglycerol could thus be used to differentiate posterior pituitary hormones from other substances by an action depending solely on pharmacological antagonism.

It was of interest to find out whether other effects of oxytocin and vasopressin are also antagonized by thioglycollate. So far the isolated mammary strip and perfused hind limb had been investigated. In the mammary strip of the rat[3] 20 mM thioglycollate antagonized the contractile effect of oxytocin but not that of acetylcholine. In the perfused hind limb of the rat[4] no antagonism of vasopressin by thioglycollate was found. These findings suggest that the thiol-sensitive receptors for S–S polypeptides on uterus and myoepithelial cells are different from the vasopressin receptors on blood vessels.

The antagonistic effect of thiols may help to shed light on the receptors on which S–S polypeptides act. One possibility is that the receptor surface itself contains an S–S group which can be inactivated reversibly by thiols, so that the reaction between S–S polypeptide and tissue receptor would be of the nature of an interaction between disulphides, perhaps a disulphide exchange[5] or a chelation involving Mg^{++} or Ca^{++}. An antagonism based on the reversible inactivation of a receptor would be expected to be different from a competitive antagonism such as might be produced by an oxytocin analogue[6]. That this is so is indicated by the log dose-effect curves in Fig. 1, which are displaced to a greater extent by increasing concentrations of thioglycollate than would be expected from a simple competitive antagonism.

PATHOLOGY

Rate of Cell Proliferation in a Mouse Squamous Cell Carcinoma

Tumours apparently grow faster than normal tissues. It seems to be a widely accepted belief that this always depends on the rapid rate of cell proliferation in malignant tumours. Growth, however, may be defined as the net gain of renewal over loss. If the 'rate of cell renewal', the input, and the 'rate of cell death', the output, are two continuous functions, $F(t)$ and $G(t)$ respectively, then at a moment t the tumour mass (M) is:

$$M = \int_0^t F(t)\mathrm{d}t - \int_0^t G(t)\mathrm{d}t$$

According to this definition, growth is dependent not on the rate of cell proliferation alone, but equally on the rate of cell loss, that is, the life-time (or maturing time) of the cells.

The assumption of a rapid rate of cell proliferation in tumours is based on the high mitotic count observed in many malignant tumours, and on the high number of labelled cells often observed in tumours with the tritiated thymidine technique. It is, however, self-evident that the mitotic count is fundamentally dependent on the mitotic duration. A long mitotic duration will give rise to a high mitotic count without saying anything of the rate of cell proliferation.

The old dogma of a constant mitotic duration for each cell type in a given species may be open for re-evaluation, at least concerning rapidly changing cell populations as epidermal cells. It has been demonstrated[1] that both mitotic duration and DNA-synthesizing time may vary considerably in mouse epidermis after application of carcinogenic substances. It has also been demonstrated that[2] the well-known daily rhythm in mitotic count in the epidermis of the mouse may be explained by variation in the mitotic duration without any significant change in the mitotic rate. Setälä[3], and Baserga *et al.*[4] have indicated that some tumours do not necessarily proliferate faster than the normal tissues of origin.

We have observed the rate of cell proliferation in an epidermoid tumour of the skin of a hairless mouse. The tumour was induced by five paintings with a 1 per cent solution of 3-methylcholanthrene in benzene and was growing rapidly when the observations were made. Histology showed a typical squamous cell carcinoma. This animal was injected with 10 μc. tritiated thymidine intraperitoneally half an hour before a biopsy of the tumour was taken. Immediately after biopsy, the animal was injected intraperitoneally with 0·1 mg 'Colcemid'. The animal was in a rather poor condition after the ether narcosis, but recovered and was finally killed 5 h after the 'Colcemid' injection. The skin with the tumour was stripped off and immediately immersed in a 4 per cent solution of neutralized formalin and afterwards embedded in paraffin. After cutting sections of the specimens, autoradiography was performed and the number of mitoses, labelled cells and labelled mitoses were registered among 30,000 tumour cells.

The results were as follows: Mean count of mitotic figures in the biopsy specimen obtained before the 'Colcemid' injections: 1·75 per cent of all cells present. The percentage of labelled cells was 8·38. Mean count of mitotic figures 5 h after the 'Colcemid' injection was 2·16 per cent of all cells present.

When, from the results shown here, we calculate the mitotic duration after the method described by Leblond and Stevens[5], the mitotic duration is estimated to about 4 h. If proportionality between mitotic count/mitotic duration, and number of labelled cells/DNA-synthesizing time exists, the DNA-synthesizing time can be calculated to about 20 h.

The number of labelled mitoses 5·5 h after the injection of tritiated thymidine was found to be 2·5 per cent of all mitoses, a value which is rather low in comparison with normal values from the epidermis. This may indicate that even the premitotic resting phase, G_2, is prolonged.

The normal mitotic duration in the epidermis of this strain of hairless mice at this hour of the day is found to be about 1 h, and the normal DNA-synthesizing time about 5 h[1]. The mitotic rate in normal epidermis of these mice is about 0·6 per cent of all nucleated epidermal cells per hour[1]. If the mitotic rate is calculated in the epidermoid carcinoma described here, it is found to be 0·4 per cent per hour.

It is fully recognized that observations from only one tumour is scarce information from which to form a definite conclusion. This tumour, however, seems to be characterized by a low mitotic rate, a high mitotic count, a long mitotic duration and a long DNA-synthesizing time, that is, a slow process of cell proliferation.

The rapid growth of this tumour may be a result of a prolonged life-time of the cells, which, instead of being normally differentiated to horny material and lost, remain relatively undifferentiated.

The routine use of a high mitotic count as a sign of rapid proliferation rate in many tumours may be disputed.

IMMUNOLOGY

A Screen for Agents Inhibiting the Immune Response and the Growth of Tumours

IN a previous communication[1] it was shown that there is a correlation between the ability of an agent to inhibit antibody production and its ability to inhibit tumour growth. Single doses of agent and T.A.B. vaccine were given simultaneously, and sera were titrated 9 days later. Under these conditions 5 of 12 compounds known to be active inhibitors of tumours in man or laboratory animals were also found to depress antibody production to a moderate or a marked extent. Of 12 compounds which were not tumour-inhibitory, none did so, even in lethal doses.

It is well known that the effect of radiation on immune processes is markedly dependent on timing; irradiation 1–2 days before administering antigen greatly inhibits antibody production, but even lethal doses of radiation are relatively ineffective if given after the antigen[2]. It was found that dependence on timing also characterized the activity of the alkylating agents and antimetabolites[3]. However, it was surprising to find that the time for most effective administration of most agents was not before injection of antigen, as it is with radiation, but 1–2 days afterwards. 'Myleran' was the only agent that resembled radiation in this respect. It seemed likely that, if dependence on time were taken into account, it might be possible to improve the correlation between the tumour-inhibiting capacity of an agent and its power to depress antibody production.

Male *A2G* mice, weighing 15–21 g, were given 0·2 ml. T.A.B. vaccine intraperitoneally and, 2 days later, a single dose of agent subcutaneously. The dose was such as to kill about 10–60 per cent of mice during the following week. Nine days after injection of vaccine, equal volumes of sera from groups of 3–5 survivors were pooled, sufficient mice being used to

microanalysis

Oh, thee!
I would not thee mislead
Who canst the smallest particle impel
To tell
Its inmost secret thought
So tell I thee indeed
Within the labyrinth of myself is caught
Of sulphur a one millionth part
For every one of me

Microanalysis may be defined plagiaristically as the art of determining more and more on less and less. The trend has been discernible, so far as qualitative analysis is concerned, over a considerable number of years; and Feigl's new two-volumed book is a measure both of the far-ranging usefulness of microanalysis and of Feigl's own massive contribution to it.

Quantitatively the impact has been sharper—largely coincident with recognition of the analytical power of chromatographic processes, but owing much to the development of physical instrumental techniques. Time was when analysis was counted among the chores of research; but now, when microworking is seen to be not incompatible with precision, the subject ranks as a prime topic for research. It is a subject brimming with possibilities and rich in manipulative techniques—separative, isolative, mensurative—some exploited, all exploitable.

For example, where once one needed to burn, laboriously, a hundred grams of oil to determine a few ppm sulphur, we in Unilever Research have turned catalytic poisoning to good effect, absorbing a microgram or so of sulphur and converting it quantitatively to methylene blue.

Or again, trimethylene glycol, undesirable in glycerine, and formerly estimated uncertainly by difference, is now assayed simply and accurately on something less than a microgram of material by gas chromatography. These are illustrative of the manner in which Unilever Research is exploring and applying the possibilities of microanalysis.

provide 2–6 such serum pools, which were then titrated for *S. typhi H* agglutinins by the Widal technique.

The response of normal mice was measured in 84 groups of 4 or 5 mice. The geometric mean titre was $1/2^{5\cdot49} \pm {}^{0\cdot67}$ (range $1/2^4$–$1/2^7$). Occasional batches of vaccine which apparently lacked potency, giving titres below this range, were not used.

Twenty-nine compounds were tested as already described. Of these, 16 were miscellaneous agents without anti-tumour activity and 13 were agents useful in treating neoplasia in man. None of the miscellaneous compounds depressed antibody production; no sera from treated mice had titres of less than $1/2^5$. In contrast, of the 13 anti-tumour agents, 12 inhibited antibody production to a significant extent and, with 10 of them, no sera from treated mice had titres in the normal range. 'Chlorambucil' was marginally effective, one serum pool out of three having a titre well below the normal lower limit. Urethane was the only agent tested that was immunologically ineffective under the conditions of this experiment (Table 1).

This test therefore appears to be useful in screening agents for ability to suppress the immune response and to inhibit the growth of tumours, except for agents such as radiation and 'Myleran', which are effective only if given before the antigen. Indeed, its efficiency in selecting tumour-inhibitory compounds is not inferior to that of many screening methods in which the effect of the agent on tumours is measured directly[4].

Kidney Specific Antigen and its Species Distribution

THE cells of a normal organ or tissue contain characteristic material which distinguishes them from other cells. Such organ-specific material is abundant in cell microsomal fractions which contain endoplasmic reticulum[1], and these fractions are used as antigens for the preparation of organ-specific antisera.

Anti-kidney sera were produced in rabbits by immunization with microsomal material from fresh human and hamster kidneys; cell fractionation and general immunological methods were the same as those used in previous studies of organ-specificity[2,3]. The anti-human-kidney serum was made kidney-specific by absorption with homogenates of human lung and liver; the anti-hamster-kidney serum was absorbed with hamster tissue and required additional absorption with sheep red cells to remove Forssman antibody.

The reactions with human and hamster tissues of the antisera before and after absorption were studied by immunofluorescence, gel diffusion, and complement fixation, and are summarized in Tables 1 and 2. Immunofluorescence staining of fresh frozen sections of kidneys and other organs was carried out by the sandwich method using goat anti-rabbit-globulin conjugated with lissamine rhodamine *B* (*RB* 200)[4].

Specific staining of human and hamster kidney was stronger when the kidney was treated with the antiserum against the corresponding species. With unabsorbed antiserum, staining of an unsystematic character but mainly endothelial in distribution was also obtained in other organs (liver, heart, testis and epididymis), but after absorption of the serum with homologous liver and lung homogenates, there was virtually no reaction with any organ other than kidney. The staining in kidney by such absorbed antisera was found mainly in the cell membranes of the nephron, particularly in the brush border of the proximal convoluted tubules. There was also some intracellular staining much the same as that reported previously for the hamster[2] but more diffuse in the tubular cell cytoplasm of the human kidney. Glomer-

	Human	0	0	0	0	0	..

ular staining, although detectable, was not conspicuous. There was no specific staining with pre-immune sera or with either antiserum absorbed with human or hamster kidney.

Gel diffusion and complement-fixation corroborated the organ-specificity of the sera: antibody activity persisted despite repeated serum absorptions by lung and liver homogenates but was virtually abolished by absorption with kidney homogenate. These serological methods were less sensitive than immunofluorescence for detecting species cross-reactions though some cross-reactivity between hamster kidney and anti-human-kidney serum was demonstrated by complement fixation; this activity was abolished by absorbing the serum with human kidney homogenate.

Table 3. RELATIVE FLUORESCENT STAINING BY KIDNEY-SPECIFIC ANTISERA OF KIDNEYS FROM VARIOUS ANIMAL SPECIES

	Anti-human-kidney serum	Anti-hamster-kidney serum
Human	Very intense	Intense
Hamster	Intense	Very intense
Other mammals (cat, rodents)	Intense	Intense
Birds (hen, pigeon)	Moderate	Moderate
Reptiles (chameleon, lizard)	Nil	Nil
Amphibians (frog, toad)	Nil	Nil
Fish—marine (cod, plaice, saithe)	Faint	Faint
Fish—freshwater (brown trout, salmon, goldfish)	Very intense	Intense

The results of immunofluorescence staining of various other animal kidneys by each of the kidney-specific antisera are summarized in Table 3. Kidney-specific antigen was found in all the mammals and birds studied, but the intensity of staining in the latter was not strong; the histological distribution was also substantially the same as already described in that cell membrane staining was always found. No reaction could be demonstrated with reptile or amphibian kidneys, but the marine fish kidneys showed faint staining of the cell membranes lining the lumen of some of the tubules. In contrast, the kidneys of the freshwater fish examined, in particular the brown trout, showed brilliant staining of parts of the tubules (Fig. 1). The kidney-specific material was more abundant than in any other species and its histological localization was different: it was confined to a broad intracellular band adjacent to the tubular lumen and giving an appearance remarkably reminiscent of a glandular secretion. In none of the species examined was any specific staining demonstrated in organs other than kidney.

The implications of these variations in kidney-specific material among the species could scarcely be surmised without more exhaustive comparative zoological studies, but its abundance in the freshwater fish might conceivably be related to special renal functional demands. Such a correlation with function would have a parallel in the behaviour of thyroid microsomal antigen, which is increased in hyperthyroidism[5].

One outcome of these findings is the suggestion that immunofluorescence may be of considerable value in providing a simple method of investigating hitherto unexplored histochemical similarities and fine differences between species.

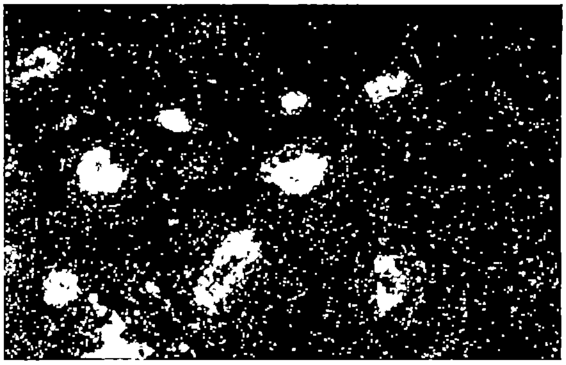

Fig. 1. Fresh frozen section of brown trout kidney, fixed in absolute ethanol at –76° C and treated first with rabbit anti-human-kidney serum absorbed with human liver and lung homogenates, and then with *RB* 200-conjugated goat anti-rabbit-globulin. Bright fluorescent staining, indicating kidney-specific antigen, is conspicuous at the inner border of the cells of several of the tubules. The dim tubular fluorescence is solely autofluorescence and the black patches, bottom left, are the normal pigment of fish kidney

BIOLOGY

Malic Enzyme Activity in Apple Fruit

The capacity of apple fruit to decarboxylate malic acid oxidatively (the malate effect) is evident early in apple fruit ontogeny[1], as well as in the stages characterized by the climacteric and post-climacteric phases of fruit respiration[2]. The stoichiometric characteristics of the malate decarboxylation reaction[1] and the symmetrical distribution of carbon-14 in malic acid resulting from $^{14}CO_2$ fixation in apple fruit[3] suggested the malic enzyme may function in both reactions. This investigation was initiated to determine if malic enzyme is responsible for malate decarboxylation and carbon dioxide fixation into malic acid in apple fruit.

McIntosh fruit were harvested at 2- or 3-day intervals, beginning approximately one week prior to the autogenous respiratory climacteric and continued into the post-climacteric stage. Procedures for preparation of peel tissue disks and manometric determination of malate decarboxylation as described by Neal and Hulme[2] were used. The assay conditions are given in the legend to Fig. 1. The malic enzyme was extracted from cortical tissue of pre- and post-climacteric McIntosh fruit. The diced cortical tissue was vacuum infiltrated with 0·2 M potassium carbonate to neutralize the acids and protect the enzyme against denaturation[4], disintegrated at 0° C with an equal weight of neutral 0·01 M cysteine, and filtered through a milk filter pad. Adaptation of 'Carbowax 4,000' fractionation procedure 1 (ref. 5), through step 3, resulted in sufficient purification of the malic enzyme for the purpose of this investigation. Glycylglycine was substituted for phosphate buffer in view of interference with manganese in the enzyme assay used. Malic enzyme activity was determined spectrophotometrically at 340 mμ subsequent to the reduction of triphosphopyridine nucleotide (TPN) by the enzyme in the presence of L-malate. The conditions of the assay are given in the footnote of Table 1.

Table 1. ACTIVITY OF MALIC ENZYME OBTAINED FROM McINTOSH APPLE FRUIT AT DIFFERENT STAGES OF MATURITY*

Stage of fruit maturity	Specific activity units (mg protein)
Immature (small green)	12
Mature (pre-climacteric)	15
Over-ripe (post-climacteric)	29

* The assay consisted of: glycylglycine, 75 μM; $MnSO_4$, 0·18 μM; TPN, 0·24 μM; L-malate, 9 μM; and enzyme in a total volume of 3·0 ml. at *p*H 6·4 and 20° C.

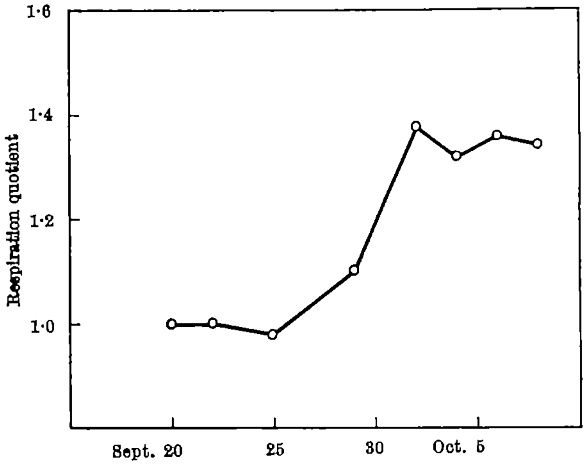

Fig. 1. Respiratory quotient for malate respiration of peel disks from McIntosh fruit gathered at various stages of maturity. The reaction mixture contained 0·5 g peel disks in 0·067 M phosphate buffer, *p*H 4·0 and 0·1 M L-malate in a Warburg vessel in the dark at 30° C with air as the gas phase

Protein content of the enzyme preparation was determined spectrophotometrically[6]. Enzyme activity is expressed in the unit defined by Ochoa[7].

The onset of the malate effect in McIntosh peel tissue was found to coincide with the beginning of the respiratory climacteric as reported for Bramley's Seedling[2] and Cox's Orange Pippin[1]. The respiratory quotient for malate respiration (Fig. 1) was close to unity prior to the onset of the climacteric and reaches a plateau value between 1·3 and 1·4 within one week. Maximal rate of malate decarboxylation was attained at approximately 0·02 M L-malate (Fig. 2). According to Neal and Hulme[2], the malate concentration within the peel tissue is approximately one-tenth the ambient concentration[2]. On this basis the malate concentration at half-maximal velocity (the apparent K_S for L-malate) would be approximately 1×10^{-3} M at *p*H

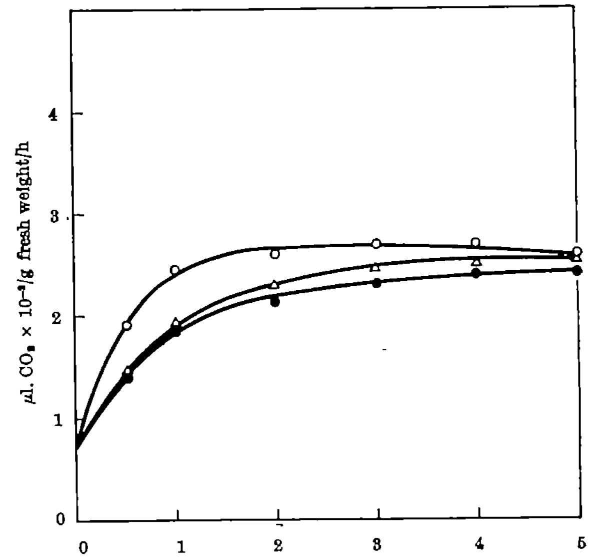

Fig. 2. Influence of L-malate concentration alone (○) and in the presence of 0·02 M malonate (Δ) or D-malate (●) on malate decarboxylation by apple peel disks. Malonate and D-malate were added after 1 h in the presence of L-malate

4·0 and 30° C. The reaction is specific for L-malate. In contrast, D-malate and malonate at 0·02 M competitively inhibited L-malate decarboxylation.

McIntosh apple fruit cortical tissue was found to contain approximately 50 units of malic enzyme activity per gram fresh weight on the basis of the assay used. This amounts to the equivalent of 336 µl. carbon dioxide per hour calculated from the extinction coefficient of TPNH ($6·22 \times 10^6$ cm^2 mole^{-1}) and the stoichiometric equivalence of TPNH and CO_2 in the malic enzyme reaction. This is the same order of magnitude as the malate decarboxylation-rate of the peel disks. Fractionation with 'Carbowax' resulted in approximately 8-fold purification with recovery of more than 90 per cent of the enzyme activity obtained in the initial extraction. The specific activity of the initial extract averaged about 5, while that of the second 'Carbowax' precipitate varied from 30 to 40 in post-climacteric fruit. The specific activity (enzyme units/mg protein) of malic enzyme was higher in post-climacteric than in pre-climacteric McIntosh fruit (Table 1). The increase in specific activity is interesting in view of the net protein synthesis observed to occur during the course of the climacteric[9]. However, a more exhaustive study will be required to establish the significance of this observation in relation to the malate effect[2].

The pH optimum of apple fruit malic enzyme was dependent on L-malate concentration[8], but not on the ionic strength of the assay medium. Activity was dependent on the presence of a divalent cation[7], the order of effectiveness being Mn > Co ≫ Mg. The enzyme was specific for TPN and L-malate; neither DPN nor D-malate would substitute. Dihydroxymaleate and dihydroxytartarate at 1×10^{-3} M were 50 and 75 per cent inhibitory, respectively; while malonate, maleic, and meso-tartarate were 10–15 per cent inhibitory at the same concentration.

The general properties of the fruit enzyme are similar to those reported for wheat germ[7] and pigeon liver[7,8]. The equilibrium constant (L-malate) (TPN^+)/(pyruvate)(TPNH)(carbon dioxide) = $19·6^{-1}$ M at pH 7·4 and 22° C[10] is favourable in the direction of fixation of carbon dioxide in a closed system. The partial pressure of carbon dioxide within the fruit and the ratio of TPN/TPNH may be important considerations in determining the direction of the reaction. A conservative estimate would place the malic acid concentration at 0·03 M in the mature apple fruit and hence would not be limiting to the decarboxylation reaction providing this concentration is available to the enzyme. However, Hulme[11] has induced a pre-climacteric malate effect by injection of malic acid into the fruit which may indicate a concentration gradient of malic acid between active (cytoplasmic) and inactive (vacuolar) pools[1]. Non-washed fruit peel tissue, with an endogenous reserve of malic acid, decarboxylates added malate, indicating that a sub-maximal concentration of endogenous malate is present in the cytoplasm.

The demonstration of malic enzyme activity in apple fruit supports its postulated participation in oxidative decarboxylation of malate[2] and the fixation of carbon dioxide into malic acid[3]. Evidence for malic enzyme activity in pre-climacteric fruit support the occurrence of the malate effect early in the ontogeny of fruit[1]. It is postulated that the malate effect is a reflexion of metabolic processes concerned with pyruvic acid utilization and is perhaps regulated by the availability of oxidized pyridine nucleotide. The quantity of malic enzyme is not considered to be the limiting factor in malate decarboxylation in matur apple fruit tissue.

Separation of the Enzymes present in the Mitochondrial Fraction from Apple Peel

As a result of investigations of the respiration of disks of apple peel, it was suggested[1] that the extra carbon dioxide evolved during the period of the respiration climacteric in apple fruits may be due, at least in part, to the operation of a malic enzyme system. Dilley[2] has recently isolated a malic enzyme, dependent on TPN and Mn^{++}, from American apples. Using Dilley's method of isolation we have confirmed the existence of a similar enzyme in the pulp of the Cox's Orange Pippin apple. We have, however, also found a similar enzyme in mitochondria isolated from the peel of the same apples[3]. At this stage it should be emphasized that by 'mitochondria' is meant the centrifugate obtained under standard conditions and that, while all the evidence suggests[3] that the preparation contains a high proportion of intact mitochondria, other particles and agglomerates having the same size/density characteristics could be present. For example, the preparations contain variable amounts of polyphenolic material[4].

The activity of the malic enzyme from various preparations obtained from apple fruits are shown in Table 1. (In Table 1 the following abbreviations are used: C.O.P., Cox's Orange Pippin Apples; p.c., postclimacteric condition; C.A., storage in a controlled atmosphere (3 per cent oxygen and 5 per cent carbon dioxide; this is often referred to as 'gas storage' in Great Britain).)

In all cases the specific activity was determined by the spectrophotometric method of Ochoa[5], except that with our preparations the protein content was measured as the nitrogen insoluble in trichloroacetic acid, multiplied by 6·25. It was impossible to obtain an accurate measure of the activity of the malic enzyme in our mitochondria by the manometric

Table 1. ACTIVITY OF MALIC ENZYME OF APPLES OBTAINED FROM VARIOUS SOURCES

Source	Specific activity	Total activity (per 2·5g original tissue)
Cortical tissue of p.c. McIntosh apples (Dilley, preceding communication)	29	—
Cortical tissue of p.c. C.O.P. apples	23	—

Mitochondria of peel of C.A. stored p.c. C.O.P. apples	8	—
S.N. fraction of sonicated mitochondria from cold stored p.c. C.O.P. apples (10 sec)	58	21
(50 sec)	41	34

determination of the oxygen absorbed and the carbon dioxide evolved because, as will be seen later, they contained, in addition to DPN and the usual DPN-dependent malic dehydrogenase, a very active carboxylase dependent on Mn^{++}. The result given in Table 1 for the supernatant (S.N.) fraction of sonicated mitochondria refers to suspensions of mitochondria treated in a sonic vibrator (25,000 cycles, 60 W) and then centrifuged at 25,000*g* for 15 min in a refrigerated centrifuge.

It remains for future work to decide whether the 'soluble' malic enzyme obtained by Dr. Dilley and by ourselves from the apple tissue arises from the breakdown of mitochondria during the isolation procedure, or whether the malic enzyme found in the mitochondrial preparations is merely 'soluble' enzyme absorbed on the mitochondria. Rutter and Lardy[6] found a malic enzyme of low specific activity in mitochondrial preparations from pigeon liver. The relatively low specific activity of the enzyme in our own mitochondrial preparations is not surprising since much of the protein in the preparations will consist of the enzymes operating the Krebs cycle. In addition, we know that the preparations contain an appreciable amount of inactive protein brougnt down by the tannin present in the material even when polyvinylpyrrolidone is used in its preparation[4].

The mitochondrial fraction also contains an active carboxylase. Some co-carboxylase must also be present, since addition of thiamine pyrophosphate increases the carbon dioxide liberated from pyruvate by only about 30 per cent. The carboxylase activity of the mitochondrial suspensions and of the supernatant solutions following high-speed centrifugation (as for malic enzyme, here) of sonicated particles is shown in Table 2. Manganese is necessary for the action of the enzyme; magnesium, at the same concentration, is only about 60 per cent as effective as manganese. The optimum *p*H of the enzyme is 6·2. The activities given in Table 2 were measured in a Warburg respirometer, the contents of each flask being as follows: 40 µmoles pyruvic acid, 400 µmoles sucrose, 18·7 µmoles potassium dihydrogen phosphate, 10 µmoles manganese sulphate, 0·1 µmole co-carboxylase, 0·25 ml. mitochondrial suspension and water to make to 2 ml.

Table 2. CARBOXYLASE ACTIVITY (AT *p*H 6·2) OF PREPARATIONS FROM THE PEEL OF MATURE C.O.P. APPLES

Source	Specific activity*	Total activity (per 2·5 g original tissue)
Whole mitochondria	11	27
S.N. fractions of sonicated mitochondria		
10 sec	27	11
50 sec	14	12

* One enzyme unit = amount of enzyme required to produce 1 µl. carbon dioxide in 5 min at 25° C under conditions described in text. Specific activity = units per mg protein.

The activities of these crude preparations are, of course, only very approximate and no allowance has been made for the inactivation due to the accumulating acetaldehyde. Nevertheless, the relatively high carboxylase activity could explain the large carbon dioxide evolution and the formation of acetaldehyde in the 'malate effect' described by Neal and Hulme[1] for peel tissue from postclimacteric apples.

The problem now arises of the separation and purification of these enzymes associated with the mitochondrial fraction, especially in order to study changes occurring during the respiration climacteric and the subsequent senescence of the fruit.

Sonication (as here) causes an obvious physical breakdown of the mitochondrial particles and, on high-speed centrifugation, a green supernatant solution is obtained which contains Krebs cycle enzymes of relatively high specific activity (malic dehydrogenase 50 per cent higher after 40 sec sonication than in the original unsonicated suspension; diaphorase, 30 per cent higher). The activity of these Krebs cycle enzymes increases with time of sonication between 10 and 100 sec, whereas the malic enzyme and the carboxylase tend to have a higher activity at the lower sonication times. This suggests that the latter two enzymes may be less tightly bound to the structure of the particles. Sonication of the preparations will clearly be a most useful first step in the isolation of the enzymes present in the mitochondrial fraction.

Effects of Kinetin and Other Plant Growth Regulators on Starch Degradation

IT has been known since the work of Hayashi[1] that gibberellins stimulate the activity of amylase in germinating barley and wheat grains. This work has been extended by Paleg[2-4], who has reported an increase in the activity of both α- and β-amylases in barley endosperm following treatment with gibberellic acid (GA_3). So far as we are aware this communication is the first to suggest that kinetin may also play a part in starch degradation. This effect of kinetin was first suspected when young excised wheat coleoptiles treated with solutions of gibberellic acid and kinetin[5] were stained with iodine. Starch was found to be present in the control coleoptiles whereas in those treated with the two growth regulators no starch was detectable. Estimations of reducing sugars in extracts of these coleoptiles, after treatment, also demonstrated that the growth response promoted by these two growth regulators was accompanied by starch breakdown (Table 1). When excised coleoptiles were grown in D-glucose solution alone the starch remained and yet the maximal growth response was as great as with kinetin. These results thus indicated that the growth responses induced by GA_3 and kinetin in young coleoptiles could be explained, at least in part, simply in terms of the liberation of D-glucose.

Table 1. AVERAGE OF THREE REPLICATE TREATMENTS OF 20 EXCISED DAY-OLD COLEOPTILES AFTER 24 H AT 25° C IN DARKNESS IN A KLINOSTAT (1 R.P.M.)

Treatment	Elongation as percentage above original length	Coleoptiles stained for starch with iodine	Reducing sugar content of extracts from 20 coleoptiles: Mg equiv. D-glucose	Reducing sugar content of extracts from 20 coleoptiles: Significant difference from controls

D(+) glucose 10^{-1} M	45·0	positive	—	

GA_3, Gibberellic acid; IAA, indolyl-3-acetic acid; K, kinetin.

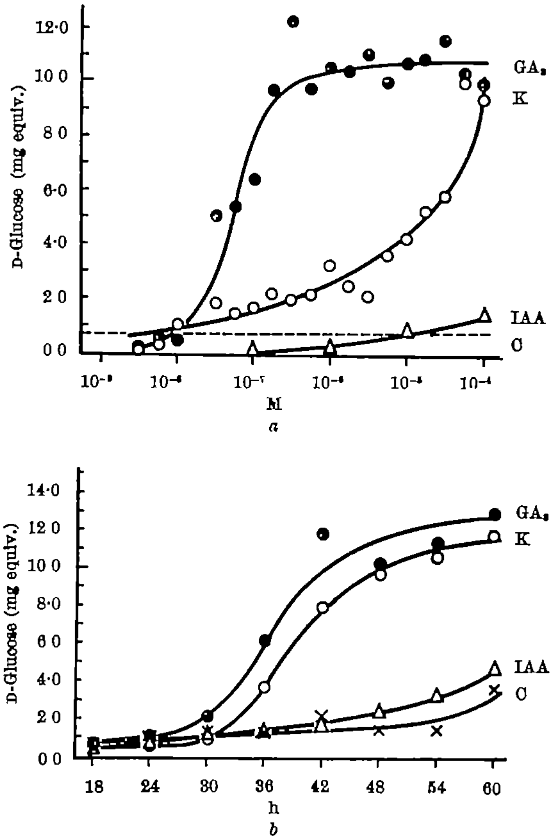

Fig. 1. Reducing sugar released from seed halves by treatment with gibberellic acid (GA$_3$), kinetin (K) and indolyl-3-acetic acid (IAA) at 26° C in darkness. *a*, Dosage response curves obtained after 36-h treatment, *b*, the effects of 10^{-4} M solutions after incubation for different periods of time

Indolyl-3-acetic acid produced no measurable effect on growth or starch breakdown (Table 1).

In order to overcome the complicating factor of growth, experiments similar to those of Paleg[2] were carried out using wheat instead of barley endosperm. Working under sterile conditions, wheat seeds were cut in half longitudinally and the embryo halves removed and discarded. Ten seed halves were placed on filter paper in Petri dishes containing 8 ml. of solution, and the reducing sugars liberated into the medium after various periods at 26° C were determined by Nelson's colorimetric modification of Somogyi's method[6]. The results were expressed as mg equivalents of D-glucose.

Dosage response curves were obtained for gibberellic acid, kinetin and indolyl-3-acetic acid after treatment of the seed halves for 36 h at 26° C in darkness, and these are shown in Fig. 1*a*. The maximum release of reducing sugars by gibberellic acid was given by a 5×10^{-6} M solution, whereas with kinetin a 10^{-4} M solution was required and even at this concentration the amount of reducing sugar released into the medium was less than with gibberellic acid. The results also indicated that indolyl-3-acetic acid caused little, if any, breakdown of starch. In another experiment the effects of 10^{-4} M solutions of gibberellic acid, kinetin and indolyl-3-acetic acid on seed halves incubated for different periods of time from 18 to 60 h were investigated and the data are given in Fig. 1(*b*). This experiment again demonstrated the similarity of kinetin and gibberellic acid, although kinetin was again less efficient than gibberellic acid in liberating reducing sugars. Preliminary experiments using paper chromatography to analyse starch degradation sugars suggest that kinetin, like gibberellic acid, affects amylases rather than the phosphorylase degradation pathway. The differences in the dosage response curves for gibberellic acid and kinetin could be explained if these two substances differ in: (*a*) their rates of movement to their site(s) of action at cell level; or (*b*) the basic mechanism by which they operate; possibilities here include the removal of an amylase inhibitor[7-9], their effects on the properties of the cell membranes, or even, perhaps, their promotion of enzyme synthesis.

Further work is in progress to find out which, if any, of these possibilities could account for the differences observed.

Growth of *Nardus stricta* on a Calcareous Soil

Recent work[1] has indicated that the addition of phosphate enables many grass species to grow successfully on a well-drained, highly calcareous soil which, otherwise, would not support their growth. The work recorded here was carried out to determine whether the addition of phosphate would enable a true calcifuge species[2], *Nardus stricta*, to grow on highly calcareous soils.

The form of the experiment and the results obtained are summarized in Table 1. The *Nardus* seedlings were transferred to boxes containing the soils immediately on germination and were harvested after twelve weeks. Each treatment, which included eight plants, was replicated three times.

The results show that *Nardus stricta* tolerates and indeed makes excellent growth on the calcareous soils where phosphate has been added as $CaHPO_4.2H_2O$; in such instances the plants showed no trace of chlorosis and inflorescences were developed. Comparison of columns *a* and *b* in Table 1 indicates that the beneficial effect of adding $CaHPO_4.2H_2O$ is not due to any lowering of the soil *p*H value. No beneficial effect was brought about by the addition of phosphate in the form of the potassium salts to the calcareous soils, and the death of plants in such cases is probably due to the harmful influence of the exceptionally high *p*H values, which arise as a consequence of adding large amounts of potassium salts to calcareous soils.

It has been suggested[3,4] that inability to obtain sufficient phosphate may be an important factor in restricting the growth of calcifuge plants on calcareous soils. Results from the above experiment

L.S.D. at 5 per cent, 10·1 μg aluminium.

showed, however, that $CaHPO_4.2H_2O$ may act, not only directly by supplying extra phosphate to the plant, but also indirectly by reducing the amount of available aluminium in the soil. Table 2 gives the data on the available aluminium content, estimated from water extracts[5] of the soils at the completion of growth.

It will be seen that there is throughout a strong negative correlation between the growth made and the available aluminium content of the soils. It is well known that aluminium is often toxic to plants, especially under very acid soil conditions where aluminium would exist in solution mainly as Al^{+++}. In soils with high *p*H values aluminium would come into solution as the aluminate ion[6], but the influence of the aluminate ion, as such, on plant growth is as yet unknown.

At present, it is not possible to distinguish between the direct and indirect effects of the extra phosphate added as $CaHPO_4.2H_2O$. There is, however, no doubt that it enables a typical calcifuge species to tolerate, and grow successfully on, highly calcareous soils despite both their high calcium content and their high *p*H.

Dyes as Artificial Hatching Agents for Beet Eelworm, *Heterodera schachtii* Schm.

ARTIFICIAL hatching agents for *Heterodera schachtii* have often been sought[1], but only two substances, 3,9-diamino 7-ethoxyacridine (rivanol) and 9-amino-acridine, have been reported to give hatches approaching that obtained in sugar-beet root diffusate[2].

I have tested 70 dyes from 16 dye-groups on replicated batches of 100 cysts of *H. schachtii* and found large differences between their ability to affect hatching. Solutions of several dyes give hatches as great as obtained in a standard beet root diffusate; others stimulate hatch less, but give a significantly larger one than is obtained in water, and many are inactive (Table 1). Tests with the most active dyes at different dilutions gave hatching curves resembling those obtained with root diffusates at different dilutions (Fig. 1).

The widely different constitutions of the dyes, their complexity and uncertainties about the structure of some, make it impossible to relate structure with hatching activity, but hydrophylic radicals, such as sulphonate or hydroxyl groups, attached to the benzene nucleus seem to lessen activity. Examples of this are the series (*a*) Janus green, Janus black and Janus blue, and (*b*) methyl red alcohol soluble, methyl red water soluble, methyl orange and orange *G*.

Little is known of the constitution of natural hatching factors for *H. schachtii*, but purified products from rape (*Brassica napus* L. var. *arvensis* (Lam.) Thellung) have several properties similar to the

H. rostochiensis factor from potato[3]. The latter is a monobasic carboxylic acid with an equivalent weight of about 220 and a formula approximating to $C_{11}H_{16}O_4$ (ref. 3), which, unlike the dyes, contains no benzene rings. The range of concentrations over which potato factor is effective has not been determined precisely, but in hatch-dilution tests using partially purified factor, activity approaches the water hatch at between 10^{-8} and 10^{-9}. The threshold concentration of auramine and nile blue sulphate (Fig. 1) lies between 10^{-6} and 10^{-7} molar, the respective absolute concentrations being 3×10^{-7} or 10^{-8} for auramine and 7×10^{-7} or 10^{-8} for nile blue sulphate. Rivanol is less effective.

Like natural hatching factors, these substances show some specificity. None stimulated *H. gottingiana* cysts and only celestin blue and methylene green stimulated *H. rostochiensis*, and then did so only slightly.

Urinary 3-Methoxy-4-Hydroxymandelic Acid Excretion and Serum Electrophoretic Patterns in the Normal and Bloated Bovine

WORK has been in progress here since 1956 to determine if a metabolic difference exists between normal bovines and those subject to tympanites (bloat). Serum epinephrine was first measured on normal and bloated animals by the method of Weil-Malherbe and Bone[1], since a difference in rate of metabolism was suspected. Although the trend for normal cattle to have a higher level of epinephrine was apparent, the results were largely inconclusive, owing to excessive variation among animals. The epinephrine averaged 2·35 and 2·03 µg/100 ml. whole blood for 27 normal and 13 bloated cattle, respectively.

Differences in excitement of the animals during taking a sample induced variable results. Because of these differences, a metabolite of epinephrine and norepinephrine (3-methoxy-4-hydroxymandelic acid) was studied using the method of Sunderman *et al.*[2]. The mandelic acid averaged 1·76 µg for 8 samples from 3 normal steers and 1·10 µg/ml. urine for 14 samples from 4 bloated steers. These samples were taken at random times throughout the day and from different treatments. These results on concentration of mandelic acid obviously did not reflect total excretion since the volume of urine was not considered. Consequently, subsequent data were expressed as a ratio between mandelic acid and creatinine[3] excretion. Table 1 shows the relationship of mandelic acid to creatinine of a normal and bloated steer with and without stress by an electric prod.

The results indicate a greater total secretion of epinephrine and/or norepinephrine (as measured by the output of mandelic acid). Furthermore, the bloated animal did not respond to stress as quickly as did the normal animal. Stress was measured by peak in mandelic acid excretion.

Table 1. AVERAGE µG MANDELIC ACID/MG CREATININE EXCRETION IN THE NORMAL AND BLOATED BOVINE*

	No stress Average of 9 hourly collections over a 12-h period	Stress† Average of 11 hourly collections over a 12-h period after stress
Normal	1·86	2·43
Bloated	1·60	1·68

* Total urine volume for the 12-h period was not obtained.
† Stressed with 10 shocks from an electric prod.

The lag in excretion prompted another collection to determine if the lag were chiefly due to a slower metabolism of epinephrine. One normal and one bloated animal were given 0·75 mg epinephrine/kg body-weight and samples collected hourly over the next 23 h. The normal animal excreted a total of 12·211 mg of mandelic acid during this period with an average of 3·14 µg mandelic acid/mg creatinine. The bloated animal excreted 5·039 mg of mandelic acid with an average of 1·90 µg mandelic acid/mg creatinine during the same period. A maximum hourly excretion of mandelic acid (3·330 mg or 9·59 µg mandelic acid/mg creatinine) was reached 6 h after administering epinephrine to the normal animal whereas the peak excretion (763 µg or 2·74 µg mandelic acid/mg creatinine) in the bloated animal was not observed until 13 h after administration of epinephrine. Thus, it appears that the total excretion of epinephrine and its subsequent metabolism to mandelic acid is impaired in the bloating bovine.

A consistent difference was found in the electrophoretic patterns[4] of serum and urine proteins from normal and bloated animals. In serum, these differences were observed in the β- and γ-globulin fractions and may represent either abnormal amounts of certain protein components, that is, lipoproteins, or variation in the γ-globulin fraction itself.

VIROLOGY

Viral Interference induced in Mice by Acute or Persistent Infection with the Virus of Lymphocytic Choriomeningitis

CONGENITAL or neonatal infection of mice with the virus of lymphocytic choriomeningitis (LCM) is often characterized by prolonged survival of the host, persistence of virus in the tissues, chronic viræmia and failure to develop specific antibodies[1]. This 'persistent tolerated infection' has been likened to the phenomenon of immunological tolerance[2]. Despite inability to form neutralizing antibody, adult mice previously infected at or before birth with LCM virus also exhibit the capacity to withstand challenge with homologous virus in a dose that would readily kill uninfected adult mice[3]. It has been postulated[3] that this resistance to superinfection (tolerant immunity) is related to lack of an allergic tissue response to LCM virus in the immunologically unresponsive host. Another possible explanation is that LCM virus in the tissues of the persistently infected mouse acts as an interfering agent[4] in much the same way that LCM virus interferes with poliovirus in the monkey[5].

The LCM virus used in these experiments was the partially attenuated *UBC* strain[3] obtained from Dr. John Hotchin of the Division of Laboratories and Research, New York State Department of Health. Stock virus prepared as a 10 per cent suspension of infected mouse brain had a LD_{50} titre of $10^{6\cdot 8}$/0·03 ml. when tested by intracerebral injection of weanling mice (12–14 g, 3 weeks old) but caused only sporadic deaths in weanling or new-born mice infected by intraperitoneal or intranasal routes. The interfering action of LCM virus was tested by challenging mice with immunologically unrelated Eastern equine encephalomyelitis (EEE) virus.

Experiments were first designed to determine the capacity of adult mice infected with LCM virus at 3–4 weeks of age to withstand subsequent challenge with EEE virus. In one such study 230 weanling mice in groups of 20–30 were infected intranasally with LCM virus at chosen intervals; 40 mice injected with saline diluent served as controls. All but 20 of the LCM infected mice were challenged intraperitoneally with a dose of EEE virus estimated to kill 90 per cent of control mice. Additional mice were similarly infected in order to determine the content of LCM virus in lung and brain at the time of challenge with EEE virus. As noted in Table 1, appreciable resistance to EEE virus developed by the second day; at this time the titre of LCM virus in lung had risen to a significant level, but none could be detected in brain. Immunity to challenge with EEE virus persisted for 8 days after LCM infection and disappeared thereafter. Titres of LCM virus in the tissues also declined as susceptibility to EEE virus returned.

Table 1. RESISTANCE TO INTRAPERITONEAL CHALLENGE WITH EEE VIRUS IN WEANLING MICE PREVIOUSLY INFECTED INTRANASALLY WITH LCM VIRUS

Interval between *LCM and EEE* Days	Mortality (%)	$\log_{10}$ LCM titres* in 10 cage-mates at time of EEE challenge	
		Lung	Brain
1	75 (15/20)	2·6	<0 5
2	40 (8/20)	3·5	<0·5
3	30 (6/20)	3·4	<0·5
5	40 (8/20)	4 8	1·5
6	30 (6/20)	4 5	3·8
7	35 (7/20)	4·0	0·5
8	40 (8/20)	2·8	1·5
9	70 (14/20)	2·2	0·5
10	95 (19/20)	2·2	<0·5
28	87 (26/30)		
No LCM	90 (36/40)		
No EEE	15 (3/20)		

* LCM virus titres in tissues determined by intracerebral injection of weanling mice.

It seemed reasonable to expect a more durable immunity to EEE virus in mice infected intracerebrally or intranasally with LCM virus a few hours after birth. Despite all precautions, most of the new-born mice injected intracerebrally died of LCM infection. However, those that survived into adulthood usually developed chronic LCM infection which lasted at least 7 months. Quantitative estimates of the degree of viræmia were made periodically and showed that 10^4 LD_{50} was not an unusual amount of LCM virus to be present in 0·1 ml. of blood several months after infection. Two separate experiments shown in Table 2 demonstrate the response of mice to intraperitoneal challenge with EEE virus 32 days after LCM infection was established at birth. In the first experiment the challenge inoculum of 1,000 LD_{50} of EEE virus was somewhat over-ambitious; but the persistently infected mice were clearly resistant as compared with uninfected controls reared from identical litters. The second experiment shows that LCM virus administered to new-born mice either intracerebrally or intranasally induced comparable degrees of protection to subsequent challenge with an LD_{50} of EEE virus.

Table 2. RESISTANCE TO INTRAPERITONEAL CHALLENGE WITH EEE VIRUS IN 32-DAY-OLD MICE INFECTED AT BIRTH WITH LCM VIRUS

Exp. No.	Interfering agent	Mortality	*Day of death,* ± S.E.	*LCM* Viræmia*
1	Controls	30/30	4·07 ± 1·1	—
	LCM (intracerebral)	9/13	7·7 ± 0·4	13/13
2	Controls	30/37	—	—
	LCM (intracerebral)	0/17	—	12/17
	LCM (intranasal)	3/10	—	10/10

* At time of challenge with EEE virus.

The results reported by Traub[4] were confirmed by studies of congenitally acquired LCM infection. In these experiments, mice born to chronically infected mothers were tested for the presence of LCM virus in blood and challenged intraperitoneally with EEE virus. These mice resisted challenge with EEE virus to about the same degree as those in which a persistent LCM infection was initiated shortly after birth. It is of interest that one experiment failed because third-generation litters of 'control' mice were found to have been inadvertently infected with LCM virus, thus rendering them resistant to EEE virus.

Many types of heterologous interference, of which the LCM–EEE system is undoubtedly an example, have been shown to be mediated by production of interferon[6]. Therefore, numerous attempts were made to demonstrate interferon in tissues of mice infected as adults or at birth with LCM virus. Infected tissue suspensions were prepared from lung or brain, dialysed at *p*H 2, concentrated tenfold by pervaporation, and assayed in *L* cells or primary mouse embryo cultures for the presence of interferon by the plaque inhibition method[7], using vesicular stomatitis as the test virus. In short, none of these tissues showed any interferon activity. These results are perhaps not too surprising in view of the difficulties sometimes encountered in detecting interferon in tissues of intact animals[7].

An attempt was also made to reproduce a model of the LCM interference system in tissue culture. It was found that LCM virus persisted in cultures of strain *L* cells, a stable line of mouse fibroblasts, for 27 passages over a period of 154 days. No consistent cytopathic changes could be demonstrated in these chronically infected cells despite the presence, on occasion, of 10^4 LD_{50} of LCM virus. The carrier cultures exhibited moderately increased resistance to superinfection with vesicular stomatitis virus. However, at no time could a non-viral resistance-promoting factor (interferon) be demonstrated in the culture fluids.

The results of these studies indicate that LCM virus acts as an interfering agent in acutely or chronically infected mice. No experimental support could be obtained for the hypothesis that resistance to superinfection is mediated by interferon produced in tissues of mice with acute or persistent LCM infection.

CYTOLOGY

Method for Distinguishing between Human and Mouse Cells in Tissue Cultures

IN recent years it has become apparent that a cell strain grown *in vitro* can very easily become contaminated with, and in time perhaps overgrown by, cells of another strain. It is possible to determine at least the species from which the cells have originated; but the available procedures are elaborate and time-consuming.

The purpose of this communication is to propose a simple procedure by which human cells can be distinguished from mouse cells in a few minutes even by an untrained person.

This procedure depends on the presence in human serum of a cytotoxic system[1] consisting of a natural antibody, complement and divalent cations[2] and on sensitivity of mouse, but not human cells, to the effects of the system.

The difference in sensitivity has been shown in experiments in which human serum (1 part to 4 parts BSS) was added to 1×10^6 cells of the strains listed in Table 1. By this treatment, cells of all four mouse strains were killed after 1 h of incubation at 37° C, whereas cells of all six human strains remained alive even after 24 h of incubation.

These observations were further elucidated in experiments to determine the ability of mouse and human cells to adsorb the antibody from serum. The cells were shaken gently with the serum for 18 h at 4° C, then centrifuged, and the clear supernatant serum was tested for its cytotoxic effect on mouse cells. Mouse cells of all four strains adsorbed the antibody and there was a relationship between the number of cells used for adsorption and the number o mouse cells surviving the effect of 'adsorbed serum (Table 1).

Table 1. ADSORPTION BY CELLS OF NATURAL CYTOTOXIC ANTIBOD FROM HUMAN SERUM

Cells used for adsorption	No. of strain *L* cells per microscopi field 24 h after addition of serur treated with following No. of cell $(\times 10^6$/ml.)					
	0	0·25	0 5	1	2	4
Mouse cells:						
Subcutaneous connective tissue (strain *L*) (ref. 3)	0	0	47	415	450	58
Lymphosarcoma (*6C₃HED*) (ref. 4)	0	1	5	201	440	52
Mammary carcinoma (TA_3) (ref. 5)	0	0	109	231	396	41
Carcinoma (Ehrlich) (ref. 5)	0	0	0	5	346	41
Human cells:						
Intestine (Henle) (ref. 6)	0	0	0	0	0	
Liver (Chang) (ref. 7)	0	0	0	0	0	
Kidney (Chang) (ref. 7)	0	0	0	0	0	
Cells from synovial fluid (McCoy) (ref. 8)	0	0	0	0	0	
Cervical carcinoma (HeLa) (ref. 9)	0	0	0	0	0	
Cells from muscle biopsy (Auersperg) (ref. 10)	0	0	0	0	0	

On the other hand, the human cells did not adsor the cytotoxic antibody, and consequently, regardles of how many human cells were used for adsorption they did not detoxify the serum (Table 1). Th ability to adsorb cytotoxic antibody was not limite to mouse cells grown in cultures: cells isolate directly from the spleen, kidney and liver of norma mice could adsorb it likewise (Table 2).

Table 2. ADSORPTION OF NATURAL CYTOTOXIC ANTIBODY FRO HUMAN SERUM BY FRESHLY ISOLATED (NOT CULTURED) MOUSE CELL

Type of mouse cells used to adsorb antibody	Strain *L* cells incubated with	Percentage of eosin-stained strai *L* cells* after 10 min incubatio at 37° C with following dil tions of serum:				
		1 : 6	1:12	1:24	1:48	0
Liver $(3 \times 10^7$ cells/ml.)	Untreated serum	96	64	19	13	1
	Adsorbed serum	26	13	17	14	1
	Adsorbed serum + cytotoxic antibody	95	80	47	13	1
Kidney $(2 \times 10^7$ cells/ml.)	Untreated serum	96	64	19	13	1
	Adsorbed serum	41	14	11	11	1
	Adsorbed serum + cytotoxic antibody	82	80	47	14	1
Spleen $(9 \times 10^7$ cells/ml.)	Untreated serum	96	64	19	18	1
	Adsorbed serum	14	12	12	12	1
	Adsorbed serum + cytotoxic antibody	92	66	37	18	1

* Injured or dead cells

These results were confirmed by an experiment o different design in which cultures of mouse cells o cells obtained directly from spleens, livers an kidneys of normal mice were incubated with heate human serum and then mixed with mouse erythro cytes. Mixed agglutination occurred in every case There was no agglutination however, when huma cells, after incubation with heated serum, were mixe with mouse erythrocytes, indicating that huma cells did not have receptor sites to bind the antibody

It was concluded that the varying sensitivities o cells to the cytotoxic system are related to th presence or absence of receptor sites for the antibod on the cells. Hence, mouse cells are killed by huma serum whereas human cells are not.

It should be pointed out that the cytotoxic reactio is not limited to mouse cells but that cells of some other species are also killed by human serum. Furthermore, human cells are not the only ones unaffecte by human serum[11]. Nevertheless, the difference i the sensitivity to human serum between human and mouse cells can be effectively utilized in some situations for confirmation and, in some cases, eve identification of species origin of the cells. If on considers that most cell strains now used in tissu culture laboratories are either of human or mouse origin and that cell contaminations are usually either by HeLa cells (human) or *L* cells (mouse), then it is possible that human serum might well be used in a routine for screening cells.

Human serum may also be useful as a cytotoxic agent in cases in which human cell cultures have become contaminated by a few mouse cells, because when added to such cell cultures it will kill the contaminant mouse cells in a few minutes, leaving the human cells unaffected.

In the application of human serum as a cell screening agent or as a cytotoxic agent, several points should be considered: (1) The cell cultures should not be too densely populated, in order that the cytotoxic antibody can attach itself to the surfaces of all, or at least most, of the cells. (2) Fresh serum should be used, because death of the cell depends on the presence of human complement which is very labile and can be easily lost on handling or storage. (3) In this reaction, human complement cannot be replaced by guinea pig complement[1,2]. (4) In case of a negative reaction (no cell death) it would be advisable to repeat the procedure using serum from other humans because in some individuals the titre of cytotoxic antibody may be too low.

This work was done while working under a grant *MA*-1024 from the Medical Research Council, Canada.

Fine Structure of Chromosomes in the Mitotic Prophase of Ascites Tumour Cells

A COMPLEX, linear structure along the axis of certain meiotic prophase chromosomes has been observed in several animal spermatocytes[1–5]. Such structure has never been detected in mitosis or other stages of meiosis. The present communication is concerned with an electron microscope study of prophase chromosomes of ascites tumour cells, in which an axial structure of the chromosomes has been revealed. Ascites tumour cells, Ehrlich ascites tumour cells and Yoshida sarcoma cells have been examined by the electron microscope following conventional osmium fixation and methacrylate or epoxy resin embedding.

Fig. 1 shows a low-power electron micrograph of the nucleus of Yoshida sarcoma cell, which is believed to be in very early prophase since it shows a disorganization of the nucleolonemata[6] with a helical structure[7]. At the lower part of the disorganized nucleolus, two parallel linear densities are visible. They are interpreted as a chromosomal axis from which lateral chromosomal elements are going to develop. Fig. 2 shows that the chromosomal axis originates

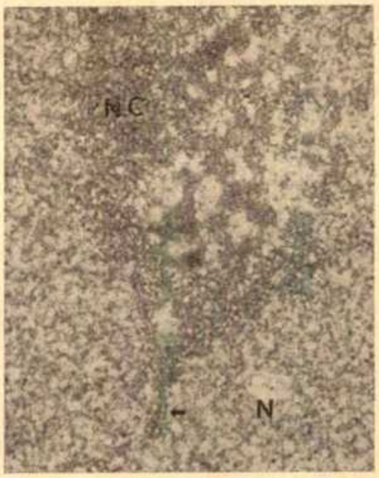

Fig. 1. The early prophase nucleus (*N*) of Yoshida sarcoma cell, showing the disorganized nucleolus (*NC*) and parallel dense lines (arrow). (× *c*. 22,400)

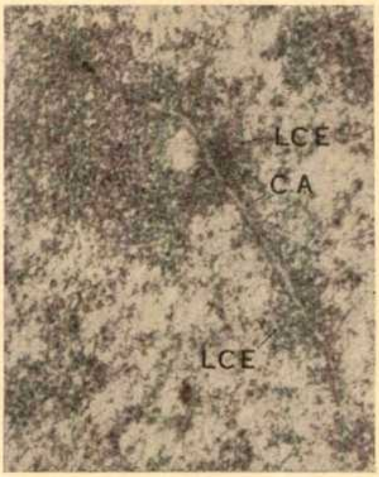

Fig. 2. A part of the prophase nucleus of Ehrlich ascites tumour cell, showing a chromosomal axis (*CA*) in a longitudinal section, lateral chromosomal elements (*LCE*) and a pair of dense dots (arrow). (× *c*. 30,400)

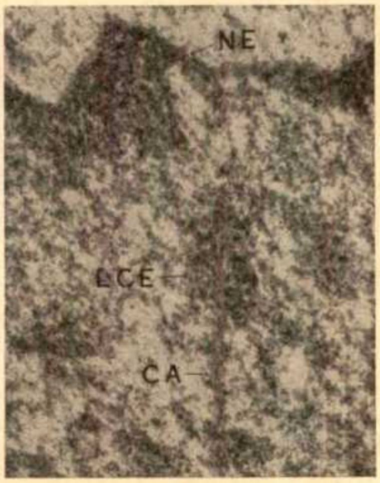

Fig. 3. A part of the prophase nucleus of Ehrlich ascites tumour cell, showing a chromosomal axis (*CA*), lateral chromosomal elements (*LCE*) and nuclear envelope (*NE*). (× *c*. 27,300)

from the nucleolus and lies in the plane of the section for a considerable distance. Two dense lines run parallel to each other, keeping a certain distance. Dense chromosomal elements seem to be reorganized almost symmetrically at both sides of the chromosomal axis. The dense elements appear to be granular at many points, but at a few points fibrillar. A cross-section through the chromosomal axis (Fig. 2) always shows a pair of dense dots, each of which has a core surrounded by a dense membrane. The mitotic chromosomal axis develops towards the nuclear envelope and finally comes to a close association with the nuclear envelope. Such structure has been confirmed with the aid of serial sections, one of which can be seen in Fig. 3.

The hypothesis of the conversion of RNA into DNA is not on a sufficiently sound basis, but the present investigation points to the nucleolus, composed of RNP functions, as the centre of the formation of early chromosomes. The association between the formation of early chromosomes and the nucleolus is of considerable interest, but has been described only briefly here. More detailed reports on this and related problems will be published elsewhere.

Preliminary Studies on the Basis of Cytoplasmic Inheritance in Amœbæ

USING the technique of nuclear transfer[1], it has been shown that many of the cellular properties of the large, uninucleate amœbæ, *Amoeba proteus* and *A. discoides*, are influenced by self-replicating cytoplasmic hereditary determinants. The characters determined in this way are those which depend on the way in which macromolecules, the specificity of which has been determined by nuclear genes, are organized into functional units[2].

The amœbæ used in the present investigations were *A. proteus*, $_{\mathrm{Tl}}P$ and *A. discoides*, $_{\mathrm{Tl}}D$. In addition to characters determined by nuclear factors $_{\mathrm{Tl}}P$ differs from $_{\mathrm{Tl}}D$ in the following cytoplasmically influenced characters: higher mean nuclear diameter, greater streptomycin sensitivity and streptomycin uptake, form when moving and shape in anti-sera. Nuclear diameter[3] and streptomycin sensitivity[4] have been used as markers in our present investigations, which are designed to determine the cellular basis of these examples of cytoplasmic inheritance.

The properties of amœbæ which make them suitable material for nuclear transfer also make possible micro-injection of cytoplasm. In the present experiments the effects of $_{\mathrm{Tl}}D$ cytoplasm injected into whole $_{\mathrm{Tl}}P$ amœbæ, and vice versa, are being investigated. 25 per cent of the receptor cells survive injections of cytoplasm equivalent to 6–10 per cent of their original volume and form flourishing mass cultures. Attempts to increase the ratio of donor to receptor cytoplasm by withdrawing cytoplasm from the receptor before injection resulted in lower survival-rate.

Measurements of mean nuclear diameter a streptomycin sensitivity of heterotransfer clon obtained from nuclear transfer experiments a shown in Table 1.

Table 1

	Amœbæ			
Character	$_{\mathrm{Tl}}P$	$_{\mathrm{Tl}}P_n \rightarrow {}_{\mathrm{Tl}}D_c$	$_{\mathrm{Tl}}D_n \rightarrow {}_{\mathrm{Tl}}P_c$	$_{\mathrm{Tl}}D$
Mean nuclear diameter (μ)	$47 \cdot 84 \pm 0 \cdot 62$	$41 \cdot 80 \pm 0 \cdot 6$	$46 \cdot 60 \pm 0 \cdot 59$	$39 \cdot 56 \pm 0$
Streptomycin sensitivity *	10·5	5·0	4·8	4·2

* Expressed as mean generation time in days in 0·36 μg strep mycin/ml.

We have found that injection of $_{\mathrm{Tl}}D$ cytoplasm into whole $_{\mathrm{Tl}}P$ amœbæ results, in approximatel 20 per cent of clones formed from amœbæ whic survive the operation, in a significant decrease i mean nuclear diameter, such that this is not significantly different from that of the $_{\mathrm{Tl}}P_n \rightarrow {}_{\mathrm{Tl}}D$ heterotransfer. When the streptomycin sensitivity of these clones was measured, it was found that this marker characteristic had been similarly changed In clones of normal amœbæ, mean nuclear diameter and level of streptomycin sensitivity are not associated.

The reverse procedure, that is, $_{\mathrm{Tl}}P$ cytoplasm injected into whole $_{\mathrm{Tl}}D$ amœbæ, gives a similar result in that 30 per cent of the surviving clones show a mean nuclear diameter not significantly different from the $_{\mathrm{Tl}}D_n \rightarrow {}_{\mathrm{Tl}}P_c$ heterotransfer.

All these measurements have been carried out o amœbæ separated by at least 50 cell divisions fro the original post-operative cell, so that its constituents will have been diluted by a factor of 2 It therefore appears that a situation in which cyt plasmic hereditary determinants can be expresse and presumably replicate, results from the injecti and assimilation of a relatively small volume non-homologous cytoplasm.

We are at present attempting to extend the list of reliable and easily measured cytoplasmically determined markers and to find out if the examples of cytoplasmic inheritance discussed here are associated with a particular cytoplasmic fraction. This system is also being used to examine examples of incompatibility between nucleus and cytoplasm of different strains, which are similar to those met in nuclear transplantation experiments with other organisms, for example, Amphibia.

Institution of Electrical Engineers, Electronics Division joint meeting with the British Institution of Radio Engineers Medical Electronics Group, at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Data Processing in Medicine".

Institution of Mechanical Engineers, Process Engineering, Refrigeration, Ventilation and Vacuum Plant Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Reducing the Cost of Maintenance".

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. B. F. Skinner (Harvard): "The Future of Teaching Machines".*

Society of Chemical Industry, London Section—(at 14 Belgrave Square, London, S.W.1), at 6 30 p.m.—Mr. G. Sykes: "Horizons in Disinfection and Antisepsis" (Jubilee Memorial Lecture).

Tuesday, October 30

University of London (in the Anatomy Theatre, University College, Gower Street, London, W C.1), at 1.15 p.m.—Dr. G. Fielder: "The Moon's Surface".*

Institution of Chemical Engineers (at Church House, Westminster, London, S.W.1), at 2.30 p.m.—Symposium on "The Economic Life of Process Plant".

Faraday Society (in the Lecture Room, Physical Chemistry Laboratory, University of Oxford, South Parks Road, Oxford), at 5 p.m.—Dr. J. H. van der Waals (Amsterdam): "Clathrates as Elementary Solutions" (Bourke Lecture).*

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Dr. J. L. Monteith: "Exploring the Air Near the Ground" (Sixth Form Lecture; to be repeated on October 31 and November 1.)

Institution of Electrical Engineers, Science and General Division P.G.S8 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof M. W. Humphrey Davies: "Fundamental Problems in Engineering Education" (Group Chairman's Address.).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. W. Klyne: "The Shapes of Molecules".* (Fifth of eighteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. B. F. Skinner (Harvard): "Recent Advances in the Experimental Analysis of Behaviour".*

Society for Analytical Chemistry, Physical Methods Group (at the Chemical Society, Burlington House, Piccadilly, London; W.1), at 6.30 p.m.—Meeting on "Recent Work in Radiochemical Methods of Analysis".

Society of Instrument Technology, Systems Engineering Section (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. P. J. Thomas: "A Factory Data Collection System".

Wednesday, October 31

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Prof. W. J. H. Butterfield: "Diabetes and the Study of Carbohydrate Metabolism in Man".*

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m —Dr. J. G. Ramsay· "The Uses and Limitations of β-Diagrams and π-Diagrams in the Geometrical Analysis of Folds"; Mr. A. Simpson: "The Stratigraphy and Tectonics of the Manx Slate Series, Isle of Man".

Institution of Electrical Engineers, Power Division (at Savoy Place, London, W.C 2), at 5.30 p m.—Dr. D.B. Irving: "Power and Society" (Chairman's Address).

Wednesday, October 31—Saturday, November 3

Radio Society of Great Britain (at Seymour Hall, Seymour Place, London, W.1)—International Radio Communications Exhibition.*

Thursday, November 1

Royal Institution, Library Circle (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Mr W. A. Dickie· "Printer and Paper Maker Pioneers. a Comparative Sketch of the Work of Caxton and Spilman".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. T. Symington: "The Pathological Physiology of the Human Adrenal Cortex and Its Relationship to Hypercorticalism".* (Sixth of eighteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Society of Chemical Industry, Microbiology Group (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Dr. H. G Pereira· "Structure and Antigenic Constitution of Adenoviruses"; Dr. J. S. Porterfield: "Some Problems of Viruses found in Warmer Climates".

Royal Institute of Chemistry, London Section (joint meeting with the Brunel College of Technology Chemical Society, at Brunel College of Technology, Woodlands Road, London, W.3), at 7 p.m.—Dr. E. F. G. Herington: "Zone Refining".

Thursday, November 1—Friday, November 2

Institution of Electrical Engineers, Power Division (at Savoy Place, London, W.C.2)—Symposium on "Plastic Insulated Mains Cable Systems.

Friday, November 2

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. V. Petrow "Steroid Progress 1962".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. R. W. Ditchburn, F.R.S.: "Some Experiments on the Way We See".

Saturday, November 3

University of London (in the William Beveridge Hall, Senate House, London, W.C.1) from 10 a.m. to 4.30 p.m.—"The Structure and Organization of the University of London"—Conference of Members of Convocation. Main Speakers: Sir Douglas Logan and Sir John Lockwood.

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Prof. Eta Harich-Schneider· "Old Court Dances in Japan".

Monday, November 5

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. D. E. Broadbent: "Theories of Short-Term Memory".

University of London (in the Anatomy Lecture Theatre, University College, Gower Street, London, W.C.1), at 5 30 p.m —Prof. C. de Jager (University of Utrecht): "The Emission of Gas by the Sun".*

Institution of Mechanical Engineers, Steam Plant Group (at Neville Hall, Westgate Road, Newcastle upon Tyne), at 6 p.m.—Meeting on "Some Design Problems arising in the Development of Very Large High Speed Turbines".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—Mr. H. Gibb: "Rituals of Rice" (Colour films with commentary).

Royal Institute of Chemistry, London Section (joint meeting with the Woolwich Polytechnic Chemical Society, at the Woolwich Polytechnic, Thomas Street, London, S.E.18), at 7.30 p.m.—Prof. R. N. Haszeldine: "Double Bonds that are Different".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer, Grade B (graduate, preferably with experience of microbiology) in Botany in the Department of Biology and Geology—The Principal, L.C.C. Norwood Technical College, Knight's Hill, London, S.E.27, quoting Ref HE.4/B/2374/10 (November 3).

Lecturer or Assistant Lecturer, Grade B (preferably with experience at postgraduate level in microbial genetics or helminthology) in either Microbiology or Parasitology—The Secretary, Royal College of Advanced Technology, Salford 5, Lancs, quoting Ref. CH/7 (November 5).

Personal Technical Assistant to Prof. Bernal, for research into the structure of liquids—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (November 5).

Research Assistant (suitably qualified graduate) in the Naval Architecture Department and in the Computing Laboratory, to prepare and run programmes for routine ship calculations—The Secretary of University Court, The University, Glasgow (November 7).

Assistant Lecturer in Numerical Analysis in the Department of Mathematics, for duties which will include using and teaching the use of the Atlas Computing Machine (previous experience of large computers is not essential)—The Registrar, The University, Manchester (November 10)

Assistant Lecturer or Lecturer in Zoology—The Registrar, The University, Sheffield (November 10).

Scientific Assistant (graduate, pass or honours) in biochemistry, physiology or chemistry; or non-graduate with research experience) for investigation of metabolism of C^{14}-steroids—Prof. A. A. Harper, Physiology Department, The Medical School, King's College (University of Durham), Newcastle upon Tyne (November 10).

Lecturer (with an honours degree in electrical or electronic engineering, and experience in some branch of electrical engineering) in the Department of Electrical Engineering—The Registrar, The University, Leeds 2 (November 12).

Lecturer (preferably with medical qualifications or interests) in the Department of Biochemistry—The Secretary, University College, Gower Street, London, W.C.1 (November 16).

Senior Lecturer or Lecturer in Bacteriology; and a Senior Lecturer or Lecturer in Pathology—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 18).

Senior Lecturer or Lecturer in Mathematics; and a Senior Lecturer or Lecturer in Physics at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 18).

Senior Technician/Technician in Veterinary Physiology and Biochemistry; a Senior Technician/Technician in Veterinary Anatomy and Histology; and a Senior Technician/Technician in Animal Husbandry at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 18).

Lecturer or Assistant Lecturer (with an interest in some branch of solid-state physics or of radiospectroscopy) in Physics—The Registrar, University College of North Wales, Bangor, North Wales (November 19).

Lecturer or Assistant Lecturer in the Department of Pure Mathematics—The Deputy Registrar, The University, Edgbaston, Birmingham 15 (November 20).

Director of the Fisheries Biochemical Research Unit—The Secretary, The University, Aberdeen (November 21).

Lecturer in Physics at Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 28).

Lecturer (permanent or temporary) in the Department of Physics at the University of the Witwatersrand, Johannesburg—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, November 30).

Senior Lecturer or Lecturer in Physics; and Teaching Fellows and Senior Teaching Fellows in Physics—The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia; or The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia November 30).

Chair of Anthropology in the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 3).

Assistant Lecturer (with a good honours degree) in Microbiology—The Secretary, The Royal College of Science and Technology, George Street, Glasgow, C.1.

Biochemist (Basic grade) (preferably with experience in routine medical biochemistry)—Group Pathologist, The Area Laboratory, West Park Hospital, Epsom, Surrey.

Experimental Officer or Assistant Experimental Officer (preferably F.I.M.L.T. or H.E.C. Biology, with experience in virology and tissue culture methods)—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey.

Hospital Physicist (Basic Grade) (honours physics graduate)—Dr. B. Levin, Pathology Department, Queen Elizabeth Hospital for Children, Hackney Road, London, E.2.

Radiation Biologist (Assistant Professor or Associate Professor) in the Department of Biology, to develop a research programme in some field of radiation biology—Prof. M. Shaw, Head, Department of Biology, University of Saskatchewan, Saskatoon, Canada.

Research Assistant (preferably with previous laboratory experience, and with G.C.E. "A" level or higher qualification in chemistry) in the Chemistry Department, Chester Beatty Research Institute, Fulham Road, London, S.W.3, to assist in analytical or biochemical studies of enzymology applied to cancer research—The Secretary, Institute of Cancer Research—Royal Cancer Hospital, 34 Sumner Place, London, S.W.7, quoting Ref. 301/B/115.

Scientific Information Officer (Abstractor) (with a degree in agriculture or natural science and able to translate from German)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire.

Technical Officer (age under 40, with H.N.C. or university degree), to take charge of the new Radiochemical Laboratory for the separation of short-lived radioisotopes produced on the medical cyclotron—The Director, Cyclotron Unit, Medical Research Council, Hammersmith Hospital, Ducane Road, London, W.12.

Technician in the Department of Microbiology—The Assistant Bursar, The University, Reading.

Zoologist (with an honours degree in zoology and research or other experience in parasitology, or a higher degree in zoology) in the Veterinary Department, Kenya, for the supervision of routine helminthological diagnosis, and research on problems of helminthiases of livestock, especially the bionomics of nematode and trematode infestations—The Director of Recruitment, Department of Technical Co-operation, 8 Sanctuary Buildings, London, S.W.1, quoting Ref. RC.217/80/06.

SCIENCE AND THE EMERGENT COUNTRIES

THE reference in Sir John Cockcroft's presidential address to the British Association for the Advancement of Science (see *Nature*, 195, 875; 1962) to the importance of adequate technical assistance for the under-developed countries and especially to the opportunities which face the Overseas Research Council struck a recurrent note in the proceedings of the Manchester meeting. In his York Lecture on the following day, Prof. P. M. S. Blackett, himself a past president of the Association, dealt specifically with the theme of science and the developing countries. Pointing out that those countries were determined to become richer by the application of science and technology, and that one thing needed to achieve this was an educational system to supply the necessary number of scientists, engineers, administrators, technicians, doctors and other professional people, Prof. Blackett said that for some years these countries would need the help of trained men and women from the advanced countries. At present there is a real shortage of such trained people in the newly independent countries of Africa, for example, and while these territories were developing educational systems which would in due course meet this need from their own populations, British scientists, engineers and technicians could make a valuable contribution by going for a period of years to one of them.

Prof. Blackett, who was addressing an audience of young people, expressed the hope that university authorities and industry would encourage young graduates to take this step before 'settling down'. Here he was advocating something which goes considerably beyond the scope of Voluntary Service Overseas but which is fully in line with the policy of the Department of Technical Co-operation. It is already clear that Mr. Dennis Vosper has the right ideas, but it is very far from being clear that he and his Department have the full support of the Government or that adequate resources are being placed at his disposal. It is not even clear that the work he is doing has the interest and support it can legitimately claim from the Minister for Science, and on this probably no more convincing evidence or assurance could be forthcoming than some indication that the Overseas Research Council was being used extensively and imaginatively on lines such as Sir John Cockcroft suggested.

In the main it is from the younger scientists and technologists that the response to this appeal for personal service must come, though their seniors have a decisive part to play in seeing that the universities and professional institutions and industry provide the conditions and initiate the measures to facilitate secondment and service overseas. There is much room for such efforts, and, as Prof. Blackett pointed out on a previous occasion, there is no reason why the universities should wait on the Government's initiative. Indeed, a real lead by universities and professional institutions should strengthen the efforts of the Department of Technical Co-operation and could have a decisive influence on the Government.

Some indication of the situation in the under-developed areas and of specific opportunities was given in a paper by Mr. H. R. Mills on technical training in those areas presented to Section X of the British Association on September 3. Mr. Mills based his paper on a survey of technical training facilities in sixteen countries of south and south-east Asia which he made for the Colombo Plan Bureau in 1961. The main object of the latter was to ascertain what technical training facilities existed and the needs of each country, and to suggest ways in which these needs could be met by developing and using more fully the facilities available within the region and by sharing facilities between neighbouring countries as part of the Colombo Plan programme of technical co-operation. The survey was supported by a special grant from the Ford Foundation, and it showed that facilities for good training exist in south and south-east Asia in practically all the branches of technology which are needed and that all countries without exception were prepared to offer their own facilities to neighbouring countries in the region.

The survey should help to dispel the widespread ignorance of existing facilities which has led to the sending of technicians to Europe or the United States for ordinary technical subjects and thus reduce a demand which has seriously taxed technical institutions in Britain and elsewhere. Nevertheless, the actual shortage at the technician-level is very serious, much more serious than that of engineers and technologists, and for social reasons alone may take a generation to remove, and there is nothing in Mr. Mills's paper that weakens the force either of Prof. Blackett's appeal or of Voluntary Service Overseas, both of which are intended to alleviate an immediate scarcity which Mr. Mills's survey seeks to remove indigenously in the long term. Moreover, his paper, which recognizes the need for communication as well as co-operation between industry and technical education institutions and for planning technical training so as to meet the needs of industry when those needs have been properly assessed, should help the intending recruit to overseas service by the clear picture it presents of what is involved in the development of human resources in these countries.

Mr. Mills stressed particularly the need to plan technical education and to execute its development in step with social changes and the supply of adequate capital and material resources. Education departments and institutions, as well as the technical departments of Government, railways, public works and telecommunications, the private sector of industry and professional institutions were all concerned. A major problem in all the countries he visited was the poor communication between these agencies. Frequently, technical training was quite out of touch with industry and oblivious of the preference of industry for men trained in their own way in their own workshops. Furthermore, some developing countries sought to take technicians to higher academic standards than were actually required for the prospective occupation, and this was encouraged by insistence on a degree as minimum qualification for Government service. Again, there was an absence in technical colleges of staff with industrial or practical experience, and sometimes a prejudice against manual labour, particularly if it involved risk of soiling hands or clothes.

There are other factors in the social structure and pay structure which discourage recruitment to careers as technicians, and the excessive prestige of university education can be a serious factor, so much so that the gap between the technician and the engineer or technologist is a serious obstacle to development in south and south-east Asia. Language is also an obstacle to communication, and Mr. Mills strongly advocates retention of English technical terms in the national language by 'phonetic inclusion'. English is generally used as the medium of instruction for professional graduate engineers, but the technician usually hears sufficient English and is aware of the limitations of the craftsman's vocabulary so that there is no serious obstacle to communication.

From Mr. Mills's survey it would seem that purely by example the technician who serves a period overseas could contribute to break down some of the prejudice against manual labour or the wearing of overalls as well as facilitate communication between craftsman or technician and the technologist, quite apart from any help he may give in alleviating an extremely serious existing shortage. It is, of course, at the graduate-level and at rather more senior level that the technologist can help to supply practical experience in the technical colleges, and this is one point at which the co-operation of industry is essential. Further, the survey shows how invaluable could be the assistance of professional institutions in Britain, not only in working out effective secondment and placement schemes and giving them due publicity, but also perhaps even more in direct assistance to corresponding institutions in the developing countries by placing their own experience at the disposal of the younger institutions.

Technical education even in its broadest sense is a particular aspect of the economics of the under-developed countries which Mr. W. B. Reddaway discussed in his presidential address to the Economics Section also on September 3. Mr. Reddaway did not touch on technical education or even on education generally, although he recognized its importance. He was concerned essentially with the question why the level of income per head in these countries is so low, and what it is that prevents it from rising more rapidly. More positively he sought to show what should be done, and by whom, to accelerate the rise.

Mr. Reddaway began by reiterating a point he made in his book, *The Development of the Indian Economy*, that in countries with no public provision for the unemployed and a very low labourer's wage. the concept of unemployment is of limited value. Accordingly, he suggested, we should consider the problem in such countries not in terms of unemployment but rather in terms of the inadequate number of openings for really productive activity, and that development should be planned as if there were an inexhaustible supply of unemployed workers. Mr Reddaway fully recognizes, of course, that this proposition has to be qualified suitably by reference to the location of the work, the skills required and the speed of recruitment, nor does he overlook the difficulties that shortage of capital may lead to, and he points out that in an under-developed country the most important criterion of efficiency is usually output per unit of capital, not output per man.

Mr. Reddaway is obviously in favour of turning the vast labour potential in these countries to at least some account in making a good network of rural roads, and perhaps in other simple improvements, such as digging small wells and improving irrigation channels. He believes that the broad strategy of India's development planning makes sense and hopes that the developed countries will make the necessary aid available as well as the necessary trade facilities. On education, however, as already noted, and on food supply, he scarcely touches, and his address is a fitting counterpart to that on "Science and Hunger" which Earl de la Warr had delivered to Section M (Agriculture) on August 30.

Earl de la Warr set out to justify the assertion that immense as are the problems of world hunger and malnutrition, they are soluble if the knowledge that we already possess is used. The first point of attack, he insisted, must be education, not merely technical education but also general education that increased the demand for and the capacity to use technical advice. He stressed particularly the need to establish institutions for training indigenous advisers; his address clearly reminds us that, however important technical assistance may be to-day. in the long term the under-developed countries must depend on their own technical staff and advisers.

Earl de la Warr briefly reviewed some of the possibilities in this field before pointing out that the food surplus of the West was quite inadequate to make any effective contribution to the relief of shortages in under-developed areas for any significant period. They could not replace the need for self-support, and Britain's task was to help these people to help themselves and in such a way that they would become permanently independent. Surpluses could. of course, be used to build up the general wealth of countries that need assistance so that they can purchase the food that they either do not or cannot produce—but this means 'trade' not 'aid'. Earl de la Warr did not deny the importance of this method, and beyond this the distribution of food surpluses can contribute to the development of agriculture in such countries if they are used as a stock of capital to be drawn on while important agricultural reforms are undertaken, and to enable idle labour to be put to work without causing inflation. Indeed, a pledging session in New York on September 5 for the United Nations World Food Programme was aimed at raising a fund of 100 million dollars in surplus agricultural products and cash for development, and Earl de la Warr's address should remove any hesitation which the British Government had in pledging 5 million dollars to the programme.

Earl de la Warr concluded by expressing the hope that the United Kingdom would play a worthy part in this great international attack on hunger, which, as he observed, is essentially an extension into wider fields of work that has been done for generations by Britain's own Colonial agricultural and other Services in areas for which Britain has been responsible. The recurrent emphasis at successive British Association meetings in recent years on the interest, the opportunities and the responsibilities of the scientist in the under-developed territories is as welcome as it is timely. Its expression at these meetings should encourage scientists generally to make their full contribution to technical assistance, to overseas research and in educational work, for example, and not least when, in spite of the establishment of the Department of Technical Co-operation, Government support seems somewhat lukewarm. The British Association meeting has undoubtedly displayed some opportunities for specific action by scientists themselves, though it probably remains true that in the broadest sense the organization of overseas research generally and the revitalizing and effective use of the Overseas Research Council are still among the most important.

Diffuse X-ray Reflections from Crystals

By Dr. W. A. Wooster. Pp. xi+200. (Oxford: Clarendon Press; London: Oxford University Press, 1962.) 35*s*. net.

WHEN Max von Laue suggested, 50 years ago, that X-rays might be diffracted by crystals, the physicists of his day were doubtful whether any observable pattern would be obtained because of the thermal vibrations of the atoms which might, they thought, smear out the diffraction spectra. However, the experiment was tried, and it succeeded so well that the question of thermal vibration effects became of secondary importance except in so far as it was interesting to study them through the temperature-sensitive diminution of Bragg intensity that they caused. The idea that there should be a definite pattern of diffuse scattering due to thermal vibration which would depend on crystal orientation (contrary to early Debye theory) was raised by Faxén and Waller in 1923, but so few crystallographers read these mathematical papers that even when the patterns were found on well-exposed Laue photographs taken with the whole radiation from copper targets (see, for example, *Proc. Roy. Soc.*, A, 125, plate 11, Fig. 6, opposite p. 674 (1929)) they were not recognized. They were in fact repeatedly seen and ignored until about 1938–39, when they were actively looked for by Laval in France and independently noted by Wadlund in the United States and Preston in Great Britain. The whole story, of which this is the briefest outline, is an amusing commentary on the 'two cultures' that can exist even within a most specialized corner of a specialized discipline when experimentalist and mathematician are unaware of each other's work.

Nowadays every X-ray crystallographer has to be familiar with the use of mathematical tools. The short statement on the inside paper cover of Dr. Wooster's book claims that "This book has been written with a minimum of mathematical analysis". Well, that may be so; but the "young research student" for whom the book is intended had better glance through it before he derives any comfort from that assurance. There is an index of symbols that runs to more than six pages with about thirty definitions on each page.

Dr. Wooster is an authority in the field and an experienced writer and teacher. Moreover, this is the first book of its kind, and it is bound, therefore, to find an honoured place in the crystallographer's library. But one cannot help regretting that the author has so deliberately restricted his treatment of the subject. He gives a general survey of the theoretical basis of diffuse scattering and of the experimental methods by which it has been observed; then adds a chapter on the determination of elastic constants from diffuse scattering, and one on the determination of the elastic frequency spectrum. Useful chapters follow on diffuse scattering due to structural imperfections and on that from molecular crystals, but there is no mention of zero-point energy, of diffuse effects due to radiation damage or of the ways in which these various effects may be sorted out experimentally. Electron and neutron diffraction effects have also been deliberately excluded, probably because the author would rather not deal with them unless he can do so exhaustively. But sometimes a brief outline may be better than nothing at all.

There are good indexes, but also several misprints and some errors. KATHLEEN LONSDALE

NUCLEAR REACTOR PHYSICS

Reactors

Vol. 2. Edited by H. R. McK. Ryder. (Progress in Nuclear Energy, Series 2.) Pp. vi+557+xii. (London and New York: Pergamon Press. 1961.) 105*s*. net.

SINCE the extensive declassification of work on the civil applications of nuclear power in the early 1950's, it has become difficult to keep up with the very large numbers of papers and reports being published in this field. The review series *Progress of Nuclear Energy* was therefore warmly welcomed when it was founded by Pergamon Press in 1955. The series is now divided into 12 sections, the volume under consideration being the second volume in the *Reactors* section.

The present book is based entirely on material presented at the 1958 United Nations Geneva Conference on the Peaceful Uses of Atomic Energy, and contains 16 papers of which ten are on reactor physics. and six are rather more general papers on specific reactor systems. Since some 2,000 papers were presented at the 1958 Geneva Conference, of which at least 250 were directly concerned with nuclear reactors, a review of the papers on reactors would have been of greater value. It is, however, to be regretted that the present work falls below the very high standards set by earlier volumes in the series, since instead of presenting reviews of the material presented at the 1958 Conference, it contains only reprints of a selection of the papers.

Although all these papers were published in the complete *Conference Proceedings* three years before the present work appeared, there is some value in having in a single compact volume a selection of papers dealing with one particular field, together with an index. However, any selection of 16 papers from so many is bound to be to some extent arbitrary, resulting in undue attention to detail in some areas at the expense of inadequate general coverage. For example, more than 150 pages are devoted to British, American and Russian work on physical measurements on fast reactor experimental assemblies, but the reader must refer to the full *Proceedings* to appreciate the relevance of such work to the design of a fast power reactor. Similarly, on a more general level, good descriptions are given of five different types of reactor system, but the reader will look in vain for any information on the design and operating experience of the two reactor systems first used for large-scale power production—the British gas-cooled graphite type and the United States pressurized water reactor.

It is easy to see that the editor and publishers have set themselves a very difficult task, but it is doubtful if this volume will meet the needs of the large body of readers who would have expected a more critical selection or review of the papers presented at Geneva. L. Rotherham

INDEX OF DIFFERENTIAL THERMAL ANALYSIS

Scifax (regd.) Differential Thermal Analysis Data Index, with Mineral, Inorganic and Organic Sections

Compiled by Dr. R. C. Mackenzie. Comprising 1630 punched cards (20 Introductory, 1012 Mineral, 287 Inorganic, 311 Organic); and Extra Code Card, 31 Guide Cards, Two 8 in. needles with handles, and Explanatory booklet. (London: Cleaver-Hume Press, Ltd., 1962.) £55.

This index consists of punched cards which are slotted to record the temperatures and sense of the principal and second differential thermal analysis peaks and whether these occur in an inert atmosphere. To code the peak temperatures, the range from less than $-100°$ C to greater than 1,800° C is divided into intervals (mainly 50° C) and to each is assigned a number from 1 to 27. The numbers are recorded on the card and also slotted on the upper edge, the other three edges remaining free. Each card is numbered and gives the name of the substance, its composition, and, if it is a mineral, a reference to Hey's *Chemical Index of Minerals*[1]. The various peaks that authors attribute to the substance, with reference to the literature as well as to other cards, are also recorded.

It is natural to compare the '*Scifax*' index with the well-known X-ray powder data card file (by A.S.T.M.). The A.S.T.M. file is available in several versions, including punched cards (but not slotted). The cards give the three principal *d* spacings and their relative intensities as well as the complete powder pattern of the substance and, if available, the experimental conditions, cell constants, system, space group, optical data and references. In comparison, the '*Scifax*' cards record only the bare minimum of information; obviously they would be more useful if the evidence of the purity of the listed samples, nature of the reactions occurring at differential thermal analysis peaks and experimental conditions were also shown. The A.S.T.M. file distinguishes data of high reliability, and this could with profit be followed in the '*Scifax*' index because there is unnecessary duplication of cards, and the proportion of questionable minerals is too high. The fault is more noticeable among the clay minerals where about 10 per cent are dubious (for example, monothermite, polynite, serpentine, hydrogoethite, beidellite, gumbrin, iron-magnesian parahalloysite, etc.).

The method of sorting cards is reasonably satisfactory, and it is usually possible to find cards from their coding without much ambiguity. The '*Scifax*' index is arranged alphabetically, but the compiler suggests resorting the cards either according to their coding (for diagnosis) or according to their chemical composition (for reference). For diagnosis, it would be necessary to code and slot two more edges with the substance reference number so as to be able to retrieve cards.

While the inorganic section consists in the main of data of well-defined compounds and is a welcome addition to the literature, the organic section includes a noticeable proportion of cards of poorly defined high-molecular weight compounds (for example, calcium resinate, humic acid, albumen, 'Amberlite' resin, fibrin, carbolignin, etc.). If a work of reference must record data of poorly defined materials it is better that they are put into a separate section.

The '*Scifax*' index is well produced and if used with caution it could be useful in identification, but its chief value lies in being a convenient source of information, especially if the data are supplemented by the user. R. Greene-Kelly

RECENT DEVELOPMENTS IN HIGH-PRESSURE TECHNIQUES

Modern Very High Pressure Techniques

Edited by Dr. R. H. Wentorf, Jr. Pp. xiv+233. (London: Butterworth and Co. (Publishers), Ltd., 1962.) 60*s*.

It is eighty-two years ago that J. R. Hannay probably first produced artificial diamonds by the application of high pressure and temperature. Since that period the interest in high pressure has increased enormously because of the fundamental importance of the properties of matter under the extremes of pressure and temperature, and the possibilities of permanently modifying the structure of common materials.

The practical difficulty of research in this field has always been the design and the materials of construction of the containing vessel and plunger. Bridgman made the first major step forward from gun design practice by using a cylinder which was subjected to progressive internal and external loading, and this enabled him consistently to reach pressures of 50 kilobars. Using a two-stage apparatus of this design he achieved pressures of up to 100 kilobars, but with the consequent penalty of a very big reduction in working volume. Bridgman probably achieved pressures of 200 kilobars in a very restricted volume in his anvil design by using what he termed "the principle of massive support". The reproducible and indeed commercial production of artificial diamonds in 1955 by a research team in the General Electric Co. of America was achieved using a 'belt' apparatus which was a development of the anvil principle. Since then there have been considerable developments and there are now several proved designs using the principle of massive support which can be used to subject samples of materials of worth-while size to pressures in excess of 100 kilobars at temperatures up to and above 2,000° C.

This book is edited by one of the original General Electric Co. team, and the authors of the various chapters have all made major contributions to this field of research. The book really forms a progress report on the present state of the art of carrying out various fundamental experiments under pressures in excess of 20 kilobars at temperatures from a few degrees above absolute zero to more than 2,000° C. Chapters are devoted to the general principles of high-pressure apparatus design, high-pressure optical and electrical measurements, Debye–Scherrer X-ray techniques for high-pressure studies, high-temperature methods at high pressure, high pressure at low temperature, etc.

The editor and contributors to this book are to be congratulated on having written a most valuable addition to the three or four books available on high-pressure techniques. The publishers are also to be complimented on their high standards in the production of this volume. B. CROSSLAND

METHODS IN ELECTROPHYSIOLOGY

Electrophysiological Methods in Biological Research

By Dr. Jan Bureš, Dr. Mojmir Petráň and Dr. Jozef Zachar. Pp. 515. (Prague: Publishing House of the Czechoslovak Academy of Sciences, 1960.) Cena vázaného vytisku Kčs 54.

THIS is an excellent book which will be of real use to neurophysiologists. It not only describes methods and equipment in general, but also sets out in detail how to perform a large number of particular experiments, from measuring the membrane potential of *Nitella* to making stereotaxic lesions in the brain of the cat. I myself know of no other book that does the same. The English translation is impeccable.

Chapter 1 is a first-class account of electrochemistry and membrane theory, with a better outline of the sodium theory of the nerve impulse than is to be found in most Western physiology textbooks. Chapter 2 deals with apparatus and technique. The electronics is sound but somewhat dated, without transistors; but the later sections on locating faults, getting rid of alternating-current hum, etc., and on how to make electrodes are highly practical. Chapters 3–9 introduce, and then describe, experiments on membrane potentials, the nerve impulse, muscle, the electroretinogram, the spinal cord, the cerebral cortex and subcortical structures—to mention the main headings. An appendix contains stereotaxic atlases of the brain of the cat, rabbit and rat.

The description of each experiment is divided into: problem, principle, apparatus, other requirements, object (animal preparation used), procedure, results and conclusions. The instructions are lucid and full; for example, detailed drawings are given of the dissection of nerves in the frog's leg. References are given throughout (the majority to papers in English), but in many instances the records illustrated do not appear to be those of the original papers; from which we may conclude that the authors have performed many of the experiments themselves. From this no doubt stems the high quality and freshness of their presentation. P. A. MERTON

LIPIDS AND LIFE

Lipide Metabolism

Edited by Prof. Konrad Bloch. Pp. xiii+411. (New York and London: John Wiley and Sons, Inc.. 1960.) 84*s*.

LIPIDS are biochemical entities of sometimes vague affiliations but most are derivatives of higher fatty acids. Until recently they were an unpopular and generally neglected subject for research, but the past decade or two has brought a striking change, reflected in the present-day wealth of research publications on lipid chemistry, metabolism and functions. The importance of lipids in the functioning of living tissue is no longer minimized.

Assessment of this advancing tide of knowledge is a matter for the specialist. The book in question contains eight monographs, all the work of acknowledged authorities and outstanding research workers in the fields they survey. The editor is likewise prominent among lipid chemists. As he comments in his preface, some important subjects had to be omitted to ensure prompt publication. One such is the biosynthesis of cholesterol, a field with which Prof. Bloch's name is closely associated. Perhaps he felt it unnecessary to include this topic, since a contemporary review on it was being prepared for publication elsewhere[1], but there is no reference in the present book to a source of information on cholesterol synthesis, for example, in sections where other aspects of cholesterol metabolism are discussed.

The subjects discussed are: (1) synthesis and oxidation of saturated fatty acids, by D. E. Green and S. J. Wakil, (2) metabolism of unsaturated fatty acids, by J. F. Mead, (3) metabolism and function of phosphatides, by R. J. Rossiter and K. P. Strickland, (4) metabolism of glycerides, by B. Borgström, (5) lipolytic enzymes, by M. Kates, (6) hormonal regulation of fatty acid metabolism, by R. G. Langdon, (7) formation and metabolism of bile acids, by S. Bergstrom, H. Danielsson and B. Samuelsson, (8) chemistry and metabolism of bacterial lipids, by F. Asselineau and E. Lederer. Some of these topics are more extensive than others, necessitating a more condensed appraisal, but all authors have succeeded in giving readable accounts of the present state of knowledge and of the steps by which it was reached. Sometimes elimination of all but a main theme gives greater cohesion; for example, Chapter 1 concentrates exclusively on 2-carbon addition or removal at the carboxyl end of the fatty acid chain, making no reference to acids with an odd number of carbon atoms or to ω-oxidation. This is not a criticism, since the authors at the outset define the limits of their subject and I myself share the editor's belief that "no worthwhile topic will remain overlooked for long". Allocation of more than 30 pages to the chemistry of bacterial lipids in a book on metabolism is justified by the unusual nature of all the compounds described.

I feel confident that no reader, whether himself a lipid specialist or not, will fail to find all the contributions stimulating and adequate within their specified fields. The consistent pattern of the whole book, its clarity of expression, and its virtually complete freedom from misprints are a tribute to the editor no less than to the authors. It has been a pleasure to read it; it is a pleasure to recommend it unreservedly.

SOUTHERN BRITAIN IN THE IRON AGE

Map of Southern Britain in the Iron Age

Scale 1 : 625,000 (About Ten Miles to One Inch). (Chessington, Surrey: Director-General of the Ordnance Survey, 1962.) Map and 56-page booklet, 17*s*. 6*d*. net; Map only, 7*s*. 6*d*.; Text only, 8*s*.

THE Ordnance Survey has recently issued a map of Iron Age sites in southern England. Along with John Betjeman's book of churches, the list of National Trust properties and the Automobile Association's *Handbook*, this publication should be in the dashboard cubbyhole of every interested motorist. It is, indeed, a very fine piece of work. Every Iron Age site of the 500 years before the coming of the Romans is categorized and mapped under various headings, each with its own symbol and colour to help distinguish the *A*, *B* and *C* and superimposed phases of the culture. No one can deny that the Iron Age in Britain was a very splendid period, and this work—it is much more than a mere map—gives at a glance an impression of its extent, importance and distribution.

The introduction describes the scope of the work, the way the map works with grid references, and gives an account of the characteristics of the things marked on it, for example, Belgic oppida, hill forts of various kinds, open settlements, lake villages, farms, fogous, shrines, cemeteries, barrows, burials, dykes, trackways and "Other Finds of Iron Age Material". It is unfortunate that no more than half a dozen lines could have been devoted to objects found at the sites or as isolated occurrences, especially as the introduction is followed by a splendid five-page article by D. F. Allen with two tables and eight full-page distribution maps devoted entirely to coin finds. While the Ordnance Survey keeps an index of small finds, it would have been most useful if even perhaps only the most important of these could have been mentioned under their sites in an extra column in the gazetteer. The Birdlip Mirror, for example, is a thing of great beauty—possibly one of the most beautiful works of art of its kind extant—but it and the many other beautifully and characteristically decorated objects that have been found are not mapped and barely referred to. When structures and coins are so well dealt with one cannot help regretting that the Celtic art—and art is the expression of culture—could not also have been catered for. On the cover of the bound edition some 30 characteristic objects are indeed incorporated, in colour, in a design, with a key to their provenance overleaf. But this is possibly misleading to the uninstructed amateur who may well think he will find information about them inside—it might have been more correctly indicative of the contents to have had drawings of hillforts, etc., or even a sketch of Maiden Castle, or a plan of Wandlebury Rings. But the specialist, of course, already knows all about Celtic art, and it is only the non-specialist who will suffer. This, after all, is a work of specialist importance. For students of the Iron Age and schoolteachers the splendid map is indispensable and O. G. S. Crawford would have rejoiced to see it.

M. C. BURKITT

THE CETACEANS

Whales

By Prof. E. J. Slijper. Translated by A. J. Pomerans. Pp. 475. (London: Hutchinson and Co. (Publishers), Ltd., 1962.) 63*s*. net.

IN this book, which is a revised translation of Prof. Slijper's *Walvissen* published in Holland in 1958, the author has concentrated on the physiology, functional anatomy and behaviour of the Cetacea. These are subjects in which he has long been interested and on which he has worked not only in the laboratory and in northern waters but also during an antarctic whaling expedition in one of the great modern pelagic whalers. His industry over a great many years has resulted in the production of a book which appears to omit nothing that is known of these aspects of whale biology. The work is not addressed to the zoologist alone, but also aims to interest "the widest possible circle of readers in the life of animals which by their size, their strange habits, and the adventurous methods by which they are caught, have for many centuries captivated the imagination of mankind".

After a historical introduction, Prof. Slijper deals with the subdivisions of his subject in separate chapters, showing that an immense amount of new information has been discovered about the biology of whales during the past fifty years; he also indicates the wide and fascinating field that awaits further study by zoologists. His concluding chapter deals with the future of whales and whaling, a matter that leads beyond the paths of zoology into the realms of economics, big business and even politics.

The author has been fortunate in his translator, A. J. Pomerans, who has performed his task most skilfully so that the text flows as smoothly as if it had been originally written in English; Prof. Slijper's own linguistic skill has no doubt contributed much to this happy result.

The book is profusely illustrated with photographs and with very beautiful, clear line-drawings which add much to its value and, probably, to its rather high price. It concludes with an extensive select bibliography grouped under the subjects of each chapter, an arrangement which is not entirely to be commended because it is not a list of references, and the works of some of the authors quoted in the text are not to be found in it. The book will undoubtedly succeed in its aim of interesting a wide circle of readers in addition to zoologists who have specialized in studying the Cetacea.

L. HARRISON MATTHEWS

EFFECT OF INSTRUMENT DEVELOPMENT ON THE PROGRESS OF CHEMISTRY*

By Sir HARRY MELVILLE, K.C.B., F.R.S.
Secretary of the Department of Scientific and Industrial Research

CHEMISTRY, very briefly, is concerned with making molecules from atoms or other molecules and in determining the structure of the molecules so produced. In the ultimate analysis both these matters are determined by interactions between atoms. However, the day is very far distant when chemistry would, in any event on paper, be a matter of being able to calculate from such atomic information the manner and the rate of chemical reactions and the kinds of molecules that will result from these interactions. Unlike physics, no fundamentally new principles have been discovered recently, but the ramifications of the subject are so large that it is necessary to be constantly on the alert for the development of new methods of doing basically simple things if progress is to be made at all. Quite a revolution in methods has occurred within the past fifteen years and there is every reason to believe that this will continue in the near future.

Systems of molecules come into a dynamic state of equilibrium once a chemical reaction ceases. The general description of equilibrium is the business of thermodynamics, to which is now added statistical mechanics, which in turn deals with energy states of molecules, and this in its turn is determined by atomic interactions. Thus, thermodynamic equilibrium depends ultimately on a precise knowledge of molecular structure. It is therefore logical to consider first the contribution of instrument development to the determination of molecules.

For convenience it may be best to deal with gases and solids separately. Liquids still constitute a very serious problem; it is not very clear whether to treat them as gases or solids, since approaches from both sides have their advantages and disadvantages. It is convenient also to consider the historical position in two parts. Let us call the period prior to 1940 'Phase 1'.

Phase 1 in solids had made enormous progress mainly due to X-ray diffraction studies. Provided the material is crystalline, then in principle no matter how complicated is the structure it can be sorted out with the position of atoms (except hydrogen) being defined with precision at least to within 10^{-3} Å. Electron diffraction has not made anything like the same progress owing to the low penetrating power of even high-voltage electrons. Maybe the disappointing feature is that electron diffraction does not really help at all in the determination of the surface layers of solids, and in particular in the monomolecular layers that are adsorbed on to the surfaces of solids. Similarly, X-ray diffraction did not contribute much to the determination of the structure of gaseous molecules or of molecules in liquids, and here there was a real lack of precise knowledge. Electron diffraction by gases was rather more successful, though the interpretation of the results was rather laborious.

With the interpretation of absorption spectra in the visible and ultra-violet regions of the spectrum, and to a very limited extent in the infra-red (instrumental difficulties here were enormous), some progress was made in the determination of the precise molecular structure of diatomic and some simple polyatomic molecules. Beyond this limit progress would seem to have come to a stop.

Even a basic measurement such as molecular weight was determined, not very precisely, by the classical methods of physical chemistry developed in the latter half of the nineteenth century. Molecular weights of more than a few hundred simply could not be determined, yet the science of high molecular chemistry was just beginning to develop. In the late 1930's the outstanding instrumental development was the oil-driven ultra-centrifuge, a combination of advanced mechanical engineering and precision optics that gave quantitatively complete evidence of the existence of large molecules with molecular weights of 10^6.

Phase 2: Modern physical methods have brought about a revolution in the matter, affecting both large and small molecules. With small molecules the introduction of a very high-precision mass spectrometer is the most significant advance by far. In this apparatus the substance is volatilized in the usual way in the ionization chamber and is ionized by electron bombardment so that only one electron is detached from the molecule. The mass of the positive ion is then measured directly. High precision is an absolute necessity because it is necessary to discriminate between molecules like N_2 and CO, both of which have almost exactly the same molecular weight, since not only is the weight of the molecule needed but also a clue to its structure.

In the case of large molecules one cannot use any method involving volatilization and so the molecules must be dissolved in a solvent, but the physical effect on a solvent is so small that exceedingly sensitive physical devices have been needed to measure the effect accurately. For example, the boiling-point of a solution is slightly greater than that of the pure solvent. This difference, which might be 10^{-4} °C, can only be detected by sensing elements such as a thermistor coupled to electronic amplifying devices of the highest sensitivity. Similarly, the osmotic pressure of such solutions may be equal to a head of a few millimetres of the solvent in question. Precise measurements can be made again only by optical and photoelectric amplifying devices. Provided certain conditions are fulfilled, solutions scatter light more than solvents. Although itself small, this effect increases with the increase in size of the solute molecule. Fortunately, even big molecules in solution are smaller than the wave-length of the visible light used, so that the theory of the method can be accurately worked out. Such solutions behave in a way which is far from ideal and hence the utmost dilution must be used. This cuts down the amount of scattered light until it is quite impossible to measure it visibly and difficult to measure it photographically. Fortunately, photomultiplier tubes have come in at the right time to provide the necessary accuracy and these enable molecules of molecular weight of up to 10^6 or even 10^7 to be determined accurately. The high sensitivity of the photomultiplier enables the scattering pattern to be determined and this gives information concerning the shape of the molecules in solution as well. This cannot be obtained absolutely in any other way, and therefore the method is invaluable in understanding the hydrodynamic properties of solutions of this kind.

---

* Substance of the Thomson Lecture delivered before the Society of Instrument Technology at the Royal Institution, London, on October 4

Instrumental development led to another advance. Chemically, it is possible to attach to the end of molecules containing maybe 10^4 or even 10^6 atoms a specific atom or defined group of atoms, for example, bromine. If, therefore, this small number of atoms can be determined in a given material the weight of the molecule can be determined. Analytical chemical methods are completely useless for this purpose. However, if the terminal atom is radioactive, for example, carbon-14, or can be made radioactive by neutron bombardment, then accurate estimation of molecular weights can readily be made, but this depends on the means for making radioisotopes and on the counting equipment essential for techniques of this kind.

It might be thought that when molecules become large enough they should be capable of being seen in an electron microscope, but a molecule of molecular weight 10^6 is only about 20 Å in diameter if it is spherical in shape. While it is true that individual molecules can be identified the method is not practical for quantitative use in determining molecular weight in any accurate way.

Coming back to the question of molecular structure, the problem of structure determination for crystalline solids is solved, but again only if sufficiently small molecules or periodic arrays of ions are concerned. When the molecule becomes larger the problems increase enormously, since the diffraction pattern simply cannot be reduced by simple calculating machines. The large molecules of biological interest, for example, the vitamins, the proteins and the viruses, are complicated and progress recently has only been possible because of the availability of digital computers. Positions of the hydrogen atom cannot be determined because of the smallness of scattering of X-rays, but their position can be inferred pretty confidently. However, if the data must be obtained, neutron diffraction is a solution, although, unfortunately, the provision of a sufficiently intense stream of neutrons is not nearly so simple a proposition as that of the production of a beam of X-rays for structure determination.

In Phase 1 of this survey infra-red absorption measurements were extremely difficult to make, not because there was any special difficulty in making infra-red spectrometers but simply because the means of measuring the intensity of infra-red radiation was practically non-existent. The advances came from improved thermoelectrical devices; here it is possible to magnify the signals from such devices by electronic means and provide a signal of such a magnitude that it can operate robust recording devices. In fact, the information now provided is so voluminous that it cannot be completely interpreted, but the important point is that in the simpler polyatomic molecules one can determine with precision the shape and atomic distances, interatomic vibrations and rotational modes of motion.

Instrumental development has brought both infra-red and ultra-violet absorption spectrometry into virtually every laboratory. Structures of relatively simple molecules can then be completely determined, but much else is obtained as well—the effects of environment on the behaviour of molecules, for example, hydrogen bonding—the modification of vibration of molecules is affected by the nature of the environments of the solvent or absorption in solid surfaces.

However, to supplement these methods there are now others. Precision is always desirable and the infra-red methods sometimes are not suitable for determining accurately the moments of inertia of certain kinds of molecules. Fortunately, the development of means of measuring the absorption of microwaves for vapours and the very considerable precision of the frequencies of absorption that can be measured makes it possible to determine inter-atomic distances with accuracies down to about 10^{-3} Å. This method is, of course, restricted to substances having a sufficiently high vapour pressure and a sufficiently simple chemical constitution.

Perhaps the most extensive recent development, simply because it is so useful, is the technique of nuclear magnetic resonance. This depends on the principle that the nucleii of certain atoms, particularly hydrogen, behave as if they were small precessing magnets in a magnetic field and under such conditions their interaction with the magnetic field makes it possible for them to occupy two neighbouring energy states. The energy difference of magnetic fields of several thousand gauss is such that the switch can be induced by frequencies of about 50–100 Mc/s, again in the microwave region. From the chemical point of view the important thing is that the environment of the nucleus can affect the energy of transition between the two states. Thus, the nature of the bonds between the hydrogen atoms and other atoms can affect this transition. Consequently, in principle, the method could become useful in the finer details of structural chemistry. While these statements can be made confidently, the usefulness of the technique has been wholly dependent on the development of microwave apparatus with suitably added recording devices so that these energy transitions can be determined with a high degree of precision in frequency and magnitude. In combination with other complementary techniques it has formed a most powerful addition to the structural tools of the chemist.

Microwaves of a similar nature have found a most useful but more restricted application in quite a different field though the principles involved are generally similar. An unpaired electron attached to an atom also spins like a little magnet and similarly in a homogeneous magnetic field has two well-defined energy states. Hence, if a substance containing such systems is placed in a wave-guide in such a magnetic field, absorption of microwave radiation can be used as a measure of the number of unpaired electrons in a given volume of material. Such chemical systems are radicals, for example, CH_3, which exist in both the gaseous, liquid and solid phases. In special circumstances their concentration can be as high as 10^{-2} moles per litre and their presence, even their concentration, can be measured by conventional magnetic balances. In the majority of chemical reactions, on the other hand, the concentration may be as low as 10^{-7} moles per litre. Here the new method of electron spin resonance comes into its own, and with suitable recording devices it provides a hitherto unattainable level of sensitivity to enable reactions occurring through the intermediary of free radicals to be studied in a unique way. As in nuclear magnetic resonance, unpaired electrons are also subject to environmental influences and therefore many of these radicals have a complex multi-lined spectrum, characteristic of the radical in question. Thus, one can literally see on a display screen the nature of the radicals changing during the course of a chemical reaction. The resolving power in time is poor, being of the order of many minutes.

Chemical Reactions

To follow the progress of a chemical reaction it is necessary to have analytical methods which will give an accurate record of what is happening chemically at all times. If the reaction is slow and can be stopped at suitable points in its course, the matter is comparatively simple. But analytical difficulties arise in determining the presence of very small proportions of certain compounds the presence of which can modify drastically the course of the reaction. However, it is far more convenient to be able to monitor the reaction continuously, in which case instrumental methods have to be used. Practically all chemical reactions take place through the intermediary of energetic molecules or fragments of molecules which are specially reactive. In fact, the concentration of these molecules determines the rate of reaction as well as its course, and the understanding of the method of creation and disappearance is indispensable in elucidating the mechanism of the reaction. Moreover, the concentration is usually so small and the life-time so short that normal analytical methods are useless in this respect. These problems have now been completely solved by the development of instrumental techniques of great sensitivity. If a reaction is exothermic in its course and, chemically, fairly well defined the rate of evolution of heat may be used. What is needed then is an extremely sensitive means of measuring rises in temperature, and this has to be done in a matter of milliseconds. In liquid systems this can be done by a variety of means. If the volume in c.c. used is small and the system is thermally insulated, then the whole reaction system is virtually adiabatic up to periods of 100 sec. As rise in temperature is then a direct measure of the extent of the reaction, the necessity of measuring small rises in temperature, for example, 10^{-4} °C, results from the following considerations. In, for example, an oxidation reaction initiated externally by ultra-violet radiation when the oxygen is already dissolved in the liquid it takes a short time, from 10^{-3} to about 1 sec, to build up the concentration of the reactive intermediates to a steady value. This lapse of time, together with the known rate of the creation of these intermediates, can be used to calculate their concentration. By the use of established methods the mechanism of the reaction can be completely worked out. Since increase in temperature affects almost every physical property of a liquid, then in principle any physical method is applicable. The direct measurement of temperature by a thermojunction or thermistor is sufficient, but the required sensitivity can only be obtained by the use of very sensitive d.-c. amplifying devices suited especially to these sensing elements for, unfortunately, it is not possible to generate an a.-c. output from the elements as happens in the case of similar devices used in the case of infra-red spectrometers. Fortunately, the response of such elements, which is up to 10^{-3} sec, is normally sufficiently short to cope with most kinds of reaction, although shorter times, for example, 10^{-4} sec, would be desirable. If a liquid is transparent, optical interferometric methods can be used, which, surprisingly, are not especially sensitive even though the precise measurement of the movement of interference fringes by photomultipliers is used as the detecting elements.

Measurement of dielectric constant at moderate frequencies, for example, 50 Mc/s, can be made extremely sensitive, and this, coupled with high-speed oscilloscope recordings, is probably the most sensitive method of all. For example, 10^{-4} per cent of chemical change in as little as 10^{-6} sec can be detected, although naturally it is only applicable to low-loss insulating liquids.

With gas-phase reactions the situation is rather more complicated because heat escapes much more quickly from such systems. Fortunately, the lifetime of the active species is shorter too. The latter factor makes it impossible to use any kind of measuring probes since the response of, for example, a wire, of even 10μ in diameter is something of the order of 10^{-2} sec, but worse still the wires distort the concentration of atomic and radical concentrations in their immediate neighbourhood. So what is measured by this method is not necessarily representative of what goes on in the bulk of the system.

The slight pressure increase which results from the heating of the gas can be measured by what is virtually a condenser microphone of great sensitivity with a diaphragm so designed that it will respond to the rapid rise in pressure. Recording presents no difficulties, but the problem of using such a detecting element in the reaction system other than at room temperature is not easy. Other methods, too, using similar information can be used, but they are not specially dependent on instrumental development. The aforementioned methods, although soundly based and accurate, depend on indirect methods of approach. This has led to various attempts to solve the problem by direct means. In those reactions which can be induced photochemically the reaction can be induced by one means or another and the technique of flash photolysis has proved invaluable. In this case, in gaseous systems, an intense flash of radiation up to an energy of 1,000–10,000 J is delivered to the system, in a time much shorter, for example, one millionth of a second, than the lifetime of the reacting species concerned. This flash generates such a high concentration of active molecules, including electronically excited species, that their concentration can be determined directly by absorption spectrophotometry. Further, the variation of concentration with time can be determined by using a momentary flash for the absorption experiments. Such an unequivocal method of identifying active species has established beyond doubt the mechanism of many gas reactions.

A somewhat similar technique in principle can be applied by using a shock wave to initiate a gas-phase reaction. The transmission of a shock wave through a gas activates the molecules in a time which is short compared with that of most chemical reactions. Thus, when the shock wave is passed there is time to see what happens chemically, not quite at leisure, but at least in the absence of any further activating process. Another advantage of the shock wave is that it is possible to raise gases to temperatures unattainable even by flames and certainly far beyond the melting-point of any impermeable container for the gases. Temperatures up to 10^4 °C can be achieved. This opens the possibility of studying chemical events under quite exceptional conditions. These phenomena occur in times of the order of a millisecond, so once again spectroscopic methods coupled with sensitive photoelectric recording methods are absolutely essential if the full potentialities of the method are to be exploited. The shock-tube technique itself in its present form is borrowed from hypersonic aerodynamics.

Analytical Chemistry

It has already been mentioned that chemistry was mainly concerned with the structure of molecules and the way in which chemical reactions take place. To enable these branches to advance, analytical methods of high sensitivity and precision are, of course, a prerequisite. But analytical methods are needed for much else besides in metallurgy and biochemistry, and many other borderline sciences. Instrumental methods have completely revolutionized this side of chemistry and made it more precise, speedier and more sensitive as well.

On the spectroscopic side infra-red, visible and ultra-violet absorption spectroscopy are used as a matter of course, not simply for structural work but for identification of substances in complex mixtures. This, of course, depends on a firm foundation of structural knowledge in the first place. Similarly, emission spectra are especially useful in identifying elements, particularly metals. The precise method of excitation depends on circumstances, and internal standards provide the means of making the method quantitative. Once this work was done by photographic methods involving measuring the density of spectral lines on a photographic plate. This method is now supplanted by using a battery of photomultipliers each fixed on a chosen spectral line and coupled to digital counting devices. By this method one can now get, within a minute or two, a complete analysis of a complex alloy with as many metals identified as are needed. Speed is essential, for example, in steel works where analysis of melts is needed quickly; without it production would be seriously impeded. The analysis of substances containing alkali and similar metals may be carried out by atomic absorption spectrophotometry. This is a matter of measuring the intensity of absorption of the metal when volatilized in a flame. The measurement of sodium is easily done, but other metals are more difficult. However, photoelectric detectors with suitable amplifiers coupled to a monochromator make it possible to extend the method readily.

Even classical X-ray diffraction analysis has been bent to serve analytical purposes. The method has the great merit of non-destructive testing. The principles are not new, but the apparatus very much depends on several recent developments. A related development is X-ray fluorescence. Here the specimen is irradiated with a beam of X-rays from a high atomic number element such as tungsten and each of the elements present emits by fluorescence its characteristic radiation. This is reflected from a suitable crystal and the intensity of the diffracted beams measured and recorded using Geiger counters. The only limitation is with elements of low atomic number when the radiations are absorbed by air. There is sometimes a positive advantage if the elements the concentration of which is sought are present only in small traces in a matrix of light elements.

An even more striking application of this kind of method is the X-ray microanalyser. Here an accelerated beam of electrons (50 kV) is focused on the specimen itself. By using the techniques learned from electron microscopy the spot can be reduced to 1μ in diameter. Characteristic X-rays are analysed by crystal diffraction and Geiger counters. Elements of low atomic number cannot be so easily estimated except by using a vacuum apparatus. The great merits of this kind of analytical equipment are that minute quantities of material can be analysed in a large bulk of foreign material and that the specimen, for example, an alloy, can be scanned over a considerable area. What is more, by means of the optical microscope used simultaneously, the precise position of the specimen so irradiated can be examined.

It is really outside the scope of this lecture to deal with radioactive methods of analysis. Suffice it to say that apart from the production of radioactive elements, the instrumental development in counters and associated equipment has made the method of extraordinary sensitivity and of direct application. As an example of extreme sensitivity it is possible in the case of strontium to count down to 8×10^{-15} g atoms per litre. Chemical methods are simply out of the question for measuring quantities of material as small as this.

The analysis of gases and vapours has always posed awkward problems for the chemist. The methods are laborious in the extreme and usually needed very large amounts of material of the order of many c.c.s at normal temperature and pressure. In fact, the lack of methods was a vital factor in holding up progress in reaction kinetics and in many analytical problems of a similar kind. Here the situation has changed more than in any other branch of chemistry. First there is the mass spectrometer. After a long period of use as an instrument for the accurate measurement of atomic weights, the development of recording devices instead of photography and means of stabilizing electric and magnetic fields made it possible to carry out chemical gas analysis. With polyatomic molecules the number of ions produced from one molecule is, of course, very high, but here again simple computers with the ability to solve large numbers of simultaneous equations made this kind of analysis a practical proposition. Before the mass spectrometer came into widespread use gas chromatography was invented. Here was really a master invention capable not only of analysing gas mixtures but almost any kind of mixture provided it can be volatilized into a stream of inert gas at a reasonable temperature. The principle of the method is simple in that the substance concerned is partitioned between the stationary liquid phase (supported on a solid) or solid phase and the vapour phase. This partitioning occurs many times during the passage of the vapour mixture through the apparatus so that there is ample opportunity for very exact separation to be achieved—better, for example, than can be achieved by distillation of liquids. The problem is then to devise an apparatus that will detect the most minute concentrations of substances mixed with a carrier gas, and, secondly, to measure the total amount of material emerging from such a column in a fixed time. Again any conventional method of physical analysis is out of the question though sufficiently sensitive thermal conductivity systems are suitable. Even gas density balances of quite exceptional sensitivity are applicable. However, gas concentration detectors of a variety of types coupled to the recording and integrating machines gives the method tremendous sensitivity. In spite of all this the instrument has to be calibrated with known substances. If, however, records of a known substance are, in fact, obtained then the mass spectrometer may have to be brought in for the purposes of identification. One of the by-products of these developments has been the scaling up of the technique as a tool for the preparation of samples of compounds of quite exceptional purity. Any help in improving the effectiveness of separation procedures is a continuing requirement in chemistry.

The instruments briefly described here are of a complex character and even for laboratory use may range up to £25,000 each. Perhaps I should therefore direct attention to true chromatography, which makes use of the simpler materials, is of great elegance, and can be quantitative when necessary.

Here again it is a matter of partitioning a substance between the stationary solid phase—a piece of filter paper—and a moving liquid phase in which the substance is dissolved. By virtue of the movement of the liquid across the paper, substances distribute themselves on the paper depending on the magnitude of the partition coefficient between the two phases. Even greater separation can be achieved by afterwards running another liquid at right angles to the motion of the first. If the substances are coloured the process can be followed visually, hence the name chromatography. If not, they can be made to react with reagents to develop colour, and thus can be observed easily. What is more, it is possible to label some of these substances with radioactive atoms and to scan a chromatogram by suitable radioactive counters to identify the positions of the materials used. Thus, we almost come back to sealing wax and string, for paper chromatography is not much removed from this in its basic simplicity. However, the signs are that although these extraordinary methods are basically simple it is not long before detecting tools are devised to make them more sensitive and more reliable.

In this short space I have tried very briefly to scan a vast field of chemistry and applied physics. There has been no opportunity to indicate the quantitative aspects of the situation and therefore to demonstrate just how much is now possible with these numerous advances. There is much talk about interdisciplinary research these days. There could not be a better demonstration of it than in this field. The advances made are due to real collaboration. The physicists have certainly invented the basic tools—it has been the groups of far-sighted chemists who have seized them with enthusiasm and explored them to the full.

FOSSIL HAND BONES FROM OLDUVAI GORGE

By Dr. JOHN NAPIER
Primatology Unit, Royal Free Hospital School of Medicine, London

IN *Nature* of December 17, 1960, Dr. L. S. B. Leakey reported on the discovery of a number of fossil bones of the hand and the foot on a living floor some 20 ft. below the uppermost limit of Bed I, Olduvai. Later (*Nature* of February 25, 1961), Dr. Leakey reported the discovery of a mandible and two parietal fragments of a juvenile from the same site and associated with a well-defined living floor of an Oldowan culture.

Fifteen of the hand bones pertaining to at least two individuals, an adult and a juvenile, have been identified and examined, and are described here. Their allocation is given in Table 1.

Table 1

Juvenile		Uncertain age		Adult	
4 Middle phalanges	*I.U.*	1 Trapezium	*I.U.*	2 Proximal phalanges	*C.D.*
		1 Scaphoid	*I.U.*		
2 Terminal phalanges (fingers)	*C.U.*	1 Capitate	*C.D.*		
		1 Base of 2nd metacarpal	*I.D.*		
1 Terminal phalanx (thumb)	*C.U.*	2 Fragments of middle phalanges	*I.D.*		

C, complete; *I*, incomplete, *D*, damaged; *U*, undamaged.

The middle phalanges (Fig. 1, second row) from the juvenile hand, lacking only their epiphyses, constitute a series II–V from the right hand. They are robust bones, rather more so than phalanges of comparable length of juvenile *Gorilla* and adult *Homo sapiens*. They are strongly curved and, palmad, bear well-defined grooves which are situated in the distal half of the bone for the insertion of flexor digitorum superficialis.

The adult proximal phalanges (Fig. 1, third row) are also more robust than bones of comparable length in modern man; they are strongly curved both longitudinally and transversely, fusiform in shape and deeply hollowed out on the palmar aspect; sharply defined fibrous flexor sheath ridges extend from the base of the bones to their necks.

The terminal phalanges (Fig. 1, top row) which are juvenile, having incompletely fused epiphyses, are characteristically *sapiens* in form. The terminal phalanx of the thumb is of particular interest; it is stout and broad and bears a deep impression for the insertion of flexor pollicis longus.

The carpal bones (Fig. 1, 4th row) are all damaged, but sufficient of their original form remains to determine their structural and functional affinities. The lunate surface of the scaphoid has a rectangular outline; and the tubercle, which is broken off at its root, was probably somewhat elongated, though not as long as in the anthropoid apes. The trapezium has a well-defined saddle-surface but the evidence provided by the other articular surfaces indicates that its 'set' in the carpus was unlike that found in modern man and similar to the condition in *Gorilla*. The capitate, though badly eroded, is generally more *sapiens* than ape-like.

Morphologically, the Olduvai hand bones cannot be closely matched with any known hominoid species living to-day. They bear, however, a greater similarity to juvenile *Gorilla* and adult *H.s. sapiens* than to adult *Gorilla*, *Pan* or *Pongo*. This is due largely to the absence in the fossil bones of any features peculiarly characteristic of brachiators. The adult

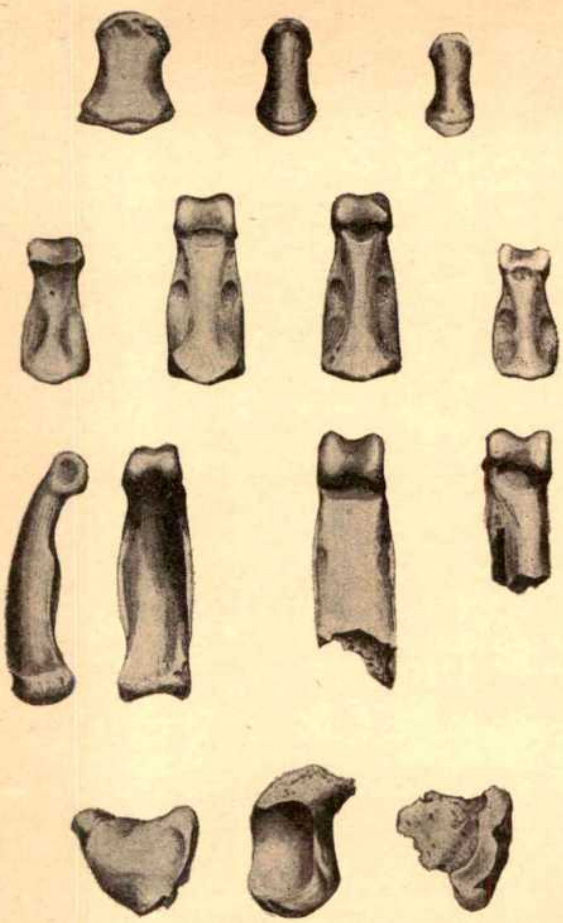

Fig. 1. Hand bone assemblage (drawings by Audrey Besterman). Top row, Juvenile. L. to R., terminal phalanx (thumb); 2 terminal phalanges (fingers). Second row. Juvenile. Middle phalanges, I–V. Third row. L. to R., proximal phalanx (adult), lateral and A.-P. views. 2 proximal phalanges (juvenile). Fourth row. Indeterminate age. L. to R. L. trapezium, L. scaphoid, L. capitate

gorilla hand has a number of specializations that are presumably related to its secondarily terrestrial mode of life and its great body-weight; these features, again, are absent from the fossil bone. The juvenile gorilla hand lacks the secondary specializations of the adult, and it is possibly for this reason alone that its bones have affinities with those of the fossil. The fossil bones differ from those of modern man in a number of features: (1) robustness; (2) dorsal curvature of the shafts of the phalanges; (3) distal insertion of the flexor digitorum superficialis; (4) strength of fibro-tendinous markings; (5) 'set' of trapezium in the carpus; (6) the form of the scaphoid; (7) the depth of the carpal tunnel. The fossil bones resemble modern man in the following features: (1) presence of broad, stout terminal phalanges on fingers and thumb; (2) form of the distal articular surface of the capitate; (3) ellipsoidal form of metacarpo-phalangeal joint surfaces.

There seems little doubt that this assemblage of fossil hand bones all belong to the same species. The difference between the juvenile and adult hand bones are no greater than the differences between the bones of an adult and a juvenile gorilla. In view of this conclusion that the two individuals on the *F.L.K. NN* 1 site are co-specific, all the hand bones are taken into account in the discussion of the functional and systematic implications of the hand as a whole.

While morphologically the precise affinities of the Olduvai hand are indistinct, functionally there seems little reason to doubt that the hand is that of a hominid.

The hand of modern man is capable of two basic prehensile movements that have been termed precision grip and power grip[1]. The power grip is used by man when a secure and strong grip is required for performing an activity in which the elements of delicacy and precision are of secondary importance. In the power grip the object is held as in a clamp between the flexed fingers and the palm, reinforcement and counter-pressure being supported by the adducted thumb. The precision grip, nevertheless, is used by man where a delicate touch and a precise control of movement is required and is achieved by means of a grip between the palmar aspect of the terminal phalanx of the fully opposed thumb and the terminal phalanges of the fingers. The essential osteological correlates of the precision grip are: (1) a fully opposable thumb with a broad spatulate terminal phalanx; (2) broad terminal phalanges on the other digits; (3) a proportion in length between thumb and digits that would permit a full pulp-to-pulp contact between them when they are approximated. While there appears to be little or no doubt that the Olduvai hand fulfils the first two requirements of the precision

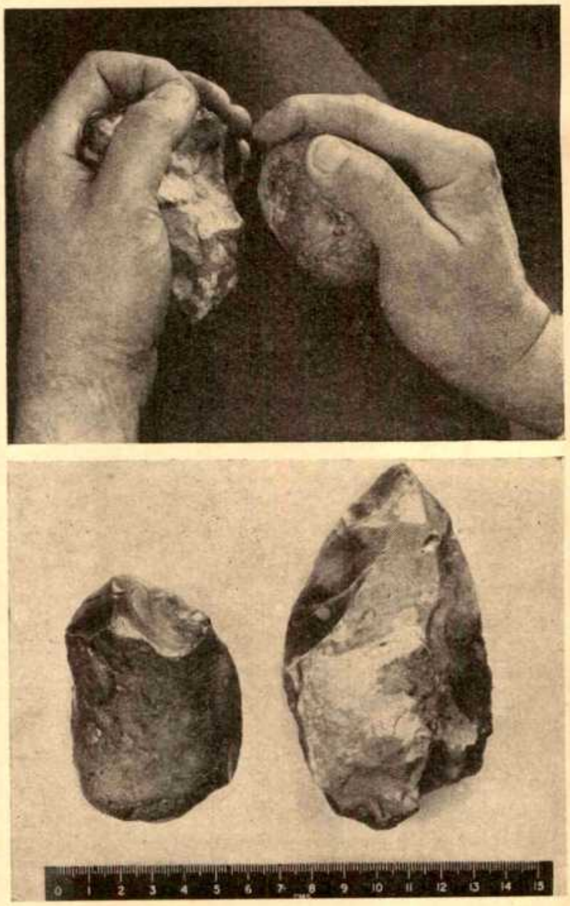

Fig. 2. Top, stone-on-stone technique of hand-axe construction using a power grip only. The flint core is being supported on the knee; bottom left, 'Oldowan' pebble-tool; right, 'Chellean' hand-axe made by me using the above technique

grip, there is no way to be certain about the last in the absence of the thumb metacarpal. While the saddle-surface of the trapezium leaves no doubt that the thumb could be rotated medially about its own axis to face towards the other digits, there is no reason for supposing that the proportions between the thumb and index finger of the fossil form are exactly as in modern man; indeed, the 'set' of the trapezium in the carpus suggests that this is not so. The question therefore is whether the thumb, having undergone rotation, is capable of pulp-to-pulp contact with the remaining digits. In the anthropoid apes while the thumb is opposable *per se*, pulp-to-pulp contact cannot be made owing to the marked disproportion of the length of fingers and thumb. It would seem, therefore, that the Olduvai hand was capable of power grip equal in performance, but, in view of the evidence of the attachment of the flexor tendons, comparatively greater in strength than in modern man. There is less certainty with regard to precision grip, which, while undoubtedly possible, may not have been as effective as in modern man. The overall picture presented by this assemblage is of a short powerful hand with strong, curved digits, surmounted by broad, flat nails and held in marked flexion. The thumb is strong and opposable, though possibly rather short.

At a recent conference at Burg Wartenstein, Austria, organized by the Wenner-Gren Foundation for Anthropological Research, an attempt was made to produce a diagnosis for the genus *Homo*. It was agreed that such a diagnosis could not be made unless certain characters and character complexes were present in combination. Included in these characters, which are referable to the skull, the brain and the post-cranial skeleton, was the criterion that 'the hand is capable of making tools of a recognizable culture'. If one assumes that the artefacts of an early Oldowan culture found on the living floor were the work of the species the remains of which are found there, then this criterion is fulfilled and, in addition, an interesting conclusion is possible: that toolmaking was established in the human lineage long before the hand had assumed its modern human form.

If, on the other hand, one bears the possibility in mind that some other, more advanced form was the toolmaker and the known incumbents of the floor were its victims, then it is in the functional morphology of the hand itself that one must look for evidence of toolmaking. On anatomical grounds there is no doubt that the Olduvai hand was sufficiently advanced in terms of the basic power and precision grips to have used naturally occurring objects as tools to good advantage. There is less certainty about toolmaking, which involves not only a peripheral but also a central intellectual factor as Oakley[2] has long insisted. The report on the Bed I juvenile skull fragments, soon to be published, may throw some light on this question by indicating the approximate cranial capacity of the juvenile skull.

Given the intellectual ability, the construction of the crude, rather small pebble-tools of the type found on the living floor, is well within the physical capacity of the Olduvai hand. Precision grip, which is imperfectly evolved in the fossil hand, is not an essential requisite at this level of craftsmanship as personal experiments in the construction of 'Oldowan' pebble-tools and 'Chellean' hand-axes have shown (Fig. 2).

THE BRITISH MUSEUM (NATURAL HISTORY)

NEW BOTANICAL EXHIBITION GALLERY

By J. F. M. CANNON

Department of Botany, British Museum (Natural History)

THE title of Prof. L. Hogben's familiar book, *Science for the Citizen*, acts as a challenge to anyone concerned with the planning and execution of a museum gallery concerned with some branch of science. The purpose of this article is to place on record the basic considerations and intentions that have guided us in the preparation of the new Botanical Exhibition Gallery which is at least the third in line of succession in the British Museum. Very little seems to be known of the exhibition at Bloomsbury, where all the departments of the British Museum were originally concentrated. A photograph shows it to have been in keeping with the austere traditions of adult education that the more enlightened and liberal Victorians were encouraging. Learning was not to be taken lightly, or perhaps only by those fortunate enough to enjoy a university education. Its successor, which was established after the move of the scientific departments to South Kensington in 1881, came to a violent end on the night of September 9–10, 1940, when, during the course of an air raid, an oil bomb was dropped on the east wing of the Museum. Although disastrous damage occurred and many valuable scientific specimens were destroyed some good resulted as it initiated a replanning of the accommodation so that additional storage space for the scientific collections, together with a fine new exhibition gallery, were made available within the existing shell of the building. The old gallery was stacked with valuable information, but made few concessions to the lay visitor drifting rather aimlessly around the Museum on a wet afternoon. In addition, the passage of time left some exhibits misleading and incomplete, while some major aspects of modern botany remained unmentioned.

It is now our duty to present the credentials of our new venture. First, for whom is it intended ? The obvious answer is that for a national museum the whole population must be the target. This, however, is a drastic over-simplification; to attempt to make a uniform appeal to all grades of intelligence and education over the population would in our opinion be disastrous. Some selection must be made to direct the main impact of the Gallery on to a particular target. Rightly or wrongly we have chosen those taking Ordinary or Advanced Level Certificate of

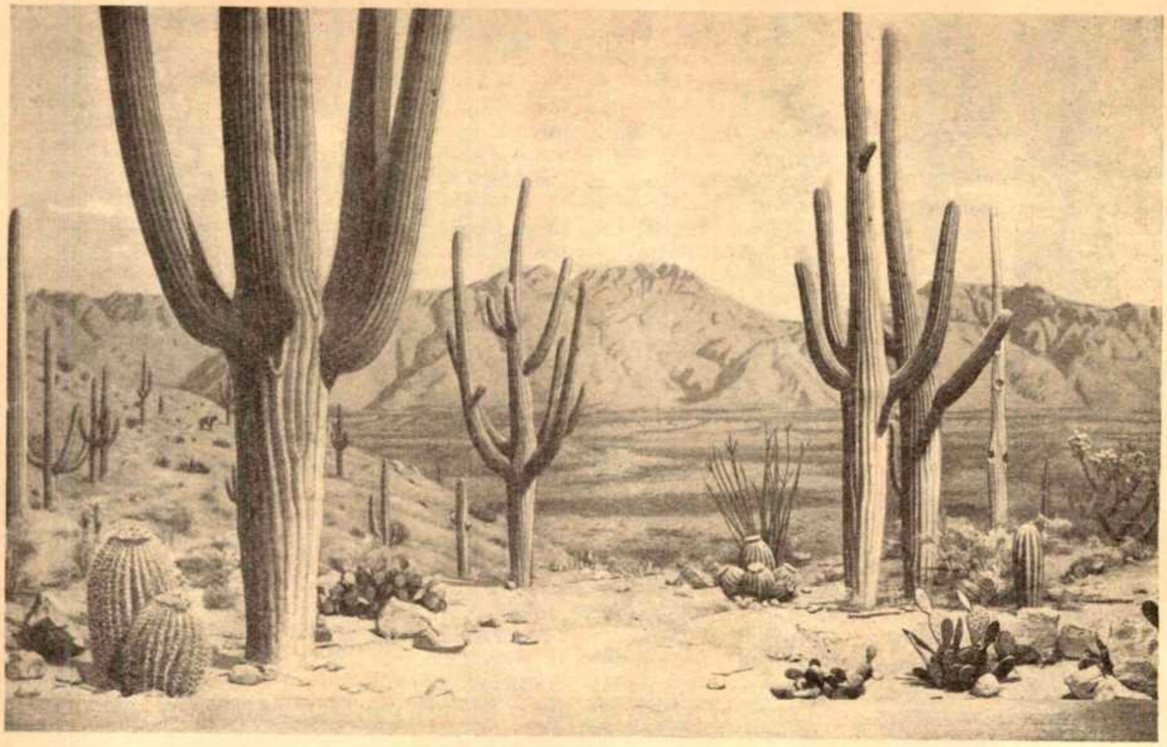

Fig. 1. A diorama of the Arizona Desert showing a group of the giant cactus (*Carnegiea gigantea*) with other desert plants. This is part of an exhibit illustrating plant life under arid conditions

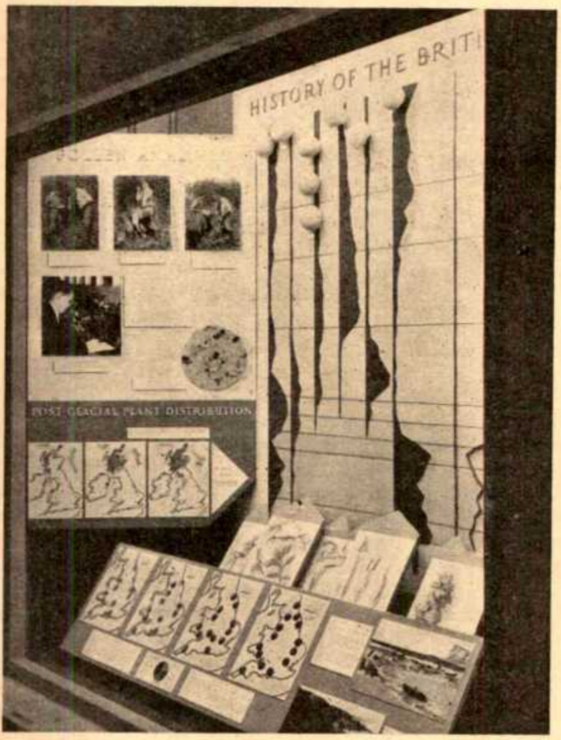

Fig. 2. Part of an exhibit which illustrates the history of the British flora since the last glaciation. The left-hand panel describes the technique of pollen analysis; large models of the most important pollen grains are placed on the diagram at the back

Education courses at school as our central group. Some preliminary research with pupils and teachers suggests that there are many ways in which a museum gallery can supplement and complement the teacher's work in classroom and laboratory. In some instances we can provide models and explanatory diagrams which are beyond the resources of the ordinary school, and which should help to explain some of the more difficult parts of the syllabus; the opportunities for supplementing the syllabus and widening the pupil's botanical horizons are, of course, limited only by the space available. While we are catering especially for this group, we try to ensure that each exhibit contains something of interest for all levels of intelligence. If we achieve nothing more than a new awareness of the extraordinary beauty of plants, then we shall not have failed in our intentions.

What then are our aims? Our chief aim is to present a broad and catholic picture of modern botany, but with the limitations of space and time, special emphasis has been given to certain topics like ecology, because they are of wide general interest and to some extent are the responsibility of everyone. In considering the chief plant groups we have mainly stressed functional morphology, rather than systematics. We have devoted quite a lot of space to plant physiology, so often neglected in museums, but which, as one of the most progressive and advanced aspects of botany, demands attention. We have tried to steer a course between the old 'carbon dioxide + water = sugar + oxygen' (a statement so simplified as to be quite misleading in the absence of further information) and the detailed results of recent scholarship which are gradually revealing the amazingly complex workings of the living cell. We

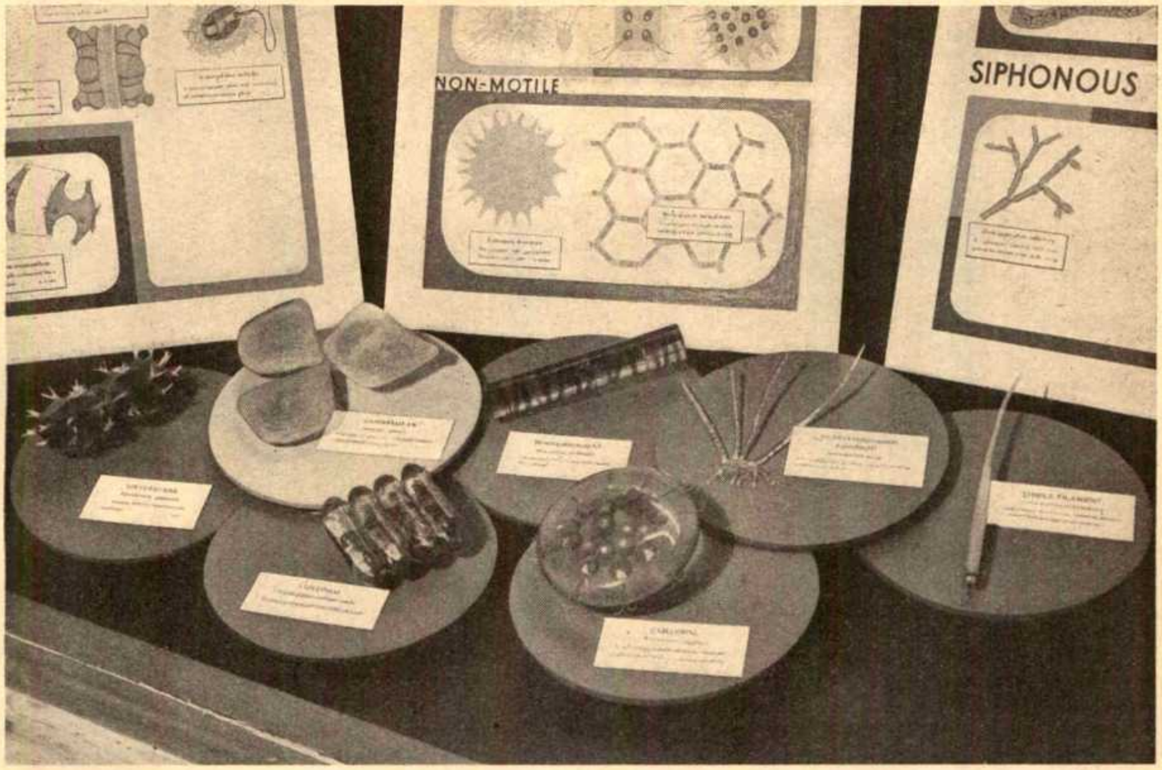

Fig. 3. A series of plastic models to illustrate the increasing complexity of structure in the algae, from unicellular species to those with a complex heterotrichous system of filaments

feel that if we present even a brief glimpse of the network of reactions controlled by enzymes we shall have achieved something.

The dioramas, which are supported by ample teaching material, form our main ecological exhibits. Each exhibit is designed to emphasize one or more basic ecological principles. Thus, the sand dune/salt marsh exhibit deals with succession in space and time, while in the British mountain case the importance of underlying rock in the determination of the land-forms, soil and flora developed is stressed. The Himalayan diorama illustrates the importance of altitude in determining the vertical zonation of vegetation, and the British mountain exhibit demonstrates the effect of altitude on individual plants. The exhibits produced jointly with the Nature Conservancy are concerned with the establishment and scientific management of nature reserves, especially the need for fundamental ecological research before sound management plans can be formulated. What more appropriate end could there be to a biological gallery ? Unless everyone becomes aware of the need for the right use of natural resources, the efforts of disarmament commissions alone will not be sufficient to preserve a world fit to live in.

We should like to commend to our fellow scientists the need for continuing improvement in our relations with the general public. This is no new idea; but it is obvious that many opportunities remain to be taken. There can be no doubt that in problems like conservation the eleventh hour is already with us, while an informed and sympathetic public opinion must form the soundest basis for expanding research. In the last analysis the public holds the purse strings for most scientific research and development and is entitled to full information, both on recent progress and the broad picture of each major branch. A public which feels that scientists have little patience with their ignorance and no time to make their work comprehensible to the layman, is less likely to support scientific research than one whose interest has been stimulated by sound information made freely available. If our new gallery has made some contribution to explaining not only botany but also the kind of work on which modern botanists are engaged, we shall not feel that we have failed.

OBITUARIES

Dr. U. S. Haslam-Jones

Dr. Ughtred Shuttleworth Haslam-Jones, who died on August 7, was the son of the Rev. M. A. Haslam-Jones, then Baptist minister of Hackney, London, but later a clergyman of the Church of England. He was born on July 12, 1903, and educated at various schools as his father moved from one church to another. From Ealing County School he obtained a mathematical scholarship to Queen's College, Oxford, in 1921. At Oxford he was awarded Firsts and the junior and senior mathematical scholarships, and then took a D.Phil. degree under the supervision of G. H. Hardy.

His thesis on the theory of functions of a complex variable contained a more memorable result than such efforts usually do. There is a well-known theorem of Hadamard that if the function $f(z) = \Sigma a_n z^n$ has singularities at points $\alpha_1, \alpha_2, \ldots$ and $g(z) = \Sigma b_n z^n$ has singularities at points $\beta_1, \beta_2, \ldots$, then the singularities of the function $F(z) = \Sigma a_n b_n z^n$ are among the points $\alpha_m \beta_n$. It is far from obvious how to extend this theorem to functions of more than one variable, but an extension to functions of two variables was found by Haslam-Jones. The result, which is not so easy to state as Hadamard's, is in the *Proceedings of the London Mathematical Society* (Ser. 2, 27, 223; 1928).

From 1927 until 1936 he was a lecturer at the University of Liverpool. The rest of his life was spent as Fellow and tutor of Queen's College, Oxford, where he succeeded his old tutor, C. H. Thompson. He was an excellent tutor and was also highly regarded as a lecturer, his usual topic being the theory of functions of a real variable. He served on the Council of the London Mathematical Society from 1937 until 1944, and was a vice-president of the Society from 1940 until 1942. From 1940 until his death he was an editor of the *Quarterly Journal of Mathematics*.

His main scientific interest was in the theory of functions of a real variable, and he published a series of papers on this subject, some of them in collaboration with Dr. J. C. Burkill. The main object of these papers is to show that even very irregular functions, which are not necessarily differentiable in the ordinary sense, still have derivatives in some generalized or approximate sense, except possibly in sets of points of measure zero.

He was a friendly and loyal colleague and will be much missed by all in Oxford.

E. C. TITCHMARSH

Mr. Simeon M. Aisenstein

THE death occurred on September 3 at Chelmsford of Mr. Simeon M. Aisenstein, a pioneer of radio communication in Europe, particularly in the development of thermionic valves.

Mr. Aisenstein was born at Kiev in 1884, and directed his attention to wireless telegraphy as a boy of 16. After studying at the University of Kiev and Charlottenburg Polytechnic, he established a private experimental laboratory prior to the formation of a wireless company. Following a visit to England, this Russian firm was merged into Marconi's Wireless Telegraph Co., Ltd., with Aisenstein as director and principal technical adviser on developments in Russia.

During the First World War, Aisenstein was responsible for all the high-power stations in Russia, and for the maintenance of communications with the Allies. He conducted experimental work in collaboration with the Army and Navy, including pioneer trials in communication with submerged submarines which attracted the attention of the British Admiralty. In 1917, during the Bolshevik revolution, Mr. Aisenstein was imprisoned, but managed to escape to England in 1921, and joined the Marconi Co. A year later he was appointed to a company established by Marconi's in Poland: he was instrumental in the development of this company, particularly in the manufacture of radio valves. In 1935 he went to Czechoslovakia to set up another valve factory, but had to return to Chelmsford in 1939. Here he was at first engaged in the design of radio equipment, and later took over the valve laboratories of the Company. On the formation of the English Electric Valve Co., Ltd., in 1947, he became the first general manager, a position he held until his retirement in 1955, after which he continued to act as a consultant to the Company.

Mr. Aisenstein had been professor at the Moscow Higher Technical School and a vice-president of the Russian Society of Radio Engineers. In recognition of his service, he was appointed a Councillor of State for the Russian Empire in 1915, and was made an Officer of the Legion of Honour by the French Government in the following year. He was the author of many patents and a number of scientific and technical papers.

NEWS and VIEWS

Bacteriology at St. Andrews: Prof. W. J. Tulloch

PROF. W. J. TULLOCH has just retired after occupying the chair of bacteriology at Queen's College, Dundee (University of St. Andrews), for 41 years. Throughout this long period, Tulloch brilliantly fulfilled the double role of teacher and research worker besides being dean of the Medical Faculty for many years and supervising the ever-growing diagnostic bacteriological services for both hospital and local authorities. He was an indefatigable and meticulously careful bench worker, and his publications consist largely of a series of major studies—on the mechanism of agglutination, the anaerobic infections of war wounds including the serological types of the tetanus bacillus, the laboratory diagnosis of smallpox, the occurrence of tubercle bacilli and brucellæ in milk, diphtheritic infections in a partially immunized community, and the laboratory diagnosis of gonococcal infections. In most of these fields of study, he was a pioneer who blazed the trail for others to follow. He gave the Harben Lectures in 1934, and for the Lister Lecture of the Royal College of Physicians, Edinburgh, in 1956, he took as his theme "Medicine as an Aspect of General Biology". Tulloch loved to teach and to the end undertook practically all the formal lectures to the undergraduate classes. He was a dramatic and very effective teacher and even in the vivas at the professional examinations, he answered most of his own questions. Undoubtedly he inspired many young men both in and outside his department, and these 'old boys' will long cherish their association with the *maestro*.

Prof. J. P. Duguid

DR. J. P. DUGUID, who succeeds Prof. W. J. Tulloch, is an Edinburgh man, born and bred. Educated at Edinburgh Academy, he went up to the University at the age of 17 and graduated with honours in both science and medicine. After some hospital experience, he was appointed lecturer in bacteriology in 1944, became senior lecturer in 1954 and was given the status of reader in 1960. He gained his M.D. with honours and a gold medal in 1949. Like his predecessor, Duguid is outstanding both as teacher and research worker. In a department with a heavy teaching load, he has taught systematic and practical courses of bacteriology for medical, dental, veterinary and science undergraduate students and in the diploma courses for public health and tropical medicine and other postgraduate classes. He has been largely responsible for the development of the Honours School in Microbiology in Edinburgh. His early research work during and after the Second World War was on the use and mode of action of penicillin, and he made the acute observation in 1946 that penicillin probably acted directly on the cell wall. Later, he did excellent work on the modes of spread of respiratory infections and their control by air disinfection, etc. More recently, he has worked in the field of bacterial cytology and physiology, using electron microscopy and other methods to investigate the structure and function of bacterial capsules, inclusions, fimbriæ and non-fimbrial adhesive factors. He is an assistant editor of the *Journal of Pathology and Bacteriology*.

Pharmacy at London: Prof. W. H. Linnell

PROF. WILFRED H. LINNELL retired from the position of dean of the School of Pharmacy, University of London, on November 1. A native of Cheshire and educated at Stockport Grammar School, Prof. Linnell has very strong ties with the north-eastern part of Britain, where, in Newcastle upon Tyne, he served his four-year apprenticeship in a pharmaceutical business. He joined the School of Pharmacy, in London, as a student in 1914 and obtained his fellowship of the Pharmaceutical Society (together with the Society's Silver Medal) in 1916. Within five weeks he was in France with the Special Brigade, Royal Engineers. After demobilization he returned to Newcastle, as a student of chemistry at King's College, where he obtained an honours degree and was Johnson Fellow and Prizeman in 1921. The award, in 1922, of the Earl Grey Memorial Fellowship took him to Lincoln College, Oxford, where he studied with W. H. Perkin. But local patriotism guided him back to Durham, where he gained his Ph.D. in 1924. After a short period at the Fuel Research Station, East Greenwich, he joined the School of Pharmacy in 1926, where the University of London had just instituted a degree in pharmacy. Prof. Linnell took charge of the Chemistry Department, in which he was appointed reader in 1927, and professor of pharmaceutical chemistry in 1944. On the retirement of Prof. H. Berry in 1956, Linnell became part-time dean of the School and supervised its transference from the old premises in Bloomsbury Square to the modern building in Brunswick Square. He remained part-time dean until his retirement from the chair in 1961, when he became full-time dean of the School. Since 1926 Prof. Linnell has been prominent in all pharmaceutical affairs. He has been examiner to the Pharmaceutical Society for Statutory Examinations since 1927, a member of the Revision Committee of the *British Pharmaceutical Codex* and a member of the British Pharmacopoeia Commission Committee.

Dr. F. Hartley

DR. FRANK HARTLEY, who succeeds Prof. W. H. Linnell, entered pharmacy in 1929, under the old 'oral and practical conditions', and after Part 1 continued his studies for the pharmaceutical chemist examination with an intercollegiate course at University College and the School of Pharmacy, University of London. He was awarded the School's silver medals in pharmaceutics, pharmacognosy and pharmaceutical chemistry and immediately commenced the study of chemistry at Birkbeck College. In 1933 he obtained an honours degree in chemistry with distinction and first prize for the course. From 1933–40 he was successively demonstrator and lecturer at the School of Pharmacy, from which Institution he took his Ph.D. in 1941 under the supervision of Prof. Linnell. Hartley helped supervise the evacuation of the School to Cardiff and then in 1940 joined Organon Laboratories, Ltd., as chief chemist and factory manager. From 1943–46 he was secretary to the Therapeutic Research Corporation and the General Penicillin Committee of the Ministry of Supply. He assumed his present position as scientific services director of the British Drug Houses in 1946. Dr. Hartley is well known in pharmaceutical circles. He has been chairman of the British Pharmaceutical Conference (1957) and is a member of the British Pharmacopoeia Commission Committee. He has also been examiner in pharmaceutical chemistry to the Pharmaceutical Society. His outstanding contributions to the subject were recognized in 1961 by his election to the Sir William Jackson Pope Memorial Lectureship of the Royal Society of Arts. Dr. Hartley has been actively associated for many years with the Royal Institute of Chemistry. He has served many periods as a member of Council and was a vice-president from 1958–60. His numerous friends and associates wish him many years of success in his return to the scene of his earlier triumphs.

Research Committee for Chemical Engineering

FOLLOWING publication of the first report of the Exploratory Committee in the April 1962 issue of *The Chemical Engineer* on the subject of chemical engineering research (see *Nature*, 195, 209; 1962), the Council of the Institution has now set up a Research Committee under the chairmanship of Dr. J. W. Barrett, director, Monsanto Chemicals, Ltd. The Research Committee will be responsible under the Council for the Institution's activities in encouraging, promoting and guiding research in chemical engineering. Broadly, the objects will be: (*a*) to help formulate and implement explicit research programmes in fields of chemical engineering in which fundamental research is thought to be required; (*b*) to help to maintain lively and realistic academic research programmes; (*c*) to suggest speculative and exploratory fields of research detached from the present-day preoccupations of industry; (*d*) to make recommendations as to the part which research institutes might play in chemical engineering research. The specific responsibilities of the Committee will include: (1) recommendation to the Council of individuals and topics for industrial research fellowships, guidance of Fellows after their appointment, receipt of their reports and recommendations for action thereon; (2) establishment of working parties and review of the working parties' activities.

U.S. Centre for Advanced Research in Astrophysics

THE Joint Institute for Laboratory Astrophysics (JILA) has announced a visiting membership programme directed at bringing scientists from throughout the United States and abroad to study at the Institute, which is situated at the University of Colorado in Boulder. The visitors will have complete freedom to work on problems of their own choice for as long as a year. Stipends are available for up to ten scientists during 1963. Visiting memberships are also available for those having other sources of funds. In providing a centre for advanced research in astrophysics, the Institute hopes to stimulate the continuous interchange of ideas from many areas. Much of the present work of the Institute concerns particular stellar atmospheres, atomic and molecular collisions and resonance phenomena. The Institute was set up last spring under the chairmanship of Dr. Lewis M. Branscomb. The original professional staff consists of eight atomic physicists from the National Bureau of Standards in Washington, two astrophysicists from the Bureau's Boulder laboratories, and a group of scientists headed by Prof. Wesley Brittin, chairman of the Physics Department, University of Colorado. The closing date for applications is January 15, and requests for application forms should be addressed to the Secretary for Visiting Members, JILA, 1511 University Avenue, Boulder, Colorado.

Radioactive Fall-out from U.S.S.R. Tests

The total amount of fall-out scattered globally from all the Soviet nuclear tests of 1961 exceeds that produced by the combined testing of the United States and Great Britain for the same time span, according to a study conducted by the U.S. Atomic Energy Commission (*Fallout from U.S.S.R. 1961 Tests*. By G. M. Dunning. Office of Technical Services, U.S. Department of Commerce, Washington 25, D.C., January 1962. 50 cents). The fall-out of fission products, as at the end of 1961, is based on 50 megatons of Soviet nuclear tests against 35 megatons of combined United States and British testing. The details show that total amount of fission products scattered globally from the test sites of nuclear explosions conducted by the U.S.S.R. from all their past tests, up to and including 1961, exceeds that for the United States and the United Kingdom during the same period. The study also shows that, from the 1961 U.S.S.R. testing alone (strontium-90 and cæsium-137), the amount of long-lived radionuclides that may be deposited in the United States (45 mc. per square mile for strontium-90 and 80 mc. for cæsium-137) would be equal to or a little more than that from the United States and United Kingdom tests in the past (40 mc. per square mile for strontium-90 and 70 mc. per square mile for cæsium-137). The amount of long-lived radionuclides from all past Soviet tests (90 mc. per square mile for strontium-90 and 160 mc. per square mile for cæsium-137) would be twice that from all past United States and United Kingdom tests.

The International Council of Scientific Unions

The Year Book of the International Council of Scientific Unions for 1962 comprises a Calendar of Arrangements for 1962 with lists of the officers of the Bureau, members of the Executive Board, national members of the Council and of the scientific members of the Council (Pp. 124. Rome: International Council of Scientific Unions, 1962). These are the international scientific unions, and the Year Book also includes details of the aims of the several unions, the officers of their various commissions, federated associations, committees or sections, and the members of the Committees of the International Council of Scientific Unions, and the joint Commissions and Executive Bodies of the International Council's permanent services. The statutes and by-laws of the Council are also given, together with the rules and charters for the scientific and special committees. There is an alphabetical list of the members of the Bureau, Executive Board, Scientific and Special Committees, Joint Commissions and other organs of the Council. The Treasurer's report and financial statement for 1961 are issued separately as a supplement. Apart from the inclusion of the calendar of arrangements, the items of which have now practically all occurred, the wealth of reference material makes it highly desirable that the Year Book should be published early in the year to which it relates: publication at least in the first quarter could be reasonably expected.

First World Conference on National Parks

The first world conference on "National Parks" was held in Seattle, Washington, during June 30–July 7. The conference was sponsored by the International Union for Conservation of Nature and Natural Resources and co-sponsored by Unesco and the Food and Agriculture Organization, in association with the United States National Park Service and the National Research Council of America. The general chairman of the conference and of the United States Steering Committee was Dr. Harold J. Coolidge, executive director of the Pacific Science Board of the United States National Academy of Sciences, who is also chairman of the I.U.C.N. Commission on National Parks. The object of the conference was to achieve a more effective international understanding and encouragement of the national parks movement on a world-wide basis. Although national parks and reserves have been established by most member countries of the United Nations, some have not yet done so. The theme of the conference was "National Parks of International Significance". The conference directed attention to the necessity of maintaining existing national parks as well as establishing new ones, and enabled Government representatives and other qualified experts to meet together to expand their efforts and co-ordinate their activities. In reviewing past international action in the national park sphere, mention should be made of the London Conventions of 1900 and 1933 for the protection of African fauna and flora. These treaties stimulated conservation programmes in many parts of Africa as well as in other continents, as did the 1942 Convention on Nature Protection and Wildlife Preservation in the Western Hemisphere which has been ratified by twelve American Republics. Many Governments in Africa and Latin America have introduced legislation for setting up and administering national parks and reserves based on the definitions and objectives contained in these important international agreements. A special supplement containing resolutions adopted by the conference is included in the *I.U.C.N. Bulletin* (4; July/September 1962).

Radio Chimica Acta

The temptation to establish new scientific journals appears to be irresistible. The first number of *Radio Chimica Acta* has a foreword by a great German radiochemist, Otto Hahn, in which he poses the rhetorical question as to whether a journal, specially devoted to radiochemistry, can discharge an important function differing from that already performed by existing chemical and physical journals (*Radio Chimica Acta*, Vol. 1, No. 1; September 1962. Pp. 1–48. Price per volume (4 issues), 72 D.M.; 18 dollars. Frankfurt a.M.: Akademische Verlagsgesellschaft; New York and London: Academic Press, 1962). After outlining briefly the history of radiochemistry, he concludes that a place is needed where the results now published in a variety of journals can be brought together. One could give wholehearted support to this view if every paper published fitted neatly into only one of the subdivisions of science and if the boundaries of the subdivisions were unambiguous. However, it is of the nature of science that these two conditions are rarely, if ever, satisfied.

This is well exemplified by the contents of the first number of this journal, which comprises ten papers and two short notes. One paper is straight radiation chemistry, two are concerned with hot atom chemistry, one with complexes of neptunium IV and one is a somewhat technological approach to fractional solvent extraction separation procedures. One cannot help feeling that most of these papers might easily have found a much wider range of readers by publication in the established chemical journals. To have an additional journal for papers of this kind recalls the words of the sonnet "So all ... is dressing old words new, spending again what is already spent". In short, interested workers must pay again to read those papers which they should reasonably be able to expect to find in the journals to which they already subscribe. This is not a situation in which one can welcome another new journal, unless it promises to be of unusually high quality and to meet a really important need which, in this case, seems unlikely.

The National Museums of Ceylon

The National Museums of Ceylon clearly recognize research as one of their functions, and the current issue of *Spolia Zeylanica*, bulletin of the National Museums of Ceylon (29, Part II; 1962), gives renewed proof of the value of their work. The part includes papers on geology, zoology and anthropology, many written by the director, Dr. P. E. P. Derniyagala. The papers are all well produced and illustrated.

Glossary of Atomic Terms

The fourth edition of the booklet *Glossary of Atomic Terms* has been published by the U.K. Atomic Energy Authority. It provides a convenient collection of easily understood definitions of more than 400 terms and abbreviations used in atomic energy. This glossary is intended to be of help to those who are studying atomic energy for the first time. It may therefore be regarded more as a layman's manual of instruction than a source book of highly scientific definitions. For those already familiar with underlying principles, more technically precise definitions have been published by the British Standards Institution in their glossary *BS* 3455: 1962. The glossary is available from H.M.S.O. at 3*s*. 6*d*. net.

Italian Rock Carvings

In the foothills of the north Italian mountains there are several areas where prehistoric figures of animals, signs and weapons occur, carved on rock surfaces. The most famous series has long been known, thanks to the research work of the late C. Bicknell. They occur in the Ligurian Alps around Monte Bego, inland from Mentone. Another group, to be found in the Val Camonica where the valley debouches on to the north Italian plain, was described some years ago by Prof. Marro. While differing in several respects from the Monte Bego series, the Val Camonica art is undoubtedly, culturally speaking, connected with it, and both can be dated to the Early Metal Age. Superpositions make it possible to determine several slightly differing 'layers' at the Val Camonica. More recently, Dr. E. Anati has studied this region, and in the August issue of *Man* he has published a note on some figures of halberds, occurring at a site called locally Roccia dei Corni Freschi which lies near the River Oglio, just north of where it enters the Iseo Lake. Figures of halberds also occur at Monte Bego, but the types are not identical. An important book on his campaigns in the Val Camonica has recently been published by Dr. Anati in the United States, but for some copyright reason the work cannot be obtained in Great Britain.

Anæsthesia and Analgesia

Advances in anæsthesia are among the most dramatic in the whole field of medicine. Inevitably, these advances have meant an increasing degree of specialization, with the result that, outside the sphere of domiciliary obstetrics, relatively few general practitioners have now much experience in anæsthetics. Anæsthesia, however, as Prof. Beecher points out in an article in a symposium on "Anæsthesia and Analgesia" in the August issue of *The Practitioner* (189, No. 1130; 1962), is merely a branch of one of the most fundamental problems in medicine—the relief of pain. It is incumbent on all clinicians to keep in touch with what is being achieved in this field. To help them do so is the purpose of this symposium. In spite of increasing specialization—or perhaps because of it—society is gradually re-learning the old lesson that the essence of the practice of medicine is holism. The patient, not his disease, is the primary concern of the doctor. Nowhere is this truer than in the alleviation of pain—whether by anæsthetic, analgesic or human sympathy.

University News: Belfast

The following appointments to lectureships have been announced: J. Graham (civil engineering); Dr. J. H. Jones (dental pathology); A. Brown (mechanical engineering); Dr. A. M. Rosie (light electrical engineering).

Cambridge

C. Strachey, of King's College, has been elected to a senior research fellowship (Title *B*) at Churchill College.

Columbia

Dr. Tsung-Dao Lee is rejoining the Columbia University Department of Physics as a full-time member of the teaching staff. For the past two years, Dr. Lee has been adjunct professor of physics at Columbia, while serving as a member of the Institute for Advanced Study at Princeton. His new title at the University for the 1962–63 academic year will be visiting professor of physics. It was while he was a member of the Columbia Department of Physics that Dr. Lee was awarded the 1957 Nobel Prize in Physics jointly with Dr. Chen Ning Yang, of the Institute for Advanced Study, for their work in the disproof of the 'principle of conservation of parity'.

London

The following titles have been conferred: *Professor*, on Dr. R. L. F. Boyd (physics), in respect of his post at University College; on Dr. Florence N. David (probability and statistics), in respect of her post at University College; on Dr. Leonard Saunders (pharmaceutical chemistry), in respect of his post at the School of Pharmacy. *Reader*, on Mr. H. H. Bentall (thoracic surgery), in respect of his post at the Postgraduate Medical School of London; on Dr. D. Mendel (physiology), in respect of his post at King's College.

Sheffield

THE following appointments to lectureships have been announced: Dr. J. C. Bowman (honorary lecturer in genetics); Dr. N. M. Atherton (chemistry); Dr. D. Bellamy (zoology); Dr. P. J. Foster (fuel technology and chemical engineering); H. Hartnagel (electrical engineering); Dr. H. K. Kohler (applied mechanics); Dr. J. N. Murrell (honorary lecturer in chemistry); P. Polak (mechanical engineering); J. Swithenbank (fuel technology and chemical engineering); Dr. G. H. Tattersall (building science); Dr. A. K. Walton (physics). D. S. Buist has been appointed to the W. J. Rees research fellowship in refractories technology.

Sussex

THE following appointments to lectureships have been announced: Dr. G. G. C. Routh (economics); I. Hunt (philosophy); Dr. J. M. Radcliffe (theoretical physics); A. D. C. Grassie (experimental physics); Dr. B. L. Smith (experimental physics); Dr. J. D. Smith (chemistry).

Graduate Plastics Programme at Princeton

A GRADUATE programme has been instituted at Princeton University incorporating engineering study and fundamental research in plastics which can lead to the degree of M.Sc.(Eng.) or in certain cases to candidateship for a Ph.D. in the Departments of Mechanical or Chemical Engineering with support of the plastics programme. Instruction covers basic theory and properties, evaluation, production, fabrication, design and application of materials, as well as chemistry of plastics. The programme includes lecture and laboratory classes, and contact with industrial plants representing various interests of the plastics industry. Fellowships covering stipend, tuition and fees are available as well as opportunities for employment as part-time research assistants. Applicants for admission must hold a first degree in engineering or physical science from a recognized institution and must meet general admission requirements of the Graduate School of Princeton University. Further information can be obtained from Prof. Louis F. Rahm, director, Plastics Laboratory, Princeton University, Princeton, N.J.

The 1963 Stanley Clifford Milk Industry Award

THE Central Milk Distributive Committee, in recognition of the valuable services rendered in the dairy industry by Stanley Clifford, who was for many years chairman of the Committee, has established a Fund for the purpose of providing awards to enable a suitable applicant to make a short study tour of the dairying industry in the United Kingdom or abroad. Employees in the dairy industry or in dairy engineering in the United Kingdom who are below the age of thirty are eligible. With the consent of the Central Milk Distributive Committee it has been decided that the 1963 Award shall take the form of a study tour of approximately ten days duration on the Continent and efforts will be made to arrange this to give the greatest benefit to the winning candidate. Candidates should make their application in the form of a short statement covering the following points: (1) length of service in the industry; (2) nature of past and present employment; (3) particulars of any training courses attended; (4) the type of tour the candidate would like to make and the benefit it is hoped to derive from it. Applications for this Award should be made to the Secretary, Society of Dairy Technology, 17 Devonshire Street, London, W.1, not later than January 31, 1963.

Fulbright Travel Grants

UNDER the provisions of the Fulbright programme, travel grants are available to citizens of the United Kingdom and dependent territories to go to the United States of America for academic or educational purposes, provided that they have adequate financial support in dollars for the proposed period of the visit to the United States, and can show proof of admission to an institution of higher learning in the United States for a minimum period of nine months. All grants cover the cost of direct round-trip travel between a candidate's home and the American university or institution. They are available between June 1 and August 15, 1963, for which application must be received by March 16, 1963, and between August 16, 1963, and April 1, 1964, for which applications must be received by June 1, 1963. Application forms and further information can be obtained from the United States Educational Commission in the United Kingdom, 71 South Audley Street, London, W.1.

Announcements

MR. W. A. C. MATHIESON (Dependent Territories) has been appointed chairman of the Executive Council of the Commonwealth Agricultural Bureaux in succession to Dr. V. Armstrong (New Zealand). Mr. H. E. Seneviratne (Ceylon) has succeeded Mr. W. G. Alexander (United Kingdom) as vice-chairman.

THE autumn general meeting of the Iron and Steel Institute and the forty-fifth meeting of the Iron and Steel Engineers Group will be held in London during November 28–29. Further information can be obtained from the secretary, K. Headlam-Morley, Iron and Steel Institute, 4 Grosvenor Gardens, London, S.W.1.

A SYMPOSIUM on "Citrate Metabolism" will be held by the Bone and Tooth Society at the Institute of Orthopædics, 234 Great Portland Street, London, W.1, on November 9. Further information can be obtained from the honorary secretary of the Society, Prof. B. Cohen, Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2.

THE autumn meeting of the Clay Minerals Group of the Mineralogical Society will be held in the apartments of the Geological Society of London, Burlington House, Piccadilly, London, W.1, on November 9. Further information can be obtained from the honorary secretary, R. M. S. Perrin, School of Agriculture, University of Cambridge, Cambridge.

THE winter meeting of the Powder Metallurgy Joint Group of the Iron and Steel Institute and the Institute of Metals will be held at Church House, Great Smith Street, London, S.W.1, during December 10–11. Included in the programme is a symposium on "Non-metallic Dispersions in Powder Metallurgy". Further information can be obtained from the Secretary, Powder Metallurgy Joint Group, 17 Belgrave Square, London, S.W.1.

THE INSTITUTE OF PHYSICS AND THE PHYSICAL SOCIETY

THE report of the Council of the Institute of Physics and the Physical Society for the year 1961 was adopted at the annual general meeting of the Institute and Society held on July 10, 1962. During the year the Council met five times. It has been decided to mark annually the anniversary of the amalgamation of the Institute and Society in May 1960 by a series of meetings and functions, and the first of these was held on May 2 and 3, 1961. Sir John Cockcroft delivered his presidential address entitled "The Development of Physics" (*Bull. Inst. Phys.*, 12, 109; May 1961) in the Royal Commonwealth Society's hall; the first annual dinner of the amalgamated body was held at the Park Lane Hotel, London; and the first annual representative meeting, consisting of the officers of the various branches and groups and past-presidents of the Institute and Society, was held at the headquarters of the Institute and Society, 47 Belgrave Square, London.

During the year under review 1,161 applications for election or transfer to the various grades of membership were received. The total membership on December 31, 1961, numbered 9,120, consisting of 1,268 Fellows, 3,054 associates and 1,997 graduates, in addition to Fellows of the Physical Society, students and subscribers. This represents an increase of 400 over the year. The two technical colleges which applied for recognition for the purpose of the membership regulations relating to approved courses were visited by members of the Membership and Education Committee and both were accepted. Fifty-four technical colleges presented 987 candidates for the Ordinary National and thirty-five colleges 455 candidates for the Higher National Certificate in applied physics. Of the larger number, 239, of candidates for the graduateship examination, 64 were successful; fifteen question papers were set. An examination for Part 1 under the new regulations was also held; only three of the twenty-three candidates who entered were successful.

The Institute and Society was one of the sponsoring societies of the international conference held in the University of Manchester during September 4–8 to mark the jubilee of the discovery of the nucleus by Lord Rutherford. Other conferences and symposia were arranged during 1961.

The report of the committee under the chairmanship of Prof. R. V. Jones on problems facing university physics departments was submitted to the Robbins Committee, and has since received wide publication. All three of the Institute and Society's monthly periodicals, the *Proceedings of the Physical Society*, the *British Journal of Applied Physics* and the *Journal of Scientific Instruments*, increased in size compared with the previous year. A table in the annual report gives details of the material published in the periodicals during 1960 and 1961. Other publications sponsored by the Institute and Society were *Noise in Electronic Devices* and *Selected Papers on Stress Analysis* consisting of papers presented at Group conferences. Two new books, *Automatic Control* by A. E. De Barr and *Viscosity and its Measurement* by A. Dinsdale and F. Moore, are to be published in the "Monographs for Students" series, together with a new edition of J. Topping's *Errors of Observation and their Measurement*. A sixth volume in the series of "Laboratory and Workshop Notes", consisting of selections from the *Journal of Scientific Instruments* and compiled and edited by Dr. Ruth Lang, is shortly to appear.

The Institute and Society maintains ten specialist groups and nine branches in Great Britain, and two branches overseas, in Australia and Malaya respectively. A summary of the activities of these sections is given in the annual report, together with a list of the Council's representatives and nominees on joint and other committees and organizations.

The Australian branch consists of six divisions, and divisional activities have included a conference in Brisbane entitled "Sun–Earth Environment" organized by the Queensland and New South Wales Divisions at which more than forty papers were discussed by 120 delegates, in addition to about fifty scientific meetings and social events.

The activities of the Malayan branch were confined to its members attending colloquia in the Physics Department of the University of Malaya. The largest of the branches, the London and Home Counties Branch, with 4,113 members, held a symposium on "The Soil" during March in conjunction with the Royal Institute of Chemistry and the Institute of Biology. The subject of the Easter conference of the Education Group was "Communication: Physics for the Non-Specialist", and the summer meeting consisted of a visit to the research laboratories and new factory of Hilger and Watts, Ltd. During February the Electronics Group joined with the British Institution of Radio Engineers in promoting a meeting on "Tunnel Diodes". In the autumn a conference was held in Leamington on "The Physics of Gas Discharge Devices". The Low Temperature Group held a number of whole-day and half-day meetings. Topics discussed included: ultrasonic absorption and attenuation in metals at low temperatures; problems in thermal insulation; the generation of high d.-c. magnetic fields; superconductivity; ferromagnetism and antiferromagnetism at low temperatures; and the thermodynamic properties of fluid helium. The Simon Memorial Prize was awarded to Dr. I. M. Lifschitz of the Academy of Sciences of the Ukrainian S.S.R., Kharkov.

On the recommendation of its Awards Committee the Council approved some changes in the arrangements concerning the various awards (lectureships, medals and prizes). It authorized a new award, to be called the Maxwell Medal and Prize, for outstanding contributions to theoretical physics carried out within ten years of the award. The recipients of the Duddell Medal, C. V. Boys Prize, and Charles Chree Medal and Prize, were Dr. J. B. Adams, Prof. A. W. Merrison and Dr. Scott E. Forbush, respectively. The text of the C.V. Boys Lecture, entitled "Counter Techniques in High Energy Nuclear Physics: Rare Decays of pi and mu-mesons", has been published (*Proc. Phys. Soc.*, 78, 1116; Dec. 1961). The Guthrie Lecture was delivered by Dr. D. Shoenberg on the subject of the de Haas–van Alphen effect and the electronic structure of metals (*Proc. Phys. Soc.*, 79, 1; Jan. 1962), and the Thomas Young Oration on the application of frequency response techniques in optics by Dr. H. H. Hopkins. The Holweck Medal and Prize was presented by the French Physical Society to Prof. A. B. Pippard in Paris on May 12.

The total response to the Physics Trust Fund Appeal at the end of the year under review was £117,146. The cost of the educational and scientific work of the Institute and Society now runs at about £25,000 a year, reflecting the substantial planned increase to meet which the Trust Fund Appeal was mainly established. The accounts included in the annual report cover the first full year's working of the amalgamated Institute and Society. S. WEINTROUB

NUCLEAR RESEARCH IN FRANCE

THE Nuclear Research Centre of Fontenay-Aux-Roses is affiliated to the Commisariat a l'Energie Atomique and employs a staff of 1,000 (the total staff of the Commissariat is 14,000 persons) (*French Science News*, No. 2, April–June 1962). The Centre comprises the following departments:

(1) *Atomic Reactors*

(*a*) *Reactor protection studies* made with reactors *Zoë* and *Triton*. *Zoë* is a moderated, heavy-water cooled, natural uranium reactor which produces a maximum thermal neutron flux of 10^{12} neutrons/cm^2/sec. It was the first reactor built in France. *Triton* is a double-core, 20 per cent enriched uranium, water-moderated swimming-pool reactor, cooled by forced water-circulation. It develops a power of 150 kW and has a flux of 10^{13} neutrons/cm^2/sec.

A 600-keV *Sames* accelerator is also available in the Department and is used for the measurement of monoenergetic neutron propagation and diffusion in matter.

(*b*) *Critical experiments*. Sections of various materials are measured in a reactor by the oscillation method: *Zoë* and *Minerve* are used for this purpose. The latter is a low-power (100 W) experimental reactor, which produces maximum thermal flux of 5×10^9 neutrons/cm^2/sec. It is also used for measuring neutron absorption in samples of the materials used for the construction of reactors, and for neutron studies on lattices moderated with light water.

(*c*) *Liquid metals*. This section carries out research on the use of certain metals in the molten state as coolants in atomic reactors. The main application is the cooling of fast neutron reactors by means of sodium, sodium–potassium alloy, lead, lead–bismuth eutectic or mercury. The results of this research are to be applied to the cooling of *Rapsodie*, which is to be built at the Nuclear Centre at Cadarache.

(2) *Controlled Fusion*

(*a*) *Research on controlled fusion*, carried out by a joint Commissariat-Euratom research group. Research covers three main subjects: the 'striction' programme, where induced discharges, carrying 150,000 amp, are studied; the 'continuous mirror' programme, which uses accelerated ion injections; and the 'pulsed mirror' programme, which uses an apparatus for studying adiabatic compression.

(*b*) *Theory of ionized gases*. This section carries out the theoretical work required for controlled fusion research.

(3) *Chemistry*

(*a*) *Investigations, research and chemical applications*. The laboratories are equipped for the study and development of: the chemical processing of uranium, thorium and beryllium ore; the purification of 0·8 90 per cent enriched uranium; the purification of elements such as beryllium and zirconium; the processing of chemical plant waste.

(*b*) *Analytical studies*. This section carries out analytical studies which are new or which are better adapted to atomic energy problems, and the initial development of special equipment such as automatic analysers.

(*c*) *Contracts*. Work here consists mainly of the technical checking of contracts between the Commissariat and other organizations.

(4) *Plutonium*

This department has a series of 'hot' laboratories for the handling and study of radioactive materials.

(*a*) *Plutonium chemistry*. Here processes whereby the constituents of an irradiated fuel are separated and recuperated in pure forms are studied. Work follows three main lines: improvement of the solvent process; influence of progress made in fuels and cladding; dry processes.

Plutonium base ceramic and transuranium elements are also investigated.

(*b*) *Plutonium metallurgy*. The initial research on plutonium alloys was to examine aluminium base alloys. A plutonium technology workshop was built and metal transformation techniques were adapted to radioactive materials.

(5) *Mineralogy*

Analytical work is carried out as well as applied research work on radiogeology.

(6) *Mines and Mining Research*

The main department is at Fontenay; but its activities cover the whole of France, former French territories in Africa, and Madagascar.

(7) *Biology Department*

(*a*) *Atomic hygiene and radiopathology*. The fundamental problems of radiological protection are studied. In atomic hygiene, the aim is to set the security-level of irradiation and radioactive contamination.

Work on radioactive contamination deals with problems of industrial hygiene concerning the possible formation of liquid or solid radioactive aerosols in laboratories or workshops, and with problems of contamination via the digestive tract or via the skin.

Two laboratories carry out analyses which show any slight contamination, whether normal or accidental, of persons or of the biological environment.

(*b*) *Radiation check and radioactive engineering*. Activities are as follows: operation of the photometry and micrometry laboratories for checking the degree of irradiation by photographic or nuclear emulsions; supervision of the radioactivity of nuclear installation surroundings; the regular radiochemical analysis of rain and run-off; the study of natural radioactivity mainly by radon and thoron assay.

RHEOLOGY IN AUSTRALIA AND NEW ZEALAND

AT the Jubilee Conference of the Australian and New Zealand Association for the Advancement of Science, held at the University of Sydney during August 20–24, a Sub-Section on Rheology was created by members of the New South Wales Branch of the British Society of Rheology, under the secretaryship of Dr. L. Dintenfass (Department of Medicine, University of Sydney) and under the presidency of Prof. R. C. L. Bosworth (Department of Physical Chemistry, the University of New South Wales). This was the first time that rheologists had been able to form a definite group within a general conference in Australasia. Some twenty-seven papers were presented to actively interested audiences.

At the opening session the president pointed out that rheology had had a particularly long pre-scientific incubation period prior to the development of scientific principles, thought and instrumentation. In Australia and New Zealand rheological principles are involved in many primary and secondary industrial activities in medicine, agriculture and engineering, but, at the moment, there is in these countries no tertiary education course devoted to the study, the teaching or the research in rheological principles as such. The time is surely coming when this omission must be made good. The address at this session was given by Mr. R. S. T. Kingston, officer-in-charge of the Timber Physics Section, Division of Forest Products, C.S.I.R.O., South Melbourne, Victoria. Mr. Kingston reviewed the historical development in rheological theory with particular emphasis on non-linear phenomenological theory and non-colinear stress arising from non-linear strain velocities. Mr. Kingston was equally concerned with thermodynamical and statistical interpretations.

A session was devoted to rheology in biological systems. Dr. M. C. M. Dodgson (Prince of Wales Hospital, Randwick, N.S.W.) gave a paper on the rheology of brain, in which the mechanical properties of brain cell material were considered. Dr. Dintenfass gave a paper on viscosity and thixotropy of blood, and Dr. A. A. Palmer (Sydney Hospital) on the flow of blood in capillaries. The viscosity of blood decreases as the rate of shear increases; the viscosity of blood samples remains nearly constant at relatively higher rates of shear. Abnormal blood may show thixotropy even at these relatively higher rates of shear. Acceleration and deceleration in branching capillaries can lead to segregation of blood cells from plasma. Dr. B. Bloch (Sydney Hospital) and Dr. G. W. Hastings (Department of Polymer Science, the University of New South Wales) gave two papers on the use of plastics and adhesives in bone fractures.

A number of papers was concerned with the rheological properties of natural products. The rheology of protein solutions was considered by Dr. A. G. Parts (Department of Physical Chemistry, University of Sydney), who based his measurements on the dielectric loss and the viscosity of amino-acid solutions. Mr. M. Feughelman (Division of Textile Physics, C.S.I.R.O., North Ryde, N.S.W.) gave a paper on the structure and the mechanical properties of wool and related the properties with the nature of a number of bonds holding polypeptide chains together. Dr. B. J. Rigby (Division of Textile Physics, C.S.I.R.O., North Ryde, N.S.W.) gave a paper on thermal transitions in collagen. The transition temperature of wet unconstrained material apparently correlates with the amount of hydroxyproline present in the collagen. Mr. F. C. H. Ottaway (Bread Research Institute, North Ryde, N.S.W.) presented a paper on the rheology of bread dough. Initial fermentation changes the properties of the gluten content and no entirely satisfactory methods are available in dough-testing machines.

A number of papers was presented on the subject of the rheology of wood and wood products. Dr. M. C. Probine (Dominion Physical Laboratory, D.S.I.R., Lower Hutt, New Zealand) presented a paper on the rheological and morphological properties of plant cells. Mr. L. D. Armstrong (Division of Forest Products, C.S.I.R.O., South Melbourne, Victoria) considered the effects of moisture change on the creep of wood. Both the strength and the modulus of elasticity of wood decrease as the moisture content is decreased. Mr. H. G. Higgins (Division of Forest Products, C.S.I.R.O., South Melbourne, Victoria) gave a paper on the structural rheology of pulp and paper, and Prof. M. Chaikin (School of Textile Technology, the University of New South Wales) gave one on the rheology of non-uniform fibres, with special reference to textile fibres subjected to longitudinal extension.

The extension of rheological principles to chemical engineering problems and the more customary uses of these principles and the assessment of properties of the products of chemical industry were considered in a number of papers. Dr. T. Hagyard (Department of Chemical Engineering, University of Canterbury, Christchurch, New Zealand) gave a paper on the viscosity of fluidized bed systems, which he illustrated by showing high-speed photographs and high-speed cinematographic records of very nearly uniform spheres. The structures shown were those of hexagonal structures over limited regions with structureless intergranular materials and with occasional 'holes'. Mr. A. Sherwood (Department of Mechanical Engineering, University of Sydney) gave a paper on the determination of stresses in gelatine models. The newer silicone plastics are also being investigated for their suitability for this purpose. Mr. R. E. Price (Central Research Laboratory, Imperial Chemical Industries, Australia and New Zealand, Ltd., Ascot Vale, Victoria) gave a paper on post-extrusion swelling in thermoplastic melts, and Dr. F. Connors (Department of Polymer Science, University of New South Wales) gave one on the rheological characteristics of polyvinyl chloride. Mr. K. R. Hall (Chemical Research Laboratories, C.S.I.R.O., Fishermen's Bend, Victoria) gave a paper on the mixing operations of non-Newtonian fluids.

A number of papers was concerned with the basic properties of certain classes of materials, and others outlined new techniques of instrumentation. Mr. D. R. Axelrad (Department of Mechanical Engineering, University of Sydney), for example, gave a paper on the flow of metals, in which he outlined present-day theories of high-temperature creep. Dr. R.

Tanner (Department of Mechanical Engineering, University of Sydney) gave a paper on non-Newtonian lubricants. Greases and those systems which approximate in their behaviour to Bingham solids give higher bearing friction than Newtonian lubricants. Mr. A. W. Findlay (Monash University, Clayton, Victoria) gave a paper on the rheology of pigment suspensions and outlined a modified Bingham approach to the properties of these systems. Mr. R. Bell (Taubmans Industries, Ltd., St. Peters, N.S.W.) gave a paper on normal stresses in fluids, and stressed the need for emphasis on truly accurately level surfaces. Changing strain velocities can give rise to large normal stresses in many systems, including glycerine and golden syrup.

Dr. H. A. J. Battaerd (Central Research Laboratory, Imperial Chemical Industries, Australia and New Zealand, Ltd., Ascot Vale, Victoria) gave an account of a high-speed cinematic record of the performance of an impact tester utilizing a falling sphere which was applied to polythene films. Dr. P. U. A. Grossman (Division of Forest Products, C.S.I.R.O., South Melbourne, Victoria) outlined some unconventional testing methods in the study of creep and vibrational properties of solids.

The Sub-Section held one conjoint meeting with the Pharmaceutical Sciences Section. Two papers were presented, one by Dr. L. Dintenfass on micro-rheological methods and techniques, and one by Prof. R. C. L. Bosworth on the rheological properties of emulsions. The papers were followed by a panel discussion in which the hosts expressed many ways in which the rheologists could be of help to them.

R. C. L. BOSWORTH

THE BRITISH GELATINE AND GLUE RESEARCH ASSOCIATION

THE twenty-third research panel meeting of the British Gelatine and Glue Research Association was held in London on May 23. The chairman of the Association, Mr. S. G. Hudson (Richard Hodgson and Sons, Beverley), who presided, directed attention to the Association's wide range of interests as reflected in the programme for the day.

The first paper, "The Chemical Nature of Elastin", was contributed by Dr. S. M. Partridge (Low Temperature Research Station, Cambridge). The identification, occurrence, physical properties and isolation of elastin were reviewed. The ease of removal of other proteins from elastin varies with the tissue concerned, but even with the ligamentum nuchae of cattle, autoclaving is necessary. It is recognized that some structural changes are possible during isolation; nevertheless, severe damage is unlikely since there is only 1 g mole of *N*-terminal residue per 350,000 g of the isolated protein. The isolated protein is readily broken down into fragments by treatment with acids and the fragments are clearly multichain, indicating the existence of cross-links in the original protein. Enzymatically degraded elastin was chromatographed to give a coloured peptide believed to be the 'core' of the elastin structure. The 'core' gives, on acid hydrolysis, at least four substances of some complexity and these are being examined. The discussion centred round the nature and significance of the 'core'.

In the second paper, Mr. J. A. Mackenzie (R. and P. Scherer, Slough) described "The Manufacture of Gelatine Capsules by the Rotary Die Process". Sheets of plasticized gelatine gel are fed on to a pair of revolving dies and the capsules are automatically filled and sealed on the die. The process calls for a high standard of precision engineering and also for considerable ingenuity in using the unique physical properties of gelatine to the best advantage. Given these factors, capsules of a great variety of shapes and sizes can be made at very high throughput-rates and with a considerable degree of automation.

Dr. R. N. Coleman (Geo. Nelson, Dale, Warwick) gave the third paper, entitled "The Dispersion of Concentrated Gelatine Gels in Hot Syrups". Sometimes high-grade gelatines are encountered which prove to be difficult to disperse in hot, concentrated sugar solutions when using the usual method of soaking the gelatine in water and then adding it as a swollen gel. The difficulty can be minimized by completely dissolving the gelatine in hot water before addition to the syrup: the grist size of the gelatine is important in assisting easy solution in this method. Even so, a few gelatines remain which cannot be dispersed unless the amount of water in the system is increased.

The final paper, "The Cross-linking of Glues with Epoxy Compounds and Formaldehyde Donors", by J. A. Gibbs, I. R. Whiteside and J. Wootton (British Gelatine and Glue Research Association), was presented by Mr. I. R. Whiteside. There has been a general desire to get away from formaldehyde as a cross-linking agent for animal glues because it is toxic and unpleasant to handle. There is a need also for cross-linking agents which can be mixed with glue to give compositions of reasonable pot-life and which can be cured to insolubility after application. It was shown that these requirements could be met by using either dimethylol urea as a donor of formaldehyde in solution or an epoxy resin.

D. A. SUTTON

EDUCATION OF TECHNICIANS AND TECHNOLOGISTS

AN international conference on this topic was held in Cracow, Poland, during September 6–10, 1961, to discuss the education and further training of technical personnel.

The conference was initiated by the Association of Engineers of the General Technical Federation of Poland (*Scientific World*, 6, No. 1; 1962). The Associations of Engineers and Ministries of Higher Education of Czechoslovakia, the German Democratic Republic, Yugoslavia, Poland, Hungary and the Soviet Union also took part in the organization of the conference. Representatives of the Prague Regional Centre of the World Federation of Scientific Workers and of the Higher Schools and Scientific Institutes

Section of the Union of Polish Teachers, as well as an observer from the International Labour Office, attended the Conference.

The reports delivered and discussed were: (1) the influence of national economic needs on higher education (Prof. J. Tymowski, Poland); (2) education in intermediate-grade technical schools (H. Haas and G. Straumer, German Democratic Republic); (3) the training of managerial personnel in Soviet secondary technical schools (Prof. B. A. Kuzmin, U.S.S.R.); (4) problems of higher technical education (Prof. I. Gerendas, Hungary); (5) the training of managerial personnel and the reform of higher technical schools in the Soviet Union (Prof. B. T. Zhadan, U.S.S.R.); (6) systems of practical training and methods of improving qualifications by institutions other than schools in Czechoslovakia (Prof. J. Koritta, J. Jirasek and Dr. I. Auerhan, Czechoslovakia); (7) further education of engineers and technicians employed in various branches of industry (Prof. S. Koncar-Djurdjevic, Yugoslavia); (8) planning for the demand for engineers and technicians (T. Wodzynski, Poland); (9) training of teachers at secondary and higher technical schools (Prof. H. Lohlmann, German Democratic Republic).

All participants emphasized the need to improve the contact between theory and production, as much by increasing the number of students wishing to become technicians or engineers as by multiplying and varying the type of practical work in production during the course of study.

Jointly with the University of Moscow and the Moscow Bauman Technical School, the World Federation of Scientific Workers held an international symposium on the training of scientists, engineers and teachers in Moscow in September 1962. Taking part in the work of the symposium were more than 200 individuals, excluding Soviet scientists, from 50 countries.

The following topics were discussed in the reports delivered at the plenary session of the symposium: (1) science and technology in the world of the future; (2) aims, tasks and conditions of education of specialists in higher educational institutions; (3) higher scientific and technological education in newly developing countries; (4) higher education and international relations. The symposium was divided into three sections: scientific and technological education, education in social and historical sciences and the training of teachers.

The reports submitted on scientific and technological education were classified under the following headings: (1) specialization in higher scientific and technological establishments; (2) mutual relations between theoretical and practical education; (3) the role of scientific research in the educational system; (4) methods of education without interrupting work (part-time and correspondence courses); (5) further improvement of the qualification of scientists, technologists and of the teaching staff; (6) the role of the humanists and social sciences, including the study of languages, in the education of students in science and technology.

At the section which dealt with education in social and historical sciences the following subjects were raised: (1) specialization in higher education in social and historical sciences; (2) mutual relations between theoretical and practical education; (3) the role of scientific research in the educational system; (4) methods of education without interrupting work (part-time and correspondence courses); (5) study of natural sciences by students in social and historical sciences.

The reports delivered in the section on teaching were under the following headings: (1) the training of teachers in universities and in special training colleges; (2) the problems of training teachers in sufficient number in newly developing countries; (3) further improvement of the qualification of teachers; (4) extra-mural education for teachers.

Further information concerning the symposium can be obtained from Dr. P. Biquard, 10, Rue Vauquelin, Paris 5e, France, or Central Committee, Educational and Scientific Workers' Union, 42 Leninsky Prospect, Moscow, U.S.S.R.

THE BRITISH COAL UTILISATION RESEARCH ASSOCIATION

THE annual report of the British Coal Utilisation Research Association for 1961, which includes abstracts of reports and published papers, besides lists of members of Council, committees and senior staff, notes that about 40 per cent of the research income was obtained from research contracts and work sponsored on a repayment basis, and that this figure seems likely to increase. Contract research during the year included work on the behaviour of coal-ash slags, total gasification of coal, smoke emission from domestic solid fuels, and research on the characteristics of graphite moderators for nuclear reactors. Much of the work of the Association is now concentrated on a comparatively few clear-cut projects, including automatic boiler equipment, especially inexpensive coal-handling equipment for small plant. Evaluation of earlier field trials with the small pipe central heating system has confirmed that the running as well as the installation costs are low for solid-fuel-fired installations. The feasibility of automatic measurement of the rate of condensation of sulphuric acid from flue gases has been established and a tentative method formulated for assessing the suitability of a coal for cyclone firing from the viscosity-temperature characteristics of the slag and the theoretical gas temperature in the plant. Viscosities of slags from a wide range of coals are being determined.

Long-term researches are concerned mainly with the mineral matter in coal, and further work has been done with the slagging fixed-bed gasifier to produce low-cost gas from the cheaper grades of coal. A new basic research programme has been initiated on the combustion of coal, particularly pulverized coal, and some initial experimental problems in the combustion and gasification of coal in which coal is heated rapidly under strictly defined conditions have been overcome. The reactivity of graphite to oxidizing gases at 450°–900° C depends on the extent of the surface area associated with both the micron-sized capillaries and those capillaries of molecular sizes that are accessible to the gases, while interpretation of a series of nuclear magnetic resonance spectra suggests that the proportion of aliphatic hydrogen in tertiary CH groups may be higher than was hitherto thought. The property of coking appears to be related to the rate of decomposition of chloroform-soluble material at near 400° C and the differences between low-rank and coking coals are now largely understood in general terms. Radioactive labelling using tritium has been used to determine the origin of fine material produced when a range of sizes is broken in a centrifuged mill; photoelasticity has been applied in a preliminary study of the stress distribution in particles and mill elements; and the energy required for fracture has been determined by controlling the propagation of a crack in a coal specimen.

NUTRITION OF THE EXPECTANT AND NURSING MOTHER

PREGNANCY imposes considerable nutritional stress on the mother. The growth of the fœtus, and enlargement and hypertrophy of the organs of reproduction and lactation, and the increase in the volume of circulating blood are important physiological changes occurring during pregnancy and lactation which increase the nutritional requirements during this period. To give precise information on the physiological changes that occur in Indian women, and the magnitude of the nutritional strain to which they are exposed, in recent years the Indian Council of Medical Research has embarked on a series of investigations. Studies have been made on the body composition in terms of cell mass, extra-cellular water, fat and active formation of lean body mass during the second trimester of pregnancy*.

It has been observed that the basic metabolism is increased in nursing women to the extent of nearly 26 per cent over the average basic metabolic rate of normal adult women; this is, presumably, due to the energy required in the production of milk. These, and other studies, are providing clear-cut knowledge about the nutritional requirements during pregnancy and lactation of Indian women. Such knowledge will lead to a more realistic planning of diets during these periods of physiological stress.

Attention was also directed to the composition and nutritive value of breast milk in Indian women. Special investigations have been undertaken by the Council to determine the concentration of nutrients in breast milk of poor Indian women and to explore the possibility of improving the nutritive quality of this milk by supplementing the mother's diet, thus benefiting in one operation both the mother and the suckling infant. Studies on the chemical composition revealed that, while the concentration of proximate principles compared well with those observed in well-nourished populations, the concentration of several vitamins in the samples from poor Indian women was much lower. It was also observed that supplementation of the maternal diet with thiamine and ascorbic acid led to significant increase in the concentration of those vitamins in breast milk, although a similar effect was not observed with vitamin A and iron.

Studies on the output of breast milk in different stages of lactation revealed that poor Indian women are in a state of almost continuous lactation throughout the child-bearing period of their lives. The implications of this observation from the point of view of health and nutritional status of the mother require careful consideration. One study, using various levels of dietary protein and measuring nitrogen balance, revealed that 0·14 g of nitrogen per kg per day would be the minimum nitrogen intake needed for maintaining equilibrium. On this basis, the minimum amount of dietary protein requirements, between 22 and 28 weeks of pregnancy, would work out to 0·9 g per kg per day, or 40·5 g per day for a pregnant woman of average weight of 50 kg.

SCOTTISH PALÆOBOTANY

TWO papers, recently published by the Royal Society of Edinburgh, add to, and at the same time simplify, knowledge of previously known plants*.

K. M. Lele and J. Walton have investigated *Zosterophyllum*, which, after repeated investigation, is appearing as a tufted rhizomatous Pteridophyte widespread on Lower Devonian marshes. The most useful of the new material consists of axes freed when rock was dissolved in the preparations of a balsam transfer; some of these axes had rotted before preservation and consist merely of the vascular core inside the cutinized epidermis. The well-developed stomata are numerous on the upper branches but rare below and confirm Lang's conclusion that this is a land plant. The course of the vascular strand in the H-shaped branches of the base of the plant is now clear and this branching, though remaining characteristic, becomes understandable and *Zosterophyllum* takes its place as a normal rather than a problematical early plant.

A. G. Long's paper is the latest of a series dealing with petrifactions from the Lower Carboniferous of Berwickshire. *Tristichia* is a new stem; it is slender (only 2–3 mm wide) and bears petioles as wide as itself, but much less vascular. The petioles (also known as compressions) fork repeatedly and their thread-like ends bear tiny terminal pinnules. Similar fertile petioles considered to be of the same plant bear terminal cupules from each of which numbers of seeds were macerated out, and the seeds are held to be the same as *Stamnostoma* previously described as petrifactions. Thus the microsporophyll alone remains unknown, but pollen grains are described from the tops of the seeds. *Tristichia* can now take its place along with *Tetrastichia* and other Lower Carboniferous Pteridosperms.

The Royal Society of Edinburgh is to be congratulated on maintaining the quality of its plates.

CHEMOTHERAPY IN MALARIA CONTROL

MASS chemotherapy has been used in malaria control programmes on a number of occasions. Where it is possible to issue pyrimethamine or chloroquin at weekly or even fortnightly intervals to all members of a community, rapid reduction of the parasite-rate will be achieved: under such conditions it is immaterial whether or not spraying is carried out. In experiments carried out in many parts of the world there has been a rise in parasite-rate after cessation of treatment because most of the experiments have been on small communities living in otherwise uncontrolled areas. In rural Africa, however, malaria is not found in small communities, but in a high proportion of the inhabitants of vast territories. There is a large, seldom static, often unco-operative and usually very low density population. The cost of spraying and regular treatment, particularly in using trained reliable staff and finding transport, tends to be high.

With these factors in mind an experiment was carried out to ascertain the reduction of parasite-rate which could be achieved under field conditions with a minimum number of treatments in a high proportion of a reasonably large population as opposed to regular treatment of a small community. The study was undertaken by Dr. E. T. Reid of the Research Laboratory, Salisbury (*Central African Journal of Medicine*, 8, No. 5; May 1962).

Two similar areas, Fungwe and Chimanda in Southern Rhodesia, were each sprayed with BHC (benzene hexachloride) annually for seven years. After five years parasite-rates remained in the region of 20 per cent and mass chemotherapy was undertaken in one of the areas.

As many people as possible were treated on each of three occasions in the Fungwe area, using a dose of 600 mg chloroquin base and 50 mg pyrimethamine. Treatment was at the beginning of the transmission season in 1959, in the middle of the next non-transmission season and at the end of the second transmission season. Parasite-rates in the area fell rapidly after these experimental treatments from 23·5 per cent to 2·58 per cent during the period of the experiment (18 months). In the control area the parasite-level remained at approximately 20 per cent. It is considered that malaria control projects in rural Africa do not sufficiently take into account people who, for one reason or another, avoid treatment or having slides taken, and who form foci of infection of unknown importance.

PALÆOLATITUDE OF EVAPORITE DEPOSITS

By E. IRVING and J. C. BRIDEN

Department of Geophysics, Institute of Advanced Studies, Australian National University, Canberra

IN many problems connected with Earth science it is useful to make numerical estimates of past latitudes and the directions of crustal features relative to the ancient meridian. Two broad lines of inquiry may be recognized: (1) studies of palæogeography which require estimates of the palæolatitude spectra of (say) a fossil genus or a type of sediment; (2) investigations of structural patterns in the crust relative to the Earth's rotational axis with the view of studying the stress history of the Earth. Palæomagnetic methods afford the means of making these estimates since the measured palæomagnetic inclinations give information on the past latitude, and the declinations information on the azimuth relative to the ancient meridian. As an example of this method results relating to the palæolatitudes of evaporite deposits are discussed in this article.

Evaporite deposits (that is, beds of chlorides and sulphates such as halite, gypsum and anhydrite, etc.) are often taken as indicators of past climate since they may be supposed to have been laid down in regions of excess evaporation; for example, their most probable place of occurrence is where temperature is high, at least at some season of the year, and rainfall fairly low. Yet the present geographical distribution of Palæozoic and Mesozoic evaporites[1,2] is asymmetrical about the Earth's equator (Fig. 4*a*), the bulk of them being in the northern hemisphere in intermediate or high latitudes often in regions which nowadays experience both heavy rainfall and low temperatures. This could be due to changes in the climatic zones, or changes in land distribution (in particular changes in latitude of the places where evaporites now occur) or to these factors working together. Some workers have suggested that the distribution can be explained in terms of a steady northward shift of evaporite occurrences going back through geological time. The shift has been estimated previously for northern continents at 0·05°/m.y.[1], and as 0·07°/m.y. for America and 0·11°/m.y. for Europe and Africa[3].

The first numerical estimates of the palæolatitudes of evaporite deposits from the palæomagnetic data were made for beds of Silurian to Triassic age from the United States; the palæolatitude range was calculated to be 0–30°[4]. Afterwards, maps showing the parallels of palæolatitude for Europe and North America were published[5–8]; these confirm, with added details, the range given here. Blackett[3] has shown that the rate of northward shift of the evaporite occurrences is similar to, but generally less than, the palæolatitude changes calculated from the palæomagnetic data (0·08°/m.y. for the Americas and 0·14°/m.y. for Europe). A further result obtained by Blackett[3] is that estimates of 'salt latitude' of reference localities made on the basis of an assumed model of the past position of the ancient evaporite zones (the ancient evaporites are assumed to be centred at a latitude of 30°, as appears to be the case nowadays (ref. 2, Fig. 32), yield changes comparable with, but systematically less than, the changes in palæomagnetic latitude; the 'salt latitudes' for the Mesozoic and Palæozoic are less than the palæomagnetic latitudes by about 10°.

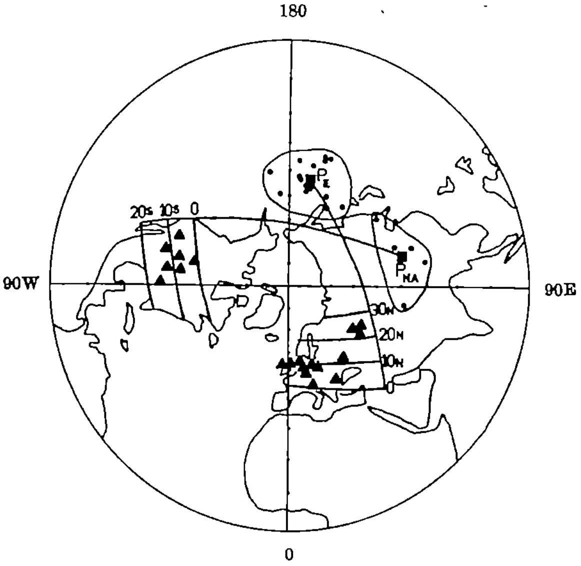

Fig. 1. Map of the northern hemisphere showing the distribution of evaporites during the Permian in Europe and North America. Evaporites are denoted by solid triangles. Individual palæomagnetic pole determinations are denoted by dots; the sets of poles from Europe (see, for example, refs. 13 and 14) and North America (ref. 15) are encircled, the mean positions P_E and P_{NA} being denoted by solid squares. The parallels of palæolatitudes are drawn across that continent to which they apply and give the values for individual deposits. It may be noted that P_E is some 63° of longitude east of P_{NA}, the arc angle between them being 47°

The purpose of work reported here is to investigate more precisely than hitherto the range of palæolatitudes in which evaporites were laid down at different times. For example, one of the possible explanations for the discrepancies just noted is that at some periods evaporite deposition was centred about the equator and this may reflect a climatic zonation different from that at present. This study is based exclusively on palæomagnetic results and methods and has the advantage that it is independent of arguments about the nature of past climates.

The directions of fossil magnetism measured in a rock unit may be used for estimating the position of the palæomagnetic pole relative to the sampling area at the time the rock was deposited. If a sequence of results in time is available from a particular continent it is possible to work back and calculate the palæolatitude of any place in that continent at any time, provided no great relative movement of the sampling area within the continental framework has occurred. The justification for this method is that there is now much evidence that polar shifts within geological periods are small in many cases: for example, in the Permian and Triassic of Europe and North Asia, and in the Triassic of North America (see for example, ref. 9). Thus, continent by continent and period by period (for those periods and continents for which palæomagnetic evidence is available), it is possible to estimate the palæolatitude of evaporite deposits.

The palæomagnetic data available at present have been used, and has been summarized in various compilations[10–13]. The estimates may be obtained by solving spherical triangles or graphically using stereograms. The latter method is sufficiently accurate for present purposes and has been used here. The procedure is illustrated in Fig. 1 in which the estimated palæolatitudes of the Permian evaporites of Europe and North America are given.

The problem of weighting arises, since a local gypsum bed should not be given equal weight with (say) the Zechstein evaporites. The method used here should suffice to a first approximation. The primary reference used here is Green[1], who has drawn a series of maps of the northern hemisphere for separate geological periods, and it is presumed that his method of notation gives a weighting approximately proportional to areal extent. He used polar projections from which geographical co-ordinates can easily be read off. These results have been supplemented from other sources (detailed in the figure legends); but this weighting procedure has, so far as possible, been preserved throughout. Detailed distribution maps have previously been given by Lotze[2] but using

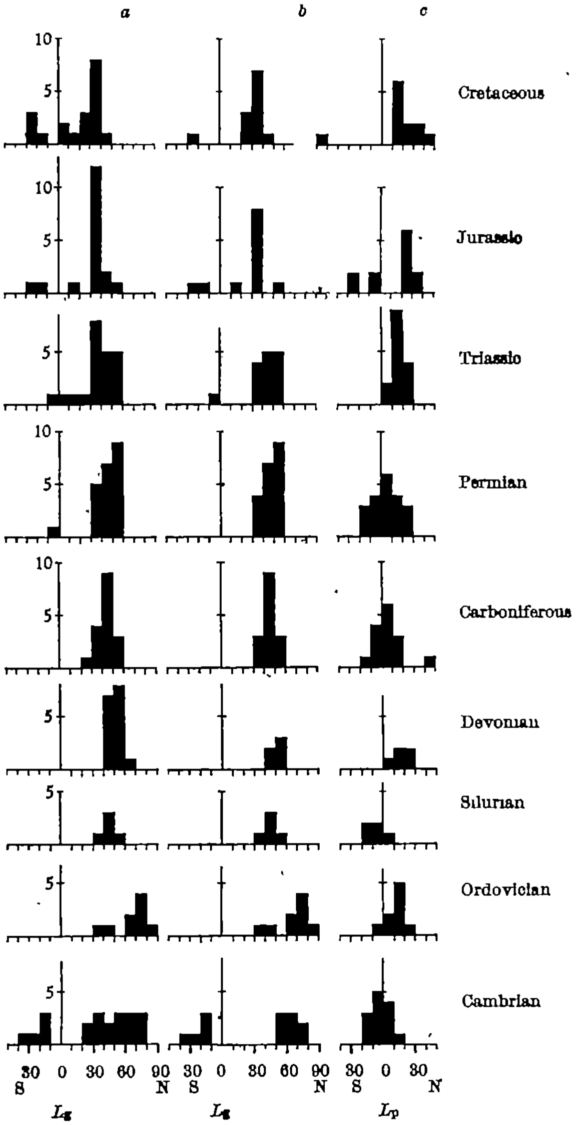

Fig. 2. Frequency histograms for different periods. Localities for all continents except Antarctica and Australia have been compiled from refs. 1, 16 and 17. Information from Australia has only recently come to light and has been obtained from the Bureau of Mineral Resources, Canberra. There are no data from Antarctica. Frequency is plotted vertically, and latitude horizontally at 10° intervals. (In some circumstances there may be advantages in plotting the frequency per unit area but this has not been done.) In this and in Figs. 3 and 4, column (*a*) shows present geographical latitude (L_π) of all evaporite occurrences; column (*b*) shows (L_π) of those occurrences for which palæomagnetic data is available; column (*c*) shows the palæolatitudes (L_P)

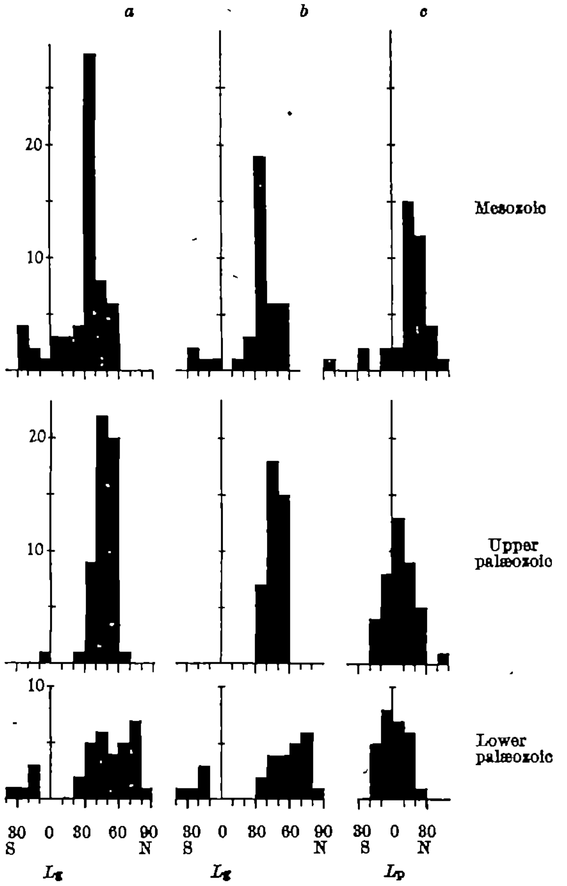

Fig. 3. Frequency histograms for broad time groups. Conventions as for Fig 2. Latitude at 10° intervals

oblique projections with a 90° network so that accurate geographical co-ordinates cannot readily be obtained. These distributions given by Lotze and Green are essentially similar and the use of one in preference to the other would not, in the present context, yield different results.

The estimates of palæolatitude are made on the basis of the assumption that the directions of magnetization observed in rocks reflect the ancient field direction, and that the Earth's magnetic field has been that of a geocentric axial dipole. The results are subject to statistical errors, the average accuracy (P = 0·05) being about 10°. This means that the results given in Figs. 2, 3 and 4 will be subject to a substantial dispersion not attributable to changes in palæolatitudes.

Relative movement between the evaporite occurrence and the palæomagnetic sampling region is assumed to be unimportant. Relative translation would only become important if it were of comparable magnitude to the experimental error, that is, relative movement within the same continental framework of the order of 1,000 km. Relative rotations cannot produce an error greater than twice the distance between the two areas which rarely exceeds the statistical error. It must also be assumed that the directions of the Earth's field did not change between the time the evaporite was deposited and the time of magnetization of the formations studied palæomagnetically. Polar shifts within geological periods are often small, and in such cases as the Permian and Triassic of Europe, where evaporite deposits and the levels studied palæomagnetically are interbedded, such errors will be negligible. Errors arising from either of these sources will only increase the scatter of values; they do not affect the mean result.

Tertiary evaporites were not studied because the changes in magnetic field appear to be rapid at this time, and the dating of many Tertiary formations studied palæomagnetically is poor, and more geological and palæomagnetic information is required before a quantitative treatment can be attempted.

Values were obtained to the nearest degree and are grouped in intervals of 5° or 10° in the frequency histograms of Figs. 2, 3 and 4. In Fig. 2 the results for each geological system are shown. In Fig. 3 they are combined into the three broad age-groups, Lower and Upper Palæozoic and Mesozoic. Fig. 4 gives the cumulative results. Because of the incompleteness of the palæomagnetic record, estimates of palæolatitudes cannot be made for all evaporite deposits. Each figure shows the present latitude distribution of evaporite occurrence and also the distribution of the values used. These are similar, suggesting that those deposits for which estimates were obtained are a representative sample of the whole.

The present latitudes of evaporites are mostly intermediate or high and predominantly northerly. The full range is 31° S.–83° N. but 73 per cent lie between 30° and 60° N. In contrast, the estimates of palæolatitudes are generally low, ranging from 59° S.–44° N., with 76 per cent of the values lying within 20° of the palæoequator. They are consistent with the view that evaporites were laid down preferentially in tropical latitudes and hence that areas of excess evaporation were in low latitude.

There is also the possibility that the effect is due to coincidences in the disposition of land and shallow seas where evaporites might be laid down; there is the possibility, through an accident of palæogeography, that in the Palæozoic and Mesozoic these did not occur in high latitudes. To investigate this the

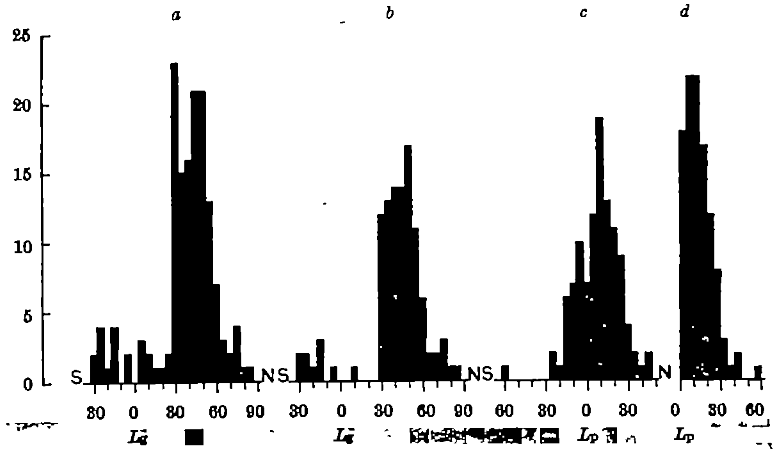

Fig. 4. Cumulative frequency histograms. Conventions as in Fig. 2, except that a 5° plotting interval is used, and in an additional diagram (d) L_p is plotted irrespective of whether the values are north or south of the palæoequator

palæolatitudes of lands and shallow seas have been estimated from magnetic results obtained from a large number of shallow water and terrestrial lavas and sediments, by the same method as has been used for evaporites. It is found that in the Lower Palæozoic the values are mainly low (less than 30°) so this may be the cause of the observed evaporite distribution. However, there is the possibility that palæomagnetic data covering this time are inadequate. In the Upper Palæozoic and Mesozoic it is found that although the most abundant occurrences of land and shallow seas are in low latitudes, their spread is much greater (80° N. to 80° S.) than that of the evaporites. For example, the palæolatitude of Australia throughout the Mesozoic determined palæomagnetically is high: there are no substantial evaporites although there is abundant terrestrial and shallow marine deposition. The possibility of palæogeographic coincidences as a general explanation of the distribution of Upper Palæozoic and Mesozoic evaporites is therefore rejected.

Comparison between the results of these latter ages suggests the possibility of detailed changes within the tropics. The Mesozoic values are predominantly in the range 10–30° N., which is broadly consistent with, although somewhat lower than, what would be expected from the distribution of present-day evaporite accumulations. The predominance of northern hemisphere values suggests the paucity of land and shallow seas in low southerly latitudes at this time, and this is supported by the analysis of palæolatitudes referred to above. In the Upper Palæozoic, however, the distribution is symmetrical about the palæoequator and the values are mostly within 20° of it. The zone of excess evaporation would appear therefore to have been centred on the palæoequator at this time. This could account for the discrepancy between the 'salt' and palæomagnetic latitudes already referred to[3], and indicate that the use of palæoclimatic models based on present climate zonations may in detail be misleading. The experiments carried out by Opdyke[7] using other models of climate zonation are of much interest in this context.

These results are consistent with the view that evaporites were laid down preferentially in low latitudes and that the contrast between the past and present latitude distribution is due mainly to changes in latitude, although a subsidiary effect due to the past distribution of land and shallow seas may be present. The results are to be considered as an early attempt to apply a comparatively new method to distribution problems in geology. Although future palæomagnetic observations may change the picture given here, the power of the method as a tool in studying such problems is apparent.

BORON CONTENT IN RELATION TO ORGANIC CARBON IN CERTAIN SEDIMENTS OF THE BRITISH COAL MEASURES

By Dr. R. M. C. EAGAR

The Manchester Museum

HARDER[1,2] has shown that much of the boron present in sediments is located in the muscovite structure of fine-grained illite, notably in the fraction smaller than 2μ, and that appreciable but smaller quantities of boron may occur in the coarser fractions of grain size 20–60μ, where it is found in tourmaline. Where tourmaline makes a very small and relatively constant contribution to a sedimentary series, as has been demonstrated, for example, in the more psammitic rocks of the German Upper Carboniferous Coal Measures[3], variation in the total boron content of the associated pelitic rocks is likely to approximate to variation in boron associated with the illite. Part of the boron in illite is a measure of palæosalinity, as well-known experiments have demonstrated. However, the process by which it appears that boron cations are installed in the lattice of dioctahedral mica is dependent on both time and temperature[2]; and, furthermore, the total boron associated with the illite can in varying measure be attributed to boron already installed in detrital illite of the source material, which may have been released by the weathering of pre-existent marine or hypersaline sediments. It is thus possible for varve-clays to have very high boron contents[1]. Nevertheless, where contributions from detrital tourmaline and other source materials remain relatively constant and conditions of sedimentation are little altered, any changes in salinity of the water in the basin of deposition might be expected to leave corresponding changes in the total boron content of the sediments concerned. Ernst and others[4,5] have in fact shown that there exists a broad correlation between total boron (microchemically determined) and palæosalinity, in so far as it is revealed by fossils, in Upper Carboniferous (Westphalian *B*) Coal Measures, both in Germany and also on a few horizons in Belgium and northern France. Comparable results have been quoted for German Devonian rocks where average boron contents are considerably less[4]. As Ernst, Harder and others have emphasized, relative changes in the boron content of rocks within a single profile, for example, in a borehole, are likely to be of more significance, both for purposes of correlation and as evidence for the palæoecologist, than absolute boron contents, whether or not these are related to illite contents.

Working on sediments of various ages, Walker[6] has successfully separated very fine-grained fractions of illites and his adjusted boron contents of illites in certain marine and hypersaline rocks show general agreement with figures for corresponding American sediments[7]. Walker, however, found the supposedly freshwater British Purbeck Beds, with illite contents of 509 and 554 p.p.m., were indistinguishable from marine Jurassic beds (520 p.p.m.). These figures contrast with those of 110 and 135 p.p.m. for illite in certain American freshwater rocks[7] and may indicate merely that the Purbeck Beds acquired their illite from the weathering of previously formed marine Jurassic sediments, which were uplifted at this time.

Recent palæoecological work by me on 37 ft. of pelitic sediments in the British Coal Measures (Upper Carboniferous, Westphalian *A*) of Worsborough district, near Barnsley, has been supplemented by chemical work on 21 samples carried out by Mr. R. Y. Gillespie and Mr. A. Parr-Burman of United Analysts, Ltd., East Boldon, and microchemical determinations of boron on the same samples by Dr. W. Ernst. Advice on chemical procedure and on the interpretation of the results has been given by Dr. G. D. Nicholls. Free silica was determined by the method of Trostel and Wynne[8]. Total carbon was determined by combustion in oxygen in a conventional combustion train, the evolved carbon dioxide being absorbed in Midvale design soda lime tubes. The carbon combined in mineral carbonates was determined by treating a portion of the sample with phosphoric acid and absorbing the carbon dioxide, again in soda lime and in asbestos. Organic carbon is defined as total carbon minus carbon from mineral carbonates. When proportions of carbon dioxide were small (less than 1 per cent by weight) carbonate was calculated as siderite ($FeCO_3$). When proportions of carbon dioxide were greater than 1 per cent approximate determinations were made of the iron, calcium and magnesium constituents and the proportionate weights of the carbonates calculated accordingly[9]. Sulphur determinations were calculated as iron sulphide. Clay minerals were then calculated as 100 per cent minus the weights of silica, organic carbon, carbonates and iron sulphide. In ten of the samples very rough checks on the content of the clay minerals were made by X-ray diffraction with the help of Dr. J. Zussman, and in three cases clay mineral content was checked by ignition loss/moisture absorptions tests[10] carried out by Mr. P. S. Keeling of the British Ceramic Research Association.

Both organic carbon and total boron vary widely (Fig. 1), the latter from 12 p.p.m. (in band *A*) to 141 p.p.m. (below band *B*). These figures may be compared with those selected for northern European Coal Measures (of almost identical age), about 109 p.p.m. (B_2O_3 = 0·035 per cent) to delimit marine from brackish water, and about 62 p.p.m. (B_2O_3 = 0·025 per cent) to separate brackish and fresh water[5]. Furthermore, it will be seen (Fig. 1) that where organic carbon is appreciable (over 1·5 per cent) total boron and organic carbon show an antipathetic relationship. Boron tends to vary with clay mineral content, as might be expected, but the inverse correlation between boron and organic carbon is slightly better than the correlation between boron and clay minerals. Nevertheless, in the case of three peaks of organic carbon out of six (bands *B*, *C* and *E*), the fall in total boron slightly precedes the rise in organic carbon. Moreover, if the total boron were assumed to reside in or to be associated with the clay minerals, then the curve boron/clay minerals tends to follow that of total boron and is thus again largely antipathetic to organic carbon. Comparing the richly carbonaceous bands *A*–*F* with the grey shales and shaly mudstones between them, the former, averaging 16·59 per cent organic carbon, have a mean boron content of 48 p.p.m., whereas the latter, averaging 1·05 per cent organic carbon, have a mean boron content of 98 p.p.m., a result confirming preliminary published figures[11].

Re-examination of the results of Nicholls and Loring[12] suggests a similar relationship between boron and carbon in a Coal Measures cyclothem at Bersham Colliery, near Wrexham (Fig. 2). These measures differ as a whole from those at Worsborough in having lower contents of organic carbon (0·19–2·64 per cent) and higher contents of free silica, that is, detrital and authigenic quartz (29·2 per cent at horizons *B.C.*3 and 9, to 43·2 per cent at *B.C.*4). At Worsborough the corresponding figures for free silica are 1·0 per cent (in band *A*) to 24·1 per cent (at 19 ft. above the coal). Total boron contents are as a whole lower at Bersham (see below) and much less variable (note the increased scale in Fig. 2). Nevertheless, the curve of total boron dips appreciably at the horizon of *B.C.*3 where organic carbon exceeds

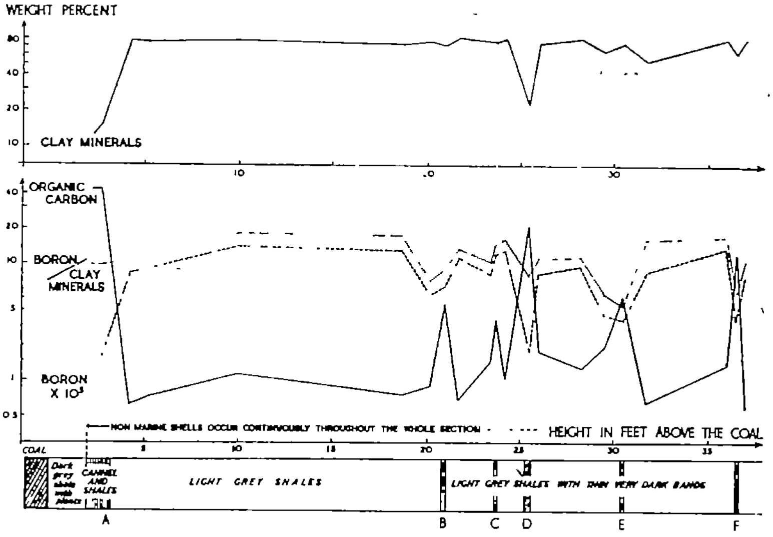

Fig. 1. Section above the Flockton Thin Coal of the Lower Coal Measures at Cold Bath Opencast, Worsborough, near Barnsley, Yorkshire. The horizon is in the lower half of the *modiolaris* Zone, near the top of Westphalian *A* and about 200 ft. below the Clay Cross (mid-*modiolaris* Zone) Marine Band. Geochemical data from analyses by United Analysts, Ltd., East Boldon. Boron determined microchemically by Dr. W. Ernst, North Rhein-Westphalian Geological Survey, Krefeld

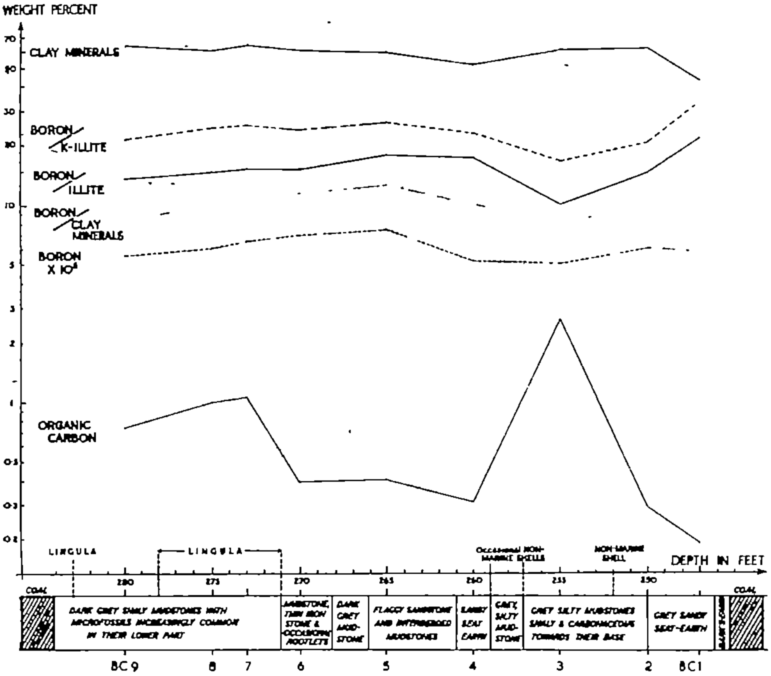

Fig. 2. Section between the Red (base) and Crown (top) Seams of the mid-*modiolaris* Zone of the Coal Measures, from an underground bore-hole at Bersham Colliery, near Wrexham, North Wales, after Nicholls and Loring, 1962, Fig. 1 and Table 9. Boron determinations were made spectrographically. Geological descriptions and palæontology adapted from D. Magraw, late of H.M. Geological Survey, in Nicholls and Loring. Depths refer to depths below the Powell Seam

what appears to be the critical value (1·5 per cent) at Worsborough. At Bersham the curves for boron/clay minerals, boron/illite and boron/potassium/illite are of essentially the same form as that of total boron. They all show more antipathy to organic carbon than sympathy with total clay mineral content (as in Fig. 1). As noted by Nicholls and Loring, increased values of the boron ratios in the seat-earths of horizons *B.C.*1 and 4 may not be real but result from detrital tourmaline in the much-increased proportions of quartz in these samples. On the other hand, I have noted that certain measures yielding high contents of boron at Worsborough, those underlying bands *B*, *E* and *F* of Fig. 1, apparently correlate through intermediate sections with thick beds of seat-earth type, yielding rootlets, at Everbridge Opencast, south of Chesterfield and nearly 30 miles south of Worsborough. Relatively high boron and illite contents, moreover, have been noted recently in several seat-earths in the Ruhr Coal Measures[13].

If the total boron in the Worsborough samples is located in the illite, then from very rough estimates by X-ray diffraction boron in illite ranges from the order of 77 p.p.m. (band *E*) to 144 p.p.m. (band *B*); whereas in the grey shales the illite contains much higher proportions of boron, computed values of 202 p.p.m. and 238 p.p.m. (at 5 and 22 ft. respectively above the coal) being probably too low.

Nicholls and Loring[12] have already pointed out that in the *Lingula*-bearing beds of Bersham, which represent the horizon of the widespread mid-*modiolaris* Zone Marine Band, boron values are no higher than in the remaining part of the section. For nine samples in the cyclothem total boron averages 60·3 p.p.m., comparing with an average of 82·9 p.p.m. for 21 samples from the Worsborough section which, it is stressed, contains a non-marine fauna of anthracosiid and myalinid lamellibranchs, ostracods, fish debris and *Spirorbis*. Furthermore, the boron content at Worsborough is relatively low in the dark, richly carbonaceous bands which palæoecological evidence suggests were laid down under tranquil conditions with relatively slow deposition of sediment[14]. These bands also contain the ostracod *Geisina arcuata* (Bean), which is generally considered to have been of brackish water habitat[15] and was probably benthonic[16]. On the other hand, boron values are high in the grey shales or shaly mudstones which the same evidence suggests were laid down under relatively turbulent conditions[14], probably with faster depositional rate, and in water which from general stratigraphical considerations one might reasonably infer to have been fresher. Furthermore, such grey shales contain non-marine lamellibranchs comparable with supposedly 'up-river' assemblages described from other horizons[17]. Moreover, decreases in the size of shell faunas such as take place at Worsborough as one passes from dark carbonaceous shales to light grey shales, by comparison with similar changes in modern brackish water faunas, are more likely to indicate decreases than increases in the salinity of the habitat[18]. Thus the evidence from total boron contents at Worsborough appears at variance with all other evidence regarding palæosalinity. The same disagreement is apparent when the Worsborough section as a whole is compared with that of Bersham, where fossil evidence suggests marine or pene-marine conditions but boron values are lower. On the other hand, at Worsborough boron values vary widely and inversely with organic carbon when the latter is appreciable, crossing values which in north Europe have been regarded as marking boundaries between marine and brackish and between brackish and fresh water. Data from Bersham follow the same pattern as at Worsborough both with regard to total boron and, with certain assumptions, to its roughly estimated content in clay minerals, but with smaller proportions of both organic carbon and clay minerals boron shows less variation.

That boron is concentrated by plants and in coals is well known. Relatively low concentrations (about 4–25 p.p.m.) of boron found in 'sapropels' of several salt water lakes in the U.S.S.R.[19] may be of relevance to the results given here. These results will be described in more detail and more fully discussed elsewhere. It may be pointed out here, however, that no matter how the total boron at Worsborough proves to be distributed among the constituents of the samples, factors other than the salinity of the waters in which these sediments accumulated have influenced their boron contents. Even when one takes into consideration contributions from detrital and authigenic illite, detrital and perhaps authigenic tourmaline and the possibility of excess borates being available from volcanic activity in the neighbourhood[20], probably very shortly before the deposition of the Worsborough sediments[21], variation in total boron content is inexplicable without consideration of the content of organic matter. It appears that the presence of organic matter and relatively low contents of total boron in these sediments are related, directly or indirectly.

POSSIBLE SIGNIFICANCE OF LINEAR PLOTS OF MOISTURE EXPANSION AGAINST LOG OF A TIME FUNCTION

By Dr. W. F. COLE

Division of Building Research, C.S.I.R.O., Highett, S.21, Victoria, Australia

IN a recent article[1] on some moisture expansion relationships for a fired kaolinite–hydrous mica–quartz clay it was established that natural moisture expansion was linear against log of time for all firing temperatures from 800° to 1,200° C. and exposure times of 4 hr.–90 days. Plots of the autoclave expansions against the log of time were also linear for specimens fired from 1,000° to 1,150° C. for autoclave times from 2 to 200 hr. However, the significance of these results was not apparent. It should be noted that the samples, after firing, were cooled to 300° C. and then removed from the kiln and cooled to room temperature in a dry desiccator, so that the measurements of length and of weight increase recorded the effect of the first exposure of the samples to large amounts of water vapour in the air and in the autoclave.

A search of the literature has revealed that kinetic processes that proceed linearly with a log function of time are by no means unusual in ceramics and chemistry. It has been established[2], for example, that the Roginsky–Zeldovich (R–Z) equation:

$$dq/dt = ae^{-bq}$$

where q is the amount of gas adsorbed at time t, and a and b are constants, holds over all the known types of chemisorption. It has also been applied to the kinetics of the following: luminescence, photoconductivity of solids, creep of metals, magnetic viscosity, magnetic permittivity of $BaTiO_3$, oxygen–uranium oxide system, oxygen–praseodymium sesquioxide system, and the dehydroxylation of muscovite mica. The integrated form of this equation shows that:

$$q = \frac{1}{b} \ln (abt + 1)$$

The R–Z equation is valid[2] if it is possible to linearize a plot of q against log $(t + t_0)$ by a suitable choice of $t_0 = \frac{1}{ab}$. It is consistent with an activated adsorption in which the activation energy gradually increases as q increases. A theoretical justification for the formula has been developed by Halsey[3] and a physical interpretation has been given to the term t_0 which, in chemisorption, takes into account desorption that accompanies sorption. The greater the amount of desorption the higher will be t_0.

In so far as moisture expansion is concerned, it has been verified that the results for natural moisture expansion of the fired clay previously described[1] can be represented by an equation of similar form to the R–Z equation. Calculation for a linear regression of expansion on log $(t + t_0)$ (using values of $t_0 = 0{\cdot}01$, $0{\cdot}1$ and $1{\cdot}10$ hr.) indicates highly significant relationships in which the sum of the squares of the deviations from the regression equation are at a minimum when $t_0 = 0$, for the majority of firing temperatures between 800–1,200° C. For $t_0 = 0{\cdot}01$ and $0{\cdot}1$ hr. the difference in the sums of squares from those for $t_0 = 0$ are negligible, whereas for $t_0 = 1$ hr. they are not. It is thus concluded that t_0 is too small to be distinguishable from zero, using the results so far obtained for the natural moisture expansion of this fired clay. Plots of natural moisture expansion against log $(t + t_0)$ for samples fired at 900°, 1,000° and 1,075° C. are given in Fig. 1. The variance ratio[4] for the sample fired at 900° C. is 486 for $t_0 = 0$, 470 for $t_0 = 0{\cdot}1$ hr., and 351 for $t_0 = 1$ hr.; for the

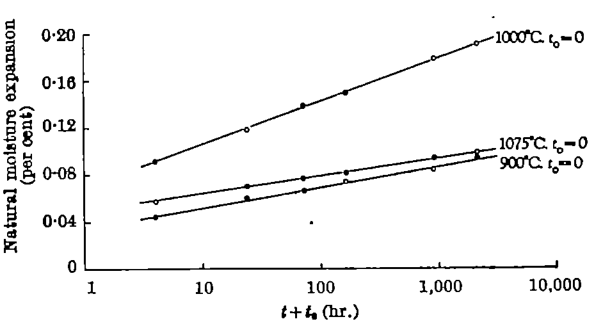

Fig. 1. Plots of natural moisture expansion against log $(t + t_0)$ for a kaolinite–hydrous mica–quartz clay fired to temperatures of 900°, 1,000° and 1,075° C.

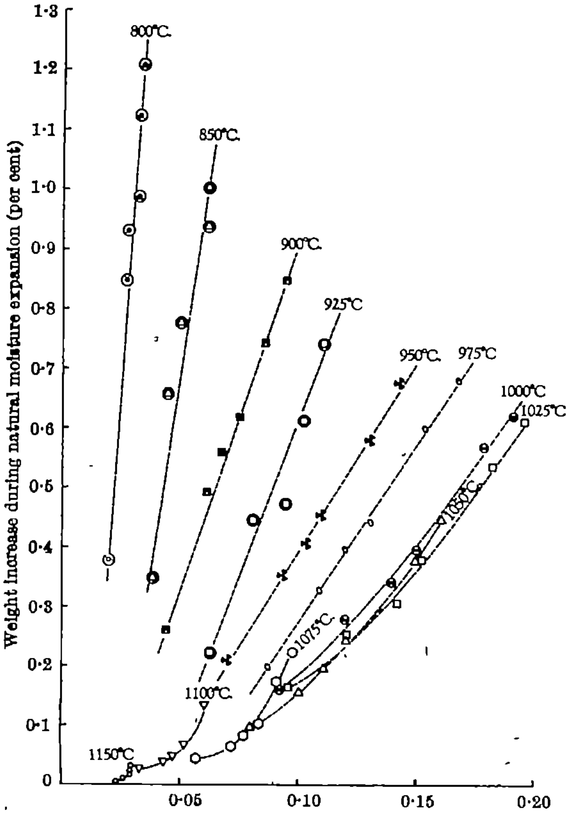

Fig. 2. Relationship between weight increase and natural moisture expansion at exposure times of 1/6, 1, 3, 7, 39 and 90 days for undried samples of a kaolinite–hydrous mica–quartz clay fired from 800° to 1,150° C.

sample fired at 1,000° C. it is 4,440 for $t_0 = 0$, 4,434 for $t_0 = 0{\cdot}1$ hr., and 3,079 for $t_0 = 1$ hr.; for the sample fired at 1,075° C. it is 1,268 for $t_0 = 0$, 1,171 for $t_0 = 0{\cdot}1$ hr. and 662 for $t_0 = 1$ hr., and for all the data n_1 and n_2 (the number of degrees of freedom) are equal to 1 and 4, respectively. The constants a and b of the R–Z equation are set out in Table 1.

Table 1. CONSTANTS OF THE ROGINSKY–ZELDOVICH EQUATION FOR THE DATA OF FIGS. 1, 3 AND 4

q	Firing temperature (°C.)	b	a	t_0 (nearest hr.)

	1,000	63·9		0
	1,075	156·2	indeterminate	0
Weight increase during natural moisture expansion (Fig. 3)	900	11·5	Indeterminate	0
	1,000	11·8	0 01689	5
	1,075	18·8	0·00062	86
Autoclave moisture expansion (Fig. 4)	1,000	44·7	0·02237	1
	1,150	40·0	0·01250	2
	1,200	28·1	0·00324	11

The data for natural moisture expansion are related to the weight increase of the samples, as shown in Fig. 2. Linear relationships exist up to a firing temperature of 1,000° C., but at higher temperatures (1,025°–1,150° C.) the relationships are curved. Since the experimental points along any temperature line are for exposure times ranging from 4 hr. to 90 days it might be expected that the weight increase could also be represented by an equation of similar form to the R–Z equation.

Calculations have consequently been made for a linear regression of weight increase on log $(t + t_0)$ using values of t_0 from 0·1 to 100 hr. Highly significant relationships are obtained in which the sums of the squares of the deviations from the regression equation are at a minimum when $t_0 = 0$ for samples fired up to 900° C., but for samples fired to higher temperatures these sums of squares require t_0 to take on increasing values with increasing firing temperature before minima are obtained. Plots of weight increase against log $(t + t_0)$ for samples fired at 900°, 1,000° and 1,075° C. are given in Fig. 3. The variance ratio for the sample fired at 900° C. is 206 for $t_0 = 0$, 200 for $t_0 = 0{\cdot}1$ hr., and 160 for $t_0 = 1$ hr.; for the sample fired at 1,000° C. it is 354 for $t_0 = 0$, 786 for $t_0 = 4$ hr., 800 for $t_0 = 5$ hr., and 773 for $t_0 = 6$ hr.; for the samples fired at 1,075° C. it is 40 for $t_0 = 0$, 1,462 for $t_0 = 85$ hr., 1,464 for $t_0 = 86$ hr., and 1,461 for $t_0 = 87$ hr.; for all samples $n_1 = 1$, $n_2 = 4$. The constants a and b of the R–Z equation are set out in Table 1.

It has also been verified that the results for autoclave moisture expansion of samples of the clay previously described[1], fired from 1,000°–1,200° C. and autoclaved for periods from 2 to 200 hr., can be represented by an equation of similar form to the R–Z equation. Calculation for a linear regression of autoclave expansion on log $(t + t_0)$ using values of $t_0 = 1$–15 hr. indicates highly significant relationships in which the sums of the squares of the deviations from the regression equation are at a minimum when t_0 is of the order of 1 hr. for samples fired to temperatures from 1,000° to 1,100° C. For samples fired to higher temperatures t_0 must increase in value with increase of firing temperature to maintain these sums of squares to a minimum. Plots of expansion against log $(t + t_0)$ for samples fired at 1,000°, 1,150° and 1,200° C. are given in Fig. 4. The variance ratio for the sample fired at 1,000° C. is 516 for $t_0 = 0$, 787 for $t_0 = 1$ hr., and 600 for $t_0 = 2$ hr.; for the sample fired at 1,150° C. it is 403 for $t_0 = 0$, 1,308 for $t_0 = 1$ hr., 3,147 for $t_0 = 2$ hr.; and 2,377 for $t_0 = 3$ hr.; for the samples fired at 1,200° C. it is 83 for $t_0 = 0$, 8,850 for $t_0 = 10$ hr., 9,420 for $t_0 = 11$ hr., and 3,850 for $t_0 = 12$ hr.; for all the data $n_1 = 1$ and $n_2 = 3$. The constants a and b of the R–Z equation are set out in Table 1. Data are not available to study the relationship between the water adsorbed during autoclaving and the time of autoclaving.

The fact that the natural moisture expansion, the accompanying weight increase, and the autoclave moisture expansion for one fired clay follow, within the limits specified, a kinetic equation of similar form to the R–Z equation is interesting and suggestive of

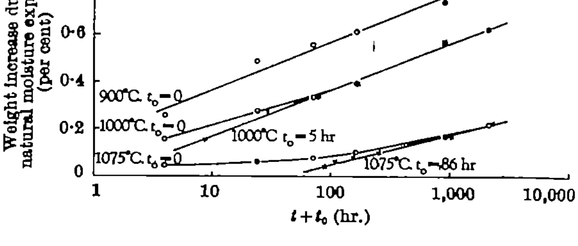

Fig. 3. Plots of weight increase during natural moisture expansion against log $(t + t_0)$ for a kaolinite–hydrous mica–quartz clay fired to temperatures of 900°, 1,000° and 1,075° C.

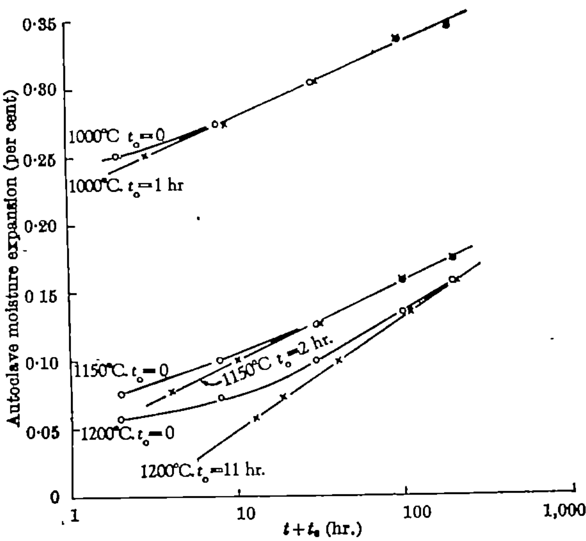

Fig. 4. Plots of autoclave moisture expansion against log $(t+t_0)$ for a kaolinite–hydrous mica–quartz clay fired to temperatures of 1,000°, 1,150° and 1,200° C.

new ways of studying the kinetics of moisture expansion. However, it does not establish that chemisorption or a chemical reaction is taking place, or the nature of the processes (the same is true of any other kinetic law), although it indicates that if chemical processes are involved there is an increase in activation energy as the water is adsorbed and expansion proceeds. Such an increase in activation energy might arise from adsorption sites which are at increasing depths below the surface of the reactable material[5]. In conformity with this there is strong but not conclusive evidence[6] from water adsorption data and surface area measurements of the fired kaolinite–hydrous mica–quartz clay to suggest that the adsorbed water has penetrated deeply beneath the surface, and is chemically combined rather than chemisorbed on the surface.

Institute for Enzyme Research, University of Wisconsin

ELECTRON paramagnetic resonance (EPR) spectroscopy[1] has been successfully used for identifying free radicals and the valency state of transition metal ions that occur in biological materials[1–4]. The technique has also furnished evidence for the functioning of certain transition metals in the catalytic turn-over of oxidative enzymes[2–4]. This communication presents a few examples of the use of EPR in studies on the function of transition metals in microbial metabolism.

Iron. A broad scan of the EPR spectrum of particles prepared from *Azotobacter vinelandii* (Fig. 1) shows sharp absorption lines at $g=1·94$, 2·00 and 4·3, superimposed on a broad underlying signal centred close to $g=2$. These particles, as isolated, are partially reduced, since on oxidation with ferricyanide the broad signal at $g=2$ and that at $g=4·3$ increased, whereas that at $g=1·94$ disappeared. On the other hand, reduction with dithionite resulted in the disappearance of the broad signal ($g=2$) and the signal at $g=4·3$, but the $g=1·94$ signal increased tenfold. There was little change in the sharp signal at $g=2·00$.

By analogy with the spectra obtained with iron complexes in other materials[6,7] it is likely that the absorptions at $g=2$ and 4·3 are associated with Fe^{3+}. The sharp signal at $g=2·00$ is probably due to flavin semiquinones. The $g=1·94$ signal in Fig. 1, which increased markedly on reduction, has been seen in materials of animal origin by Sands, Beinert and Lee[8–10]. These authors attribute this signal to a reduced form of non-hæm iron which functions near flavin in the respiratory chain. The signal appears under reducing conditions, such as deprivation of oxygen in the presence of endogenous substrates, addition of specific substrates or of chemical reductants. Although several variants of this general signal type have been observed, the main characteristics are an absorption peak (maximum slope in first derivative curve) at $g=1·93$ to $g=1·95$, pronounced temperature sensitivity (short relaxation time) (for general reviews of the EPR technique see refs. 11 and 12) and in most cases a minor component at $g=2·00$ near the free radical absorption. This characteristic EPR signal has been found in whole heart and liver tissue, in isolated mitochondria and in particles and enzymes derived from them, for example, succinic and DPNH dehydrogenases[2,10,13]. More recently the signal has also been identified in a series of metal containing enzymes, namely, xanthine oxidase of milk[4,5], aldehyde oxidase of rabbit liver, and dihydro-orotic dehydrogenase from *Zymobacterium oroticum*[5].

In the azotobacter particles the reduced iron species ($g=1·94$), which is obviously closely related to the reduced non-hæm iron complex found in animal

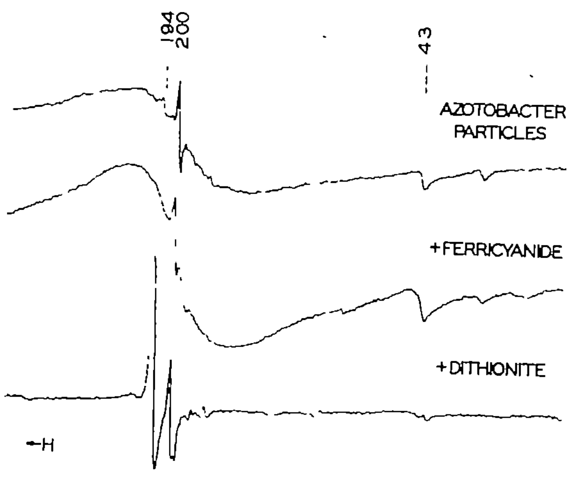

Fig. 1. EPR spectra (first derivative in all figures) of particles from *Azotobacter vinelandii OP* (34 mg protein/ml.) suspended in 0·01 M phosphate buffer, *p*H 7·5) prepared by ultrasonic treatment of the cells for 15 min (ref. 16). Particles collected between 25,000*g* and 144,000*g* for 60 min in a Spinco preparative centrifuge. Spectra recorded at −170°. Upper curve, spectrum of particles as isolated; middle curve, after oxidation with ferricyanide; lower curve, after reduction with dithionite. The *g* values of the various signals are indicated

tissues, was at best only a small fraction of the iron appearing in the oxidized form at $g = 2$ and 4·3 (Fig. 1). The iron signals in the oxidized state may be wholly or partly due to hæm proteins, whereas that at $g = 1·94$ has been observed in materials devoid of hæm iron[3,5,9,10]. The non-hæm iron species is probably associated with a new type of electron carrier[3,10].

The two smaller signals at lower field in the dithionite-reduced spectrum of Fig. 1 are probably components of a Mn^{++} sextet. The other components of this sextet are obscured by the iron signal.

The non-hæm iron complex at $g = 1·94$ occurs in a variety of micro-organisms, as shown in Fig. 2. A comparison with an EPR spectrum of a DPNH dehydrogenase from beef heart[14] confirms that the iron species ($g = 1·94$; $g = 2·00$), in addition to its occurrence in *Azotobacter*, is present in extracts of *Micrococcus lactilyticus* and in *Escherischia coli*.

Manganese. A Mn^{++} signal (six equally spaced components, centred at $g = 2·01$) overlaps the iron signal in a number of bacterial preparations, for example, in *E. coli* and in *Clostridium pasteurianum* (Fig. 2). In crude extracts of *C. pasteurianum* the Mn^{++} signal was so strong that it obscured that of the non-hæm iron complex. The addition of pyruvate to either preparation enhanced the signal at $g = 1·94$–1·95 and decreased the intensity of the Mn^{++} signal, presumably by the formation of Mn^{++} complexes. The iron signal can also be differentiated from the Mn^{++} signal by its different temperature sensitivity. Since Mn^{++} has a relatively long relaxation time, the iron signal at $g = 1·94$ decreased rapidly relative to that of Mn^{++}, when the temperature was raised. The separation of a 'nitrogenase' fraction from the crude extract[15] eliminated practically all the Mn^{++} and a very clear signal of the non-hæm iron appeared when this preparation was treated with hydrogen gas or when pyruvate was added (Fig. 2). The Mn^{++} sextet was recovered in the fraction concerned in the evolution of hydrogen and carbon dioxide from pyruvate, after inactivation of the nitrogenase activity by heat treatment. It is not known at present whether Mn^{++} has a specific function in the metabolism of pyruvate by this fraction. Similarly the significance of relatively large amounts of manganese that we have readily detected by EPR in other bacteria, for example, *Aerobacter aerogenes*, *Bacillus polymyxa*, *Nitrobacter agile*, *Rhodospirillum rubrum* and *Pseudomonas aeruginosa* and in algæ and higher plants is not clear.

Molybdenum. EPR spectroscopy together with low-temperature optical reflectance spectroscopy has been used to study particles from *Azotobacter vinelandii OP*. Particles, prepared from cells grown without combined nitrogen, fix atmospheric nitrogen[16,17] and these were compared with those extracted from the same organism, grown with an ammonium salt as the source of nitrogen (Fig. 3). These are designated N_2 and NH_4^+ particles, respectively. Thus the N_2 particles had a signal at $g = 1·97$ which varied in intensity with batch, but was always more intense in particles that were actively fixing nitrogen. A signal of this *g* value has been observed previously in nitrate reductase from *Pseudomonas aeruginosa*[18] xanthine oxidase of milk[4,5] and aldehyde oxidase of rabbit liver[5] and is probably associated with Mo^{5+} in the three enzymes. The Mo^{5+} signal in these enzymes disappears on oxidation or on further reduction and these effects are also observed with the $g = 1·97$ signal in the *Azotobacter* particles. It is likely, therefore, that this signal in *Azotobacter* is also due to Mo^{5+}, but at its present intensity no fine structure, indicative of Mo^{5+}, could be resolved. The state of molybdenum after extensive reduction, when the Mo^{5+} signal disappears, is not known at the present time.

When the N_2 particles were gassed with hydrogen and a medium factor[16] was added, the iron signal increased markedly indicating reduction of the electron carriers. Combined optical spectroscopy showed that the cytochromes were extensively reduced under these conditions as shown in Fig. 4

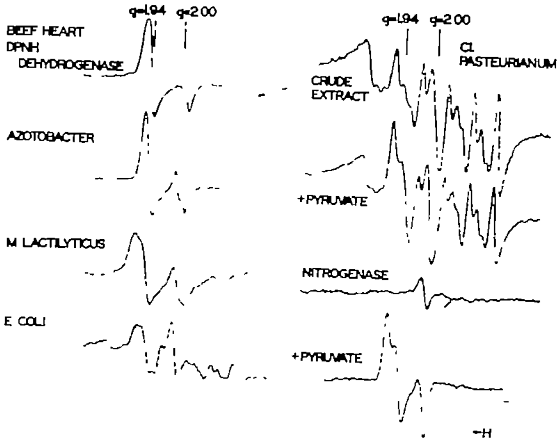

Fig. 2. EPR spectra of various preparations showing the typical signal at $g = 1·94$ recorded at −170°. Left column from top to bottom: DPNH–coenzyme *Q* reductase from beef heart (50 mg protein/ml., ref. 14); particles from *Azotobacter vinelandii* (36·5 mg protein/ml.) prepared as in Fig. 1; crude water extracts of *Micrococcus lactilyticus* prepared with the ultrasonic probe for 15 min, centrifuged at 10,000*g* for 15 min, supernatant fraction adjusted to *p*H 8·0 (95 mg protein/ml., ref. 23); and *Escherischia coli* (*K*12) grown anaerobically, extracts prepared in 0·05 M phosphate *p*H 7·5 as described for *M. lactilyticus* (34·5 mg protein/ml.). All preparations reduced with dithionite

Right column from top to bottom: a crude extract of *Clostridium pasteurianum* in 0·05 M phosphate buffer, *p*H 6·6, centrifuged at 20,000*g*, supernatant fraction used (32 mg protein/ml.); the same extract plus pyruvate (final concentration 0·07 M); a purified nitrogenase preparation of *Cl. pasteurianum* (84 mg protein/ml.) in 0 05 M phosphate, *p*H 6·5; nitrogenase plus pyruvate as above. In *E. coli* and in the crude extract of *Cl. pasteurianum* Mn^{++} signals are visible which overlap with the $g = 1·94$ line. The latter becomes visible when the extracts are completely reduced

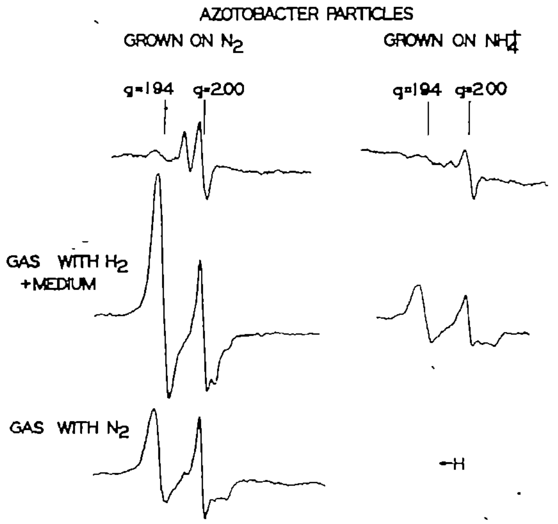

Fig. 3. EPR spectra of particles from *Azotobacter vinelandii OP* (48 mg protein/ml.). Cells disrupted in culture medium, in which they were grown, with an ultrasonic probe (ref. 16). Particles collected between 25,000 and 144,000*g* for 60 min in a Spinco preparative centrifuge. Particles aerated at 0° for 10 min before assay partially to oxidize the respiratory carriers. Spectra recorded at −170°. Left column, particles actively fixing nitrogen (0·12 atom per cent ^{15}N excess); right column, particles that do not fix nitrogen, prepared from cells grown with an ammonium salt as nitrogen source.

Upper row, spectra of particles as isolated. In the N_2-fixing particles there is a signal at $g = 1·97$, probably associated with Mo^{5+}. Middle row, after addition of 10 μl. of culture medium, in which organism had been growing, and gassing with hydrogen. Lower curve, after gassing with nitrogen after hydrogen

(upper curve) and the Mo^{5+} signal disappeared. The same treatment had some effect on the NH_4^+ particles, but the extent of the reduction was less (Fig. 3). Addition of hydrogen or the media factor singly was less effective than in combination (Fig. 4, centre curve). The addition of nitrogen gas to the nitrogen-fixing particles resulted in a partial re-oxidation of the electron transfer components as shown by EPR and optical spectroscopy. There was no effect when helium was used instead of nitrogen and no reversal was achieved with a nitrogen treatment of the NH_4^+ particles.

Copper. Cell-free extracts have been prepared from *Nitrosomonas europaea* that will oxidize hydroxylamine to nitrite, provided a suitable carrier, such as mammalian cytochrome *c*, phenazine methosulphate or methylene blue was added[19]. Particles prepared from this bacterium contain flavin and cytochromes of the *b*, *c* and *a* type. The EPR spectra of this particle clearly show that they contain a copper protein with a signal centred around $g = 2·1$ and the hyperfine structure typical of Cu^{2+} (Fig. 5). The observed signal is strikingly similar to that recently reported for cupric chloride in pyridine-chloroform solution[20]. On addition of substrate the copper signal of the enzyme undergoes complex changes, which indicate that the metal is involved in the oxidase system. (Similar results were observed with whole cells but the spectral changes were more rapid.) These changes are not those expected should copper be fully reduced, otherwise the signal would be similar to the type seen when sodium dithionite was added (Fig. 5). In earlier studies, Beinert *et al.* showed that the interaction of hydroxylamine with the copper of cytochrome oxidase from beef heart resulted in drastic changes in the EPR spectrum. By analogy it might appear that also in the *Nitrosomonas* oxidase hydroxylamine

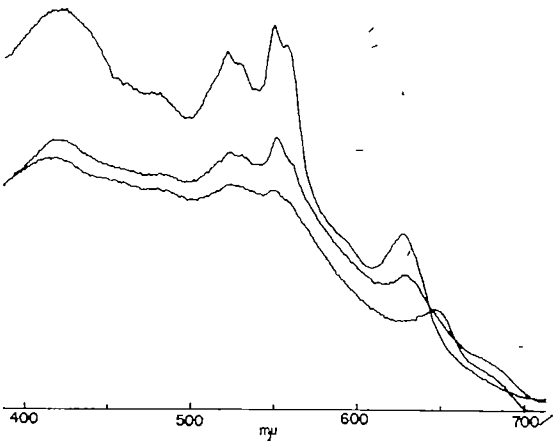

Fig. 4. Optical reflectance spectra of *Azotobacter* N_2 particles as in Fig. 3, recorded at −90° with a Cary spectrophotometer, model 14, and a modified diffuse reflectance attachment (ref. 2). Ordinate: absorbance in arbitrary units as obtained by reflectance. Lower curve, particles as obtained after aeration (see legend to Fig. 3); centre curve, after gassing with hydrogen; upper curve, after gassing with hydrogen and subsequent addition of 10 μl. of culture medium

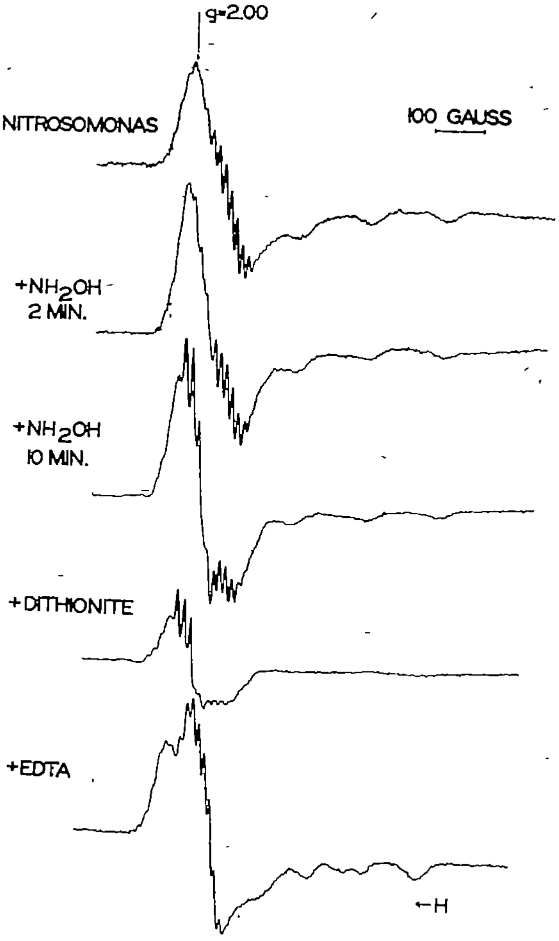

Fig 5. EPR spectra of particles from *Nitrosomonas europaea* (31 mg protein/ml.) at −170°. Cells suspended in 0·05 M *tris* buffer, *p*H 7·5, treated with the ultrasonic probe for 20 min, particles between 15,000 and 144,000*g* for 60 min suspended in the buffer. Top to bottom: untreated particles; 2 min at 0° after addition of hydroxylamine, final concentration 0 02 M; 10 min after addition of hydroxylamine; after reduction with dithionite; 30 min with 3·5 mM EDTA final concentration. The three lower curves were recorded at a lower amplification, 0·8 times for curves 3 and 4, and 0·6 times for the bottom curve. Similar results were obtained with whole cells

attacks the copper directly. This interpretation of the spectral changes is, however, inconsistent with the observation that the EPR spectrum changes much faster when cytochrome *c* is present together with the enzyme and hydroxylamine. The spectral changes therefore seem to arise as a consequence of electron transfer from hydroxylamine via cytochromes to the oxidase rather than by a direct non-specific interaction between the copper protein and hydroxylamine.

Beyond this we are unable to interpret the complex spectra of this copper protein. It would appear, however, that spectra of two different species of copper are superimposed. This interpretation is supported by the effect of ethylenediamine tetraacetic acid (EDTA) on the particles, as shown in the lowermost spectrum. The two copper components respond in a different way; the signal of the copper EDTA complex rises at the lower field, whereas the other component appears to be unaffected. These changes can be reversed by dialysis against 0·05 M *tris* buffer.

This survey shows that EPR spectroscopy, which has already proved its usefulness in investigations with mammalian enzyme systems, may also provide a new parameter in determining the function of transition metals, among which are iron, copper, manganese and molybdenum, in microbial metabolism. Since the application of this technique to biochemical systems is relatively new, many of the observed spectra cannot be interpreted fully at the present time. As more experience is gained, however, a whole range of catalytically active metal complexes might be identified by making critical comparisons between materials of different origin. Thus the field of active iron complexes in particular has gained prominence recently. It is now clear that the iron porphyrin compounds are only one group of a whole array of iron compounds that participate in metabolism. One of the recently discovered groups are the iron proteins of low molecular weight, such as photosynthetic pyridine nucleotide reductase (PPNR)[21] and ferredoxin[22] which participate in electron transport. Another newly discovered type of catalytically active compound is discussed in this communication, which is readily identified by its EPR spectrum in the reduced state. It should be emphasized that the latter group of iron proteins is quite different in all known properties from the ferredoxin and PPNR types.

This work was supported by research grants from the U.S. National Institutes of Health (*RG*-5073, *RG*-6762 and *E*-1417) and National Science Foundation *C*2826, and by Atomic Energy Commission contract *AT* (11-1)-909.

We thank Drs. Nakamura and Burris for preparations of *Clostridium pasteurianum*; Dr. N. McCormick for a culture of *Micrococcus lactilyticus*; Mr. M. A. Wright, Bristol, for supplies of *Nitrosomonas europaea*, Dr. M. Kobayashi, who collaborated in early phases of these experiments, and Mrs. I. Harris and Mrs. M. Fraser for technical assistance.

INFRA-RED ABSORPTION BANDS OF THE PEPTIDE GROUP

BENDIT[1] has recently suggested that the absorption at 3,190 cm^{-1} in keratin and at 2,400 cm^{-1} in deuterated keratin arises in the amorphous regions only, and he considers that the assignment of these two bands is difficult. He rejects the assignment of the corresponding bands in monosubstituted amides[2] and polyamides[3,4] to overtone and combination modes enhanced by Fermi resonance. Badger and Pullin[5] first proposed this explanation for the 3,080 cm^{-1} band in collagen. We consider that the position and intensity of the bands in the NH and ND stretching regions of all N substituted amides may be likewise explained.

Keratin is an unsuitable substance for examining the assignment of the 3,190 cm^{-1} and 2,400 cm^{-1} bands for three reasons. These are, first, the complication of the spectrum by the broad and ill-defined bands in the NH and ND stretching regions which arise from the NH and OH and ND and OD bonds in the side groups; secondly, the uncertainty of the physical structure of keratin[6], which prevents a conclusive interpretation of the dichroism measurements; thirdly, the lack of a fully N deuterated keratin spectrum.

Keratin[1] shows a strong peak at 3,290 cm^{-1}, a shoulder at 3,190 cm^{-1} and a weak peak at 3,050 cm^{-1}. In addition, a very broad absorption extends from about 2,800 cm^{-1} to about 3,400 cm^{-1} which is almost completely removed on deuteration; this absorption is presumably due to the side-groups. The 3,290 cm^{-1} and 3,050 cm^{-1} bands are reduced in intensity on deuteration. The 3,190 cm^{-1} shoulder does not disappear as claimed by Bendit but is also only reduced in intensity; the asymmetry of the 3,290 cm^{-1} band is quite clear in Bendit's spectrum. The two new ND bands at 2,460 cm^{-1} and 2,400 cm^{-1}

have approximately equal intensity and are assigned by Bendit to the modes corresponding to the 3,290 cm^{-1} and 3,190 cm^{-1} NH absorption in the amorphous regions. (The fate of the 3,050 cm^{-1} band on deuteration is not considered by Bendit.) He suggests that the equal intensity of the ND bands is accounted for by assuming the complete exchange in material exhibiting the 3,190 cm^{-1} band (amorphous) and the partial exchange in material exhibiting the 3,290 cm^{-1} band (amorphous and crystalline). If completely deuterated keratin showed approximately equal ND bands this assumption would be invalidated; complete deuteration has not been achieved with keratin[7], but in other amides where it has been achieved the two ND bands are found to be approximately equal in intensity. Though there are significant and as yet incompletely understood intensity differences between the accessible and inaccessible regions the 3,190 cm^{-1} and 2,400 cm^{-1} absorptions are not restricted to the accessible regions. (In deuterium exchange studies it is usually assumed that the regions accessible to deuterium oxide are amorphous and that the inaccessible regions are crystalline. This over-simplification only confuses our understanding of the structural problems and we shall use the terms accessible and inaccessible.)

The absorption of the side-groups and the uncertainty of the difference in structure between the accessible and inaccessible regions necessitates very cautious interpretation of the dichroism measurements, especially in the light of recent proposals for the structure of keratin[4]. In addition, Bendit's point (c) is not valid as the parallel dichroic ratio shown by the 3,290 cm^{-1} NH band after deuteration is less than 3. Hence the contribution of the deuterated α helices to the 'perpendicular' spectrum must be greater than one-third of their contribution to the 'parallel' spectrum.

We consider that the following examples are in accord with the Fermi resonance assignment and contrary to Bendit's proposals.

Crystalline substances. Two (or more) amide ND bands of approximately equal intensity are present in the spectrum of single crystals of fully N deuterated α diglycine[8] in which the ND_3^+ bands are separated from the COND bands in the polarized spectra. In single crystals of deutero-acetanilide the ND bands are complex and bands on the high-frequency side of the main peak have no equivalents in the NH region[9]. Crystalline deutero NN′dimethyl oxamide[10] and deutero-diformyl hydrazine[10] show multiple bands in the ND region.

NN′diacetylhexamethylenediamine[11] shows a band at 3,185 cm^{-1} and various completely crystalline polyamide oligomers show a 3,200 cm^{-1} band[3].

Liquids. Pure liquid N alkyl amides show both the 3,200 cm^{-1} shoulder and the 3,300 cm^{-1} bands, for example, N ethyl acetamide[12] and N butyl acetamide[13]; the latter, on deuteration, shows two ND peaks of equal intensity[2]. In many cases, spectra recorded with a sodium chloride prism do not show the 3,200 cm^{-1} shoulder after reproduction[2,11,14] but the doubling of the ND band is clearly seen, for example, N methyl acetamide[15].

Polymeric materials. In polyamides of different crystallinity (estimated by X-rays) there is no parallel between the crystallinity and the intensity of the 3,200 cm^{-1} shoulder, for example, in the low crystallinity copolymers[3]. Poly-DL-alanine in the α form was found[15] to have a single NH band at 3,305 cm^{-1} and after almost complete deuteration the two ND bands at 2,465 cm^{-1} and 2,400 cm^{-1} were nearly equal in intensity.

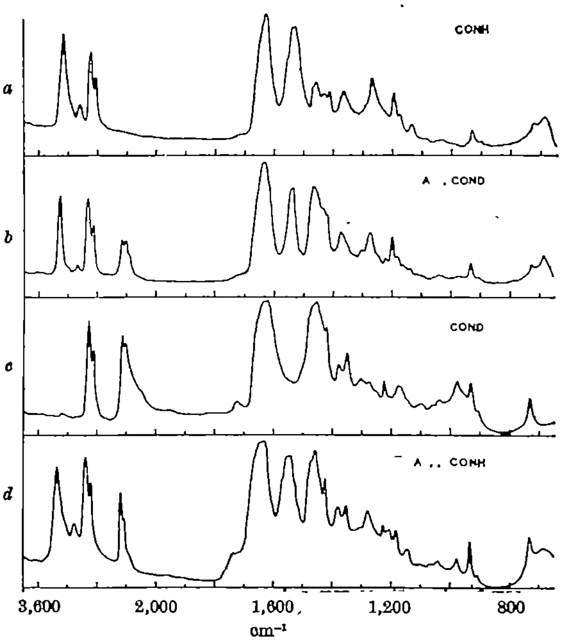

Fig. 1. *a*, Normal nylon 6 6; *b*, nylon 6·6 after exchange with excess deuterium oxide at room temperature until no further exchange occurs (60 h); *c*, fully N deuterated nylon 6·6; *d*, N deuterated nylon 6·6 after exchange with water (conditions as for *b*). *A*, Accessible groups

The absorption bands of accessible and inaccessible CONH and COND groups in nylon 6·6 have been obtained[16] by deuterating the accessible part of the normal polymer with deuterium oxide and by hydrogenating the accessible part of a fully deuterated polymer with water (both at room temperature). The spectra are shown in Fig. 1. Figs. 1*a* and *b* show that on partial deuteration nylon behaves like keratin; a small shoulder remains at 3,200 cm^{-1} and the two strongest ND bands (2,470 cm^{-1} and 2,414 cm^{-1}) are equal in intensity. On complete deuteration (Fig. 1*c*) the ND bands are still of approximately equal intensity and on hydrogenation of the accessible regions (Fig. 1*b*) the residual inaccessible deuterated groups show two ND bands. Furthermore, the relative intensities of the 3,300 cm^{-1} peak and the 3,200 cm^{-1} shoulder is almost the same as in the normal polymer (Fig. 1*a*). According to Bendit's suggestion the 3,200 cm^{-1} shoulder should now be much greater in intensity. It is clear that accessible and inaccessible amide groups in 6·6 nylon show a different relative intensity for the two ND bands, but the 2,414 cm^{-1} band is still quite strong in the inaccessible regions. This problem is under investigation, and an explanation in terms of combination bands, the intensity of which depends on the extent of Fermi resonance, is most probable since significant differences in the amide fundamental frequencies are detectable between accessible and inaccessible groups.

In silk films the main NH peak is at 3,290 cm^{-1} and the 3,200 cm^{-1} shoulder is absent[17-19]. On deuteration of the accessible material, silk shows two ND bands with approximately equal intensity[19,20]. The inaccessible NH band is considerably narrower than the total NH band and on subtracting these two bands it is found that the accessible NH absorption consists of a broad but single band with no sign of a shoulder in the 3,190 cm^{-1} region[20]. This result is confirmed by hydrogenating the accessible material in a fully deuterated film. The two bands in the fully deuterated film are at 2,465 cm^{-1} and 2,415 cm^{-1}, but in this case the lower frequency band is slightly more intense; this intensity difference is maintained during the hydrogenation process.

These results for crystalline substances, liquids and polymeric materials show that the assignment of the 3,190 cm^{-1} and 2,400 cm^{-1} bands to amorphous (accessible) material in keratin as suggested by Bendit[1] is untenable.

The details of the assignments on the basis of overtone and combination bands enhanced by Fermi resonance still require elucidation, but we consider that this is the most probable explanation for all the bands in the NH and ND regions. For polymeric materials, a prerequisite is the complete assignment of the amide fundamentals for both the proto- and deutero-compounds in both the accessible and inaccessible regions.

A long-standing criticism of this type of explanation for the 3,080 cm^{-1} band, assigned to the overtone of amide II, has been based on the presence of a similar band in lactams where amide II is absent; this difficulty has been convincingly overcome[21].

THE evidence presented by Cannon *et al.* invalidates my suggestion that the 3,190 and 2,400 cm^{-1} bands are associated exclusively with the amorphous phase in keratin. However, I do not think that their assignment in terms solely of Fermi resonance offers a complete explanation; it now appears likely that these bands do not have a unique origin, and that they are a composite of the peptide modes favoured by Cannon *et al.* and other bands characteristic of the material. This opinion is based on the following considerations.

(1) There are limitations when applying the frequency assignments of the amide group to proteins. In the first place, in simple amides or polyamides there are no intra-chain interactions to give rise to frequency perturbations, such as were investigated by Miyazawa and Blout[1] for the amide I and amide II bands. Secondly, side-chain absorption modes may occur, not all of which are broad and ill-defined. For example, the CONH$_2$ absorption of such groups as glutamine has been shown by Elliott[2] to occur at 3,225 cm^{-1}, with a weaker band near 3,370 cm^{-1}, and I thank Dr. R. D. B. Fraser for directing my attention to this. The effect is exhibited in the spectra of silk, keratin and gliadin (Figs. 2*a* and *b*), which show good correlation between CONH$_2$ content and the absorption at 3,200 and 2,400 cm^{-1}. (The CONH$_2$ content of these proteins, expressed as a percentage of the number of residues containing amide groups to the total number of residues is about 1, 10 and 40 per cent respectively.) Another source of side-chain contribution may be basic groups such as arginine, which absorb strongly near 3,200 cm^{-1}.

(2) Important evidence in favour of my original suggestions was the apparent disappearance of the 3,190 cm^{-1} band on deuteration, while Cannon *et al.* claim that the asymmetry of the main NH peak in deuterated keratin indicates that the band is still present. This claim cannot be regarded as established, as the main NH peak has various asymmetrical features in most polypeptides, both on the high- and low-frequency side[3]. Even in the case of poly-DL-alanine, which is given by Cannon *et al.* as an example of a substance exhibiting a single peak, asymmetry is clearly apparent. It is also worth noting that in a number of proteins tested, the disappearance of the shoulder near 3,200 cm^{-1} is more rapid than the decrease in intensity of the main NH peak, thus indicating that at least part of the absorption near 3,200 cm^{-1} is caused by accessible material.

(3) The variations of relative intensity of the ND doublet on re-hydrogenation, particularly as they are not accompanied by any significant frequency shifts of the peaks, are consistent with the presence of two components, although this type of behaviour does not rule out a Fermi resonance assignment. The effect, which is shown for gelatin in Fig. 2*c*, has also been observed for a number of other proteins, including keratin. Furthermore, whatever the correct assignment of the ND doublet, it is clear from the

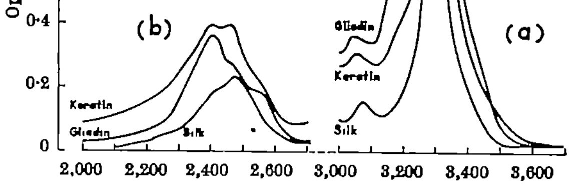

Fig. 2. *a*, Spectra of undeuterated films of gliadin and silk, and of keratin in the form of a section of horse tail hair; *b*, spectra of gliadin, silk and keratin, partially deuterated from the vapour phase; *c*, spectra of partially deuterated gelatin during the re-hydrogenation process. Times of exposure of specimen to water vapour are stated

re-hydrogenation results that the accessible and inaccessible phases exhibit different absorption intensities at 2,400 cm^{-1}, which must reflect, at least in part, structural differences between these phases.

(4) As most materials containing amide groups have an absorption mode near 3,200 cm^{-1}, which is assigned by Cannon[4] to the combination band amide I + amide II, enhanced by Fermi resonance, its absence in silk, which exhibits these fundamental modes as prominently as any other protein, calls for comment.

(5) In view of the above considerations, as well as the evidence presented in my earlier report, it would appear that in keratin the assignment of the controversial NH and ND modes exclusively to overtone and combination bands enhanced by Fermi resonance is not justified, and that other factors may well play an important part.

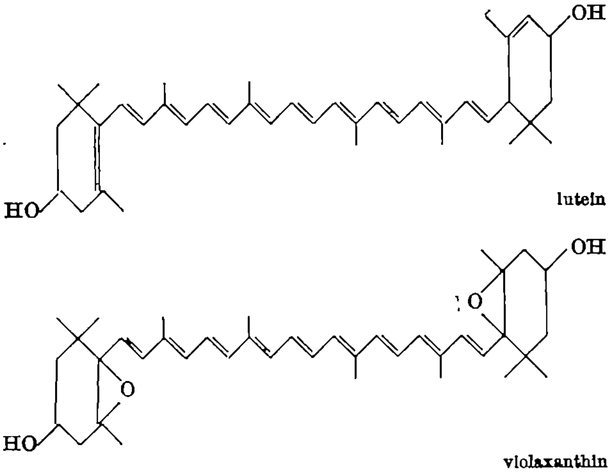
ISOTOPIC OXYGEN INCORPORATION IN XANTHOPHYLLS OF *SPINACEA OLERACEA* QUANTASOMES

By ELIE A. SHNEOUR* and Prof. MELVIN CALVIN, For.Mem.R.S.

Lawrence Radiation Laboratory and Department of Chemistry, University of California, Berkeley

CAROTENOIDS in general, and xanthophylls in particular, are universally associated with the chlorophylls of photosynthetic organisms[1]. Among the possible functions for the xanthophylls, the role of oxygen transport resulting from the photolysis of water[2] was first suggested by Dorough and Calvin[3]. Sapozhnikov *et al.* have shown that the two major leaf xanthophylls, lutein and violaxanthin (Fig. 1) are interconvertible: dark aerobiosis resulted in an increase in violaxanthin at the expense of lutein, while strong light anaerobiosis led to the reversal of this reaction[4,5]. The existence of this relationship was confirmed by Blass, Anderson and Calvin using $^{14}CO_2$ labelling of these xanthophylls and showing them to have very nearly equal specific activities[6].



lutein

violaxanthin

Fig. 1

Yamamoto, Chichester and Nakayama have reported recently that no oxygen-18 enrichment was detectable in violaxanthin from *Spinacea oleracea* chloroplasts exposed to $H_2{}^{18}O$ and Hill reaction with ferricyanide, but that a small incorporation was observed in lutein[7].

Hill and Scarisbrick demonstrated that illuminated chloroplasts evolve oxygen in the presence of an artificial electron acceptor[8]. More recently, Park and Pon isolated chlorophylls and carotenoids-containing lamellæ from *Spinacea oleracea* chloroplasts which possessed enhanced Hill activity[9]. These authors provided evidence to suggest that the ultimate sub-units which have this activity are oblately spherical particles 100 × 200 Å, to which the designation 'quantasome' has now been given.

In this article, we report on an investigation similar to that of Yamamoto, Chichester and Nakayama, but with quantasome aggregate fractions of *Spinacea oleracea* which can evolve oxygen in the presence of a suitable electron acceptor, but which lack the ability to fix carbon dioxide.

Locally grown fresh spinach stalks were used throughout. Selected leaves were ripped from the stalks by hand, and the quantasome fraction was prepared according to the procedures described by Park and Pon[9]. Hill activity, chlorophylls and xanthophylls concentrations were determined by optical methods against appropriate controls[10]. The electron acceptor used for the Hill reaction was recrystallized 2,3′,6-trichloroindophenol, sodium salt (Eastman Kodak *P*3467) (TCI). Oxygen-18 enriched water and 99·4 per cent gaseous molecular oxygen-18 were obtained from the Isotope Division of the Weizmann Institute of Science (Rehovoth, Israel). Pure samples of lutein and violaxanthin used in co-chromatography were provided by Dr. Harold H. Strain, Argonne National Laboratory, Chicago, Illinois, and Dr. James H. C. Smith, Carnegie Institution of Washington, Stanford. California.

In all experiments to be described the quantasome fractions were diluted with 0·01 N phosphate buffer *p*H 7·8 to yield chlorophyll concentrations of 4 ± 0·2 mg/ml. and initial oxidized TCI concentrations of 2·7 ± 0·3 μM/mg chlorophyll. For experiments with $H_2{}^{18}O$, 3·0-ml. aliquots of diluted quantasome preparations containing 10 ± 0·5 atom per cent oxygen-18 were placed in 20-ml. sample flasks with an argon atmosphere. For experiments with molecular oxygen, 3·0-ml. aliquots containing no excess $H_2{}^{18}O$ were placed in 20-ml. sample flasks connected

to a vacuum glass-manifold arrangement which permitted the introduction into the sample flasks of a gaseous atmosphere consisting of 20 per cent oxygen-18 and 80 per cent argon by volume at atmospheric pressure. Each experiment consisted of two 3·0-ml. aliquots, one of which was kept in total darkness for 30 min at 20° ± 2° C, while the other was kept in darkness during the initial 25 min and then exposed to 10,000 ft.-candles heat-filtered incandescent illumination for the following 5 min. After 30 min, both the dark control and the illuminated samples were diluted with 15 ml. of a boiling mixture of acetone–methanol (7 : 2). Each sample was then repeatedly extracted until colourless, under reduced illumination, with 5-ml. fractions of peroxide-free diethyl ether, after the addition of 50 ml. aqueous saturated sodium chloride solution to the sample. The diethyl ether fractions from each sample were then combined, dried with sodium sulphate, brought down *in vacuo* to a small volume and stored under argon in a deep freeze for further treatment.

Lutein and violaxanthin were separated from chlorophylls without recourse to saponification of the diethyl ether extracts by adsorption chromatography on linear polyethylene powder. Linear polyethylene powder, melt index 0·9, was obtained through the courtesy of the Dow Chemical Co., Midland, Michigan, and was prepared for adsorption chromatography according to the method described earlier[6].

Each extract was developed with 85 per cent aqueous methanol on a 32 × 150 mm linear polyethylene column under positive argon pressure. By this procedure, it was also possible to recover quantitatively the TCI used as the Hill reagent. TCI, violaxanthin and lutein were obtained by elution. Each xanthophyll eluate was diluted with 10 ml. thiophene-free benzene and 100 ml. saturated sodium chloride aqueous solution. The benzene phase was quantitatively recovered, dried over sodium sulphate, filtered and stored in the deep freeze for further purification. Each benzene extract, evaporated *in vacuo* to a small volume, was chromatographed on a pretreated 32 × 150 mm 'Micro-Cel *C*' (Johns-Manville Co., synthetic calcium silicate, 95–200 m^2/g active surface), and developed under argon-positive pressure with 10 per cent acetone in light petroleum ether. The desired band was obtained by extrusion of the column. Pretreatment of the 'Micro-Cel *C*' adsorbant consisted of pyrolysis at 400° C for 1 h followed by washing with dry light petroleum ether. The separation and purification obtained by this method could not be distinguished from a procedure which involved a crystallization step.

Two-dimensional co-chromatography with authentic samples of lutein and violaxanthin on Kieselguhr-treated paper[11] developed in darkness under an argon atmosphere with isopropanol in petroleum ether, in one direction, followed by 20 per cent chloroform in petroleum ether in the other, did not yield more than one detectable component[12].

Sufficient quantities of lutein and violaxanthin were thus obtained without the necessity of using dilution with carrier and its attendant uncertainties. Neoxanthin, however, was not available in the required amount to obtain meaningful data.

Each of the two xanthophylls from these experiments were then converted to carbon dioxide according to the procedures of Rittenberg and Pontecorvo[13]. All glassware was preheated at 500° C for 12 h, and both samples and oxidant were exhaustively dried in high vacuum to remove residual oxygen and water from the system. Pyrolysis with mercuric chloride was carried out at 500° C for 1 h, and the oxygen-16/oxygen-18 ratio was determined by one of us on the Consolidated Electrodynamics Co mass spectrometer model 21–130, a cycloid tube type which permits accurate measurements with relatively small samples. Results are given in Table 1.

It can be seen from Table 2 that results in Table 1 confirm all previously reported data on oxygen incorporation in xanthophylls[3,6]. In all cases and conditions examined, very little isotope appears in these compounds. The technique used for obtaining the results reported here was also applied to the carotenoid spheroidenone of the photosynthetic bacterium *Rhodopseudomonas spheroides* in an oxygen-18 atmosphere. These experiments yielded very substantial incorporations of the label into this compound, thus confirming the validity of the method used[14]. It is possible to estimate the minimum expected incorporation if only one xanthophyll oxygen per quantasome was involved in oxygen transport during photosynthesis. There are approximately 180 chlorophyll molecules per *Spinacea oleracea* quantasome[15], and about one-third this number of carotenoid molecules, of which 40 are xanthophylls[16]. The relative fraction of lutein, violaxanthin and neoxanthin are 0·57, 0·26 and 0·17, with 2, 4 and 3 oxygen atoms, respectively[7]. Thus, we can calculate the total number of xanthophyll oxygens as follows:

Table 2

Organism	Treatment	Xanthophylls	$H_2{}^{18}O$ atom (per cent)	Atom (per cent) incorporated	Ref.
Chlorella pyrenoidosa (whole cells)	5 h high-intensity illumination	unresolved	3·01	0·245	(3)
Chlorella pyrenoidosa (whole cells)	dark	unresolved	3·06	0 233	(3)
Spinacea oleracea (chloroplasts)	$Fe(CN)_6^{+++}$ 30 min high-intensity illumination	Lutein Violaxanthin	3·95	0·225 0·206	(6)
Spinacea oleracea (chloroplasts)	$Fe(CN)_6^{+++}$ Dark	Lutein Violaxanthin	3 95	0·224 0·206	(6)
Spinacea oleracea (quantasomes)	TCI, 25 min dark, then 5 min light	Lutein Violaxanthin	10·0	0 206 0 212	this article
Spinacea oleracea (quantasomes)	TCI, 30 min dark	Lutein Violaxanthin	10 0	0 203 0·225	this article

Lutein = 40 × 0·57 × 2	45·6
Violaxanthin = 40 × 0·26 × 4	41·6
Neoxanthin = 40 × 0·17 × 3	20 4
Total xanthophylls oxygen atoms per quantasome	107·6

Water in equilibrium with the system contained 10·00–0·20 = 9·80 atom per cent excess oxygen-18.

If only one of these 108 oxygen atoms per quantasome could exchange with the $H_2{}^{18}O$ the resulting overall xanthophyll enrichment would be:

$$\frac{9\cdot80}{108} = 0\cdot09 \text{ atom per cent excess oxygen-18}$$

But the maximum incorporation actually observed was:

$$0\cdot22–0\cdot20 = 0\cdot02 \text{ atom per cent excess}$$

From these considerations it is possible to conclude that the xanthophylls of green plants probably do not function as principal oxygen carrier in photosynthesis.

This work was done during the tenure by one of us (E. A. S.) of an advanced fellowship from the American Heart Association and was supported, in part, by the U.S. Atomic Energy Commission.

We thank Prof. C. C. Delwiche for advice on the theory and use of the mass spectrometer and Prof. R. B. Park for information on the preparation of *Spinacea oleracea* quantasome fractions.

HISTAMINE METABOLISM *VIA* THE NUCLEOTIDE PATHWAY

By Dr. SABURO MURAOKA, MIE SUGIYAMA and Prof. HIDEMASA YAMASAKI

Department of Pharmacology, Okayama University Medical School, Okayama, Japan

Enzymatic Formation of Histamine Riboside from Histamine Ribotide

A PREVIOUS communication[1] from our laboratory described the formation of histamine ribotide from histamine-adenine dinucleotide using a phosphodiesterase and some properties of this ribotide. The present report, which is a continuation of studies to elucidate the possibility of liberation of free histamine from histamine dinucleotide *in vivo*, describes the formation of riboside from histamine ribotide by a human prostatic acid phosphatase, and some chemical and biological properties of histamine riboside.

The degradation of histamine ribotide was carried out by the use of the partially purified human prostatic acid phosphatase[2], in a medium containing 2 μmoles of ribotide, 0·2 ml. of 0·2 M acetate buffer (*p*H 5·0), 0·1 ml. of 0·01 M magnesium chloride and 0·2 ml. of enzyme, in a total volume of 0·6 ml. The liberation of inorganic phosphate was 73 per cent of the theoretical value after 60 min incubation at 37° C. The rate of the reaction appears to be somewhat slower than that with 5′-adenylic acid. The use of a purified preparation of 5′-nucleotidase from snake venom (*Agkistrodon halys blomhoffi* Boie)[3] or bull semen, in an amount sufficient to decompose 5′-adenylic acid completely in 5 min, failed to give evidence for the presence of inorganic phosphate in 60 min which should be liberated from histamine ribotide. A comparatively large amount of crude snake venom liberated inorganic phosphate from histamine ribotide, but this was probably due to the non-specific monoesterase contained in the venom.

Histamine riboside was isolated from the reaction mixture of histamine ribotide and prostatic enzyme after incubation at 37° C for 3 h at *p*H 5·0 in a nitrogen phase, by McIntire's method[4] for purification of tissue histamine, which involves butanol extraction at *p*H 12·5 and adsorption–desorption by cotton acid succinate. The riboside can be separated from the starting ribotide by the use of 'Dowex-50' (H^+ form), but column chromatography with cotton acid succinate has the advantage of allowing the use of a more dilute acid (0·004 N hydrochloric acid) as the eluting solution. Each fraction of the eluate was submitted to optical density measurement for the histamine moiety at 220 mμ. The fractions containing the riboside were lyophilized, and the riboside was crystallized from a mixture of ethanol and ether (1 : 1). The crystals were so highly hygroscopic at room temperature that accurate measurement of the melting-point was impossible; but the analytical values shown here clearly indicate that this sample is the histamine riboside. One μmole of this sample contained 0·99 μmole of ribose, measured from periodate consumption, by taking the optical density of histamine dihydrochloride at 220 mμ, at *p*H 7·0, as the standard. Hydrolysis of the riboside by heating with 2·5 N hydrochloric acid at 170° C for 5 h in a sealed tube showed that the amount of histamine bound was 0·93 (calc. 1·00) by the assay with guinea pig ileum and 0·96 by the spectrofluorometric method[5], both values agreeing well with the theoretical value. This sample of riboside did not contain free histamine detectable either biologically or fluorometrically, and inorganic phosphorus was not detected in the foregoing acid hydrolysate.

Paper electrophoretic studies indicated that the basicity of histamine riboside is fairly close to that of histamine, that is, on electrophoresis in 0·1 M phosphate buffer (*p*H 7·2) at 300–400 V, 1 m.amp/cm, for 120 min, histamine moved 4·6 cm towards the cathode, while the riboside moved 3·5 cm in the same direction. Under the same conditions, the ribotide and dinucleotide moved 1·0 and 0·4 cm in the reverse direction, respectively. The R_F values on paper chromatography, using a mixture of 0·1 M acetic acid/ethanol (1 : 1) as a solvent, were 0·82 for the riboside, 0·53 for the dinucleotide and 0·68 for the ribotide. The ultra-violet spectrum of the riboside showed an absorption maximum at around 210 mμ, agreeing with that of the ribotide. The diazo reaction of the riboside with sulphanilic acid developed a yellow coloration on the paper chromatogram. The absorption spectrum of this reaction solution lacked the peak at 530 mμ characteristic of free histamine, as in the case of the ribotide and dinucleotide, and one peak at around 380 mμ was noted. Similar to the ribotide which was previously described, the orcinol reaction for ribose was completely negative. Attempted formation of a fluorescent product by condensation with *o*-phthalaldehyde, observed by Shore *et al.*[5] with histamine, failed in these three compounds which have a histamine–ribose bond. This result could be utilized for the determination of free histamine in the presence of these compounds.

As in the case of the ribotide[1], 0·1–0·3 μmole of histamine riboside caused a slow increase of tone of the guinea pig ileum piece sensitive to 0·0005 μmole of histamine, apparently distinguishable from the action of histamine. Arterial pressure of a pentobarbitone-anæsthetized cat, which showed a characteristic fall with 0·001 μmole of histamine, was not affected by intravenous injection of 0·2 μmole of the riboside or 0·5 μmole of the ribotide. Only a higher concentration (0·5–1·0 μmole) of the dinucleotide showed a very slight and transitory fall, somewhat slower than that of histamine. The local blueing[6] of the skin by intracutaneous injection in a guinea pig previously administered pontamine sky blue by cardial puncture was negative in all these three histamine derivatives even with 0·5 μmole, while histamine was positive at 0·001 μmole.

Nucleotide Pathway of Histamine

Previously, we confirmed the work of Alivisatos *et al.*[7] that histamine-adenine dinucleotide is synthesized from histamine and diphosphopyridine nucleotide (DPN)[1]. Following up this investigation, we subjected this dinucleotide to the action of phosphodiesterase from snake venom and were able to isolate a pure preparation of histamine ribotide[1]. Further, we succeeded in the formation and isolation of histamine riboside from the resulting ribotide with the use of human prostatic acid phosphatase (preceding communication). Recently, Abdel-Latif *et al.*[8] reported an alternative pathway of enzymatic formation of histamine ribotide or riboside by the direct interaction of histamine on the ribotide or riboside of nicotinamide. Preliminary evidence[9,10] also indicates that histamine ribotide is formed from histamine and phosphoribosyl pyrophosphate in the presence of adenosine triphosphate. In earlier experiments, imidazoleacetic acid riboside was isolated from urine of rats injected with ^{14}C-labelled histamine or imidazoleacetic acid by Tabor and Hayaishi[11], and Karjala[12]. These findings suggest a possibility that histamine metabolism *via* the nucleotide pathway plays some physiological part *in vivo*.

This report deals with results of *in vitro* experiments conducted to find out whether or not this pathway includes the degradation of histamine riboside and the reverse reaction, the formation of the riboside, by nucleosidases especially by nucleoside phosphorylase. The liberation of free histamine from histamine riboside was investigated taking as its criterion the contraction of the guinea pig ileum suspended in a Tyrode bath kept at 37° C in the presence of the riboside and enzyme preparation. Nucleoside hydrolase[13], prepared from *Lactobacillus delbrueckii*, did not cause a contraction of the ileum, but when 50 mμmoles of histamine riboside were added after, simultaneously, or before the treatment with enzyme, the ileum did contract, and this contraction was relaxed by antihistamine ('Neoantergan') (Fig. 1). However, nucleoside phosphorylase[14] from rat liver, nicotinamide ribosidase[15] from bovine liver, hæmolysed human erythrocyte and snake venom (*Agkistrodon halys blomhoffi* Boie) did not cause the contraction of the ileum under the same conditions.

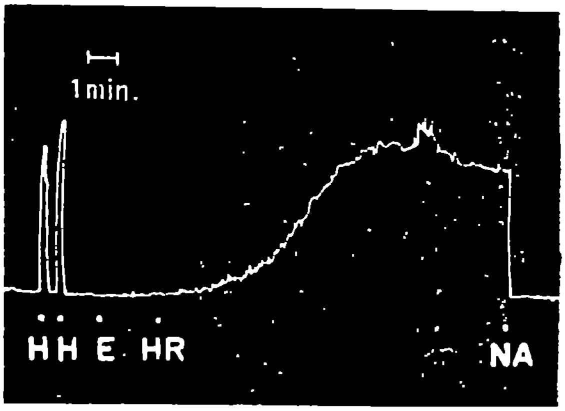

Fig. 1. The liberation of free histamine from histamine riboside by nucleoside hydrolase from *Lactobacillus delbrueckii*. *H*, histamine 2 mμmoles; *HR*, histamine riboside 50 mμmoles; *E*, nucleoside hydrolase (1 mg protein); *NA*, 'Neoantergan' 0·02 μg in 10 ml. Tyrode bath (37° C)

The liberation of ribose-1-phosphate or ribose from the histamine riboside was estimated by the orcinol reaction. It was found that the orcinol reaction of the medium remained negative even after 1–5 h incubation at 37° C; this medium contained 1·5 μmoles of histamine riboside, 30–320 units of nucleoside phosphorylase[14] purified from rat liver, 1·0 ml. 0·1 M phosphate buffer (*p*H 7·4), in a total volume of 3·0 ml. In the presence of diamine oxidase[16] partially purified from hog kidney the oxygen uptake proved to be 38·4 μl. by histamine, 1·8 μl. by histamine riboside, 2·4 μl. by histamine ribotide and 1·9 μl. by histamine dinucleotide in 2 μmoles each for 1 h. Therefore, this enzyme can be said to act almost specifically on free histamine only. In view of the fact that the phosphorolytic cleavage of inosine was coupled with the xanthine oxidase reaction[17], an excess amount of diamine oxidase was added to the reaction system just mentioned, including histamine riboside and nucleoside phosphorylase, but an acceleration of the reaction failed to take place. On the other hand, in the case of nucleoside hydrolase from *Lactobacillus delbrueckii*, the liberation of an equivalent quantity of ribose and histamine was observed by the orcinol reaction and by the bioassay with guinea pig ileum. In an attempt to form histamine riboside from histamine and ribose-1-phosphate in the presence of nucleoside phosphorylase, with a total volume of 3·0 ml. of the medium containing 1·5 μmoles of inosine, 50 units of nucleoside phosphorylase, 400 units xanthine oxidase and 1·0 ml. of 0·1 M phosphate buffer (*p*H 7·4) under the conditions where ribose-1-phosphate can be liberated quantitatively from inosine, an equivalent amount of histamine was added to the medium. However, the formation of histamine riboside was not demonstrable because free histamine determined by the diazo reaction did not decrease in the reaction mixture even after 1–4 h incubation.

From these results, it seems that the nucleotide pathway of histamine does not involve the process of phosphorolytic cleavage of riboside and the reverse reaction. Previously, we reported that histamine-containing nucleotides or nucleoside all show no histamine-like effect as proved by tests on the contraction of guinea pig ileum, the fall in blood pressure of the cat and on the local accumulation of circulating dye in guinea pig skin (preceding communication). These facts, signifying that even *in vivo* the histamine–ribose bond of these compounds is difficult to split, agree well with the results of the present experiment. Consequently, the final product(s) of the nucleotide pathway of histamine must be histamine riboside and/or its derivatives, and the fact that these intermediates are physiologically inactive offers a promising possibility of this pathway being included in a part of the detoxication mechanism of histamine.

In the early period of our studies, from the fact that the anaphylactic release of histamine from guinea pig lung was inhibited by nicotinamide[18], an inhibitor of DPNase and nicotinamide ribosidase, we proposed a tentative hypothesis that part of the released histamine might be liberated from the nucleotide pathway. Thus we assumed that either one of two processes, sensitive to nicotinamide, the formation of histamine dinucleotide by DPNase or the degradation of histamine riboside by nucleosidase might be contained in this pathway. It has been recently confirmed, however, that the DPNase activity of guinea pig lung tissue is not affected by sensitization or antigen–antibody reaction[18]. Furthermore, as it was not possible to catalyse the degradation of histamine riboside with mammalian enzymes in the present study, the nucleotide pathway seems not to be involved in the mechanism of nicotinamide inhibition of histamine release.

INFLUENCE OF RIBONUCLEIC ACIDS FROM THE LIVER ON IMPLANTATION AND GROWTH OF TRANSPLANTABLE TUMOURS

By N. N. AKSENOVA, V. M. BRESLER, V. I. VOROBYEV and J. M. OLENOV

Laboratory of Cancer Cytology, Institute of Cytology, Academy of Sciences of the U.S.S.R., Leningrad

SEVERAL investigations have shown that ribonucleic acids (RNA) from normal tissues can inhibit the growth of tumours[1-3]. The results obtained are in agreement with our own[4]. This article summarizes our results and those of some more recent experiments.

The cells of a transplantable strain of the liver mucous cancer (Malyugina's strain) were used as a recipient. The preparations of RNA of donor cells were obtained by the phenol method at $pH = 6{\cdot}0$ and contained neither protein nor DNA. Tumour cells before implantation into outbred rats were incubated with RNA in Hank's solution at room temperature (about 25°). The suspension of tumour cells incubated under similar conditions without RNA served as a control. The results of the experiment were checked 25 days after inoculation. In all more than 900 rats were used for these experiments.

Incubation with liver RNA results in a strong inhibition of tumour growth (Fig. 1). The effect depends on concentration of the RNA and time of incubation. No tumours were observed after 8-h incubation at concentrations of 0·1 mg/ml. and higher. At the site of inoculation there appeared small, glassy nodules the transplantation of which was not successful. The inhibitory effect of the liver RNA on the growth of the liver mucous cancer is notable even at 0·05 mg/ml. The cells incubated with the liver RNA do not display any morphological deviation from the control. The viability of these cells has been confirmed by a successful explanation *in vitro*.

RNA from the cells of the liver mucous cancer produced a weaker effect (Fig. 1). The tumours grown from the cells incubated with RNA from the mucous cancer were easily transplanted. The unavoidable admixture of RNA from normal tissues probably may explain the inhibitory effect of RNA preparations from the mucous cancer.

The treating of RNA preparations with RNase (0·2 mg/ml. of RNA was incubated with 0·004 mg/ml. of RNase at 37° for 1 and 2 h) fully eliminated the effect. The completeness of inactivation has been confirmed by the fact that in a special experiment with mucous cancer cells incubated only with RNase (without RNA) the inhibition of tumour growth is greater than in the experiments with RNA treated with RNase. It is worth mentioning that the inhibitory effect of RNase is well known.

Contrary to RNA, preparations of liver DNA do not inhibit tumour growth.

The difference between the experiment and the control decreases considerably when rats are injected

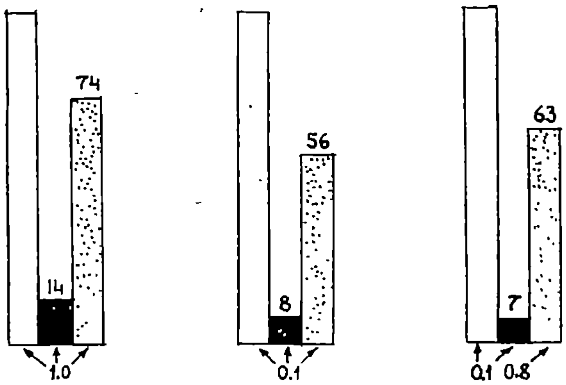

Fig. 1. Influence of preliminary incubation of implanted cells performed with RNA from the rat liver and mucous cancer of the rat liver on the growth of mucous cancer.
White, control; stippled, RNA from mucous cancer; black, RNA from rat liver.
Left, 2·5-h incubation; middle, 8-h incubation; right, 8-h incubation. Figures above columns designate the average weight of tumours (in percentage of the control assumed to be 100 per cent) and figures under the columns are concentration of RNA in incubation medium

with cortisone. This gives some grounds for believing that changes which occur in tumour cells under the influence of liver RNA may reduce their resistance towards protective mechanisms of the animal. Therefore, on weakening that protection, the effect of RNA either becomes insignificant or disappears altogether.

We have compared the effect of liver RNA on the growth of the liver mucous cancer and sarcoma 45 (Fig. 2). It was found that the growth of sarcoma 45, unlike the liver mucous cancer, was not suppressed by liver RNA. (As is seen from Fig. 2, the weight of tumours even increases in comparison with the control. It may be explained, probably, by the improvement of the survival conditions of the cells due to the enriching of the incubation media.)

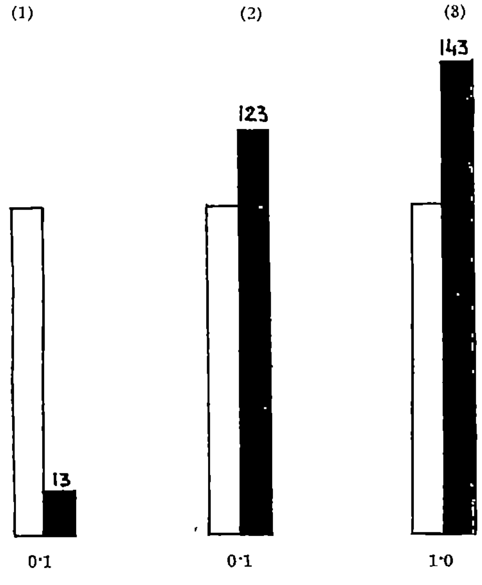

Fig. 2. Comparison of effects from preliminary incubation (8-h) of implanted cells performed with liver RNA on the growth of mucous cancer of the liver and sarcoma 45.
White, control; black, experiment–incubation with RNA from rat liver. Figures above columns designate the average weight of tumours (in percentage of the control assumed to be 100 per cent) and figures under the columns–concentration of RNA in incubation medium 1, mucous cancer of the liver; 2 and 3, sarcoma 45

However, this difference is not to be regarded as an evidence of the organospecific effect of the liver RNA, for different kinds of interpretations of the results obtained are quite possible. Perhaps, not all tumour strains react to RNA from normal tissues in the conditions of our experiments.

The results of the following experiment probably may testify to the organospecific character of the effect of liver RNA from normal tissues (Table 1). As usual, the cells of the liver mucous cancer were used as a recipient. These cells were treated with RNA extracted from a rat kidney. In this case RNA concentration exceeded by ten times the usual concentration of liver RNA (1·0 mg/ml. instead of 0·1 mg/ml.) with the maximal time of incubation.

Table 1. INFLUENCE OF PRELIMINARY INCUBATION OF IMPLANTED CELLS PERFORMED WITH RNA FROM THE RAT KIDNEY AND GUINEA PIG LIVER

Preparation	RNA concentration (mg/ml.)	Time of incubation (h)	No. of animals	Average weight of tumours	Growth inhib. of tumours (%)*
Control (without RNA)	—	8	19	5·1	
RNA from rat kidney	1·0	8	20	2·4	53
RNA from guinea pig liver	1·0	8	40	2·7	47

* The coefficient of inhibition was calculated by means of the formula $\frac{Mc - Mex}{Mc} \times 100$, where *Mc* and *Mex* present the average weight of tumours in the control and experiment respectively.

Despite these conditions, the effect was weaker than in all experiments with liver RNA of lower concentration. Our experiments also show that the action of RNA from the guinea pig liver is characterized by the same weak inhibitory effect (Table 1).

When discussing our results it is necessary to take into consideration the fact that the inhibitory effect of RNA from rat liver on the growth of the tumour, for example, the liver mucous cancer, may not be explained by the presence of admixtures of toxic agents for, on one hand, this explanation is not in agreement with the data showing different effectiveness of preparations obtained from cells of the rat liver, mucous cancer of the rat liver, rat kidney and guinea pig liver; on the other hand, RNase inactivates preparations. Besides, as already mentioned, we have not found any morphological changes in the cells treated with RNA before implantation.

Thus, our experimental results, as well as those obtained by some other authors[1–3], indicate that the capacity of tumour cells for autonomic growth decreases after their incubation with RNA from normal tissues. Possibly, this effect, in a certain degree, is organospecific.

We believe that an investigation of this effect may be helpful for the analysis of the nature of epigenetic changes[5,6] and their role in the carcinogenesis. The results of the effect of RNA from normal tissues on the growth of tumours seem to be important also for the evaluation of the generalized virus theory of tumour origin.

FROST INJURY IN LIVING CELLS

By ÉIZO ASAHINA

Institute of Low Temperature Science, Hokkaido University, Japan

BY freezing the β-lipoprotein of human plasma at a definite low temperature with various single salt solutions, Lovelock found that the higher the eutectic temperature of the suspending solution above the freezing temperature the greater the degree of denaturation of the lipoprotein[1]. This may illustrate, as he suggested, a new type of frost injury in extracellularly frozen cells. It seemed, however, very difficult to apply his method in the case of living cells, especially of animal origin, because they are very susceptible to a high concentration of single salt solutions. Fortunately the egg cell of the sea urchin is remarkably resistant to some single-salt solutions. This made possible experiments to examine the effects of salt solutions on a freezing cell at eutectic temperatures of the solutions.

Unfertilized eggs of *Hemicentrotus pulcherrimus* were used as material. The egg cells of this species of sea urchin were found to be very resistant to a rapid rate of freezing. In a frozen mass of egg cells suspended in sea water the cells could tolerate a rapid cooling rate of at least 20° C/min without any formation of intracellular ice. The media for the egg cell suspension were: 0·54 M potassium nitrate; 0·54 M potassium chloride; 0·54 M sodium nitrate; 0·54 M sodium chloride; 0·38 M magnesium chloride and 0·34 M calcium chloride solutions. None of these media seems to exert any harmful effect on the egg cells at least for 1 h at 15° C. When transferred into normal sea-water from these media nearly all the egg cells could cleave normally after insemination.

Test-tubes containing 0·5 ml. of egg suspension were cooled in special cooling baths in which brine stratified well from top to bottom according to the temperature. The temperature of the egg cell suspension was measured with a fine thermocouple inserted in the suspension, and was recorded automatically. The egg cell suspension in each test-tube was first cooled in the coldest bottom layer of brine. When the suspension was cooled to a desired temperature higher than the temperature of bottom layer, the test-tube was pulled up to the upper brine layer which had been kept at the same desired temperature. In this way the cell suspensions were cooled to various planned temperatures from −2·5° C to −35° C within about 3 min and kept at the same temperatures for 1 min. Each test-tube was then rapidly transferred into the water at 20° C. When the egg cell suspension was planned to be cooled to a temperature higher than −10° C, it was seeded in each test-tube with small ice-crystals when it was cooled to about −2° C. Egg cells frozen and thawed in this way were observed under a microscope for counting the intact cells. The results of the experiment are shown in Table 1 in which the percentage survival is based on the number of cells capable of resuming development after insemination.

Table 1 shows clearly that at least in solutions of single potassium salts all the suspended cells suffer fatal injury within only 1 min at a freezing temperature just below the eutectic point of the surrounding solution. In the solutions of sodium salts the suspended cells are rather resistant to freezing. They promptly die, however, at a freezing temperature about 10° C below the eutectic point. Freezing at temperatures below −35° C seems to be fatal to the suspended cells regardless of the kind of medium. When 1 M sucrose solution was used as the medium instead of single-salt solutions, all the suspended egg cells were killed at a freezing temperature of −20° C within only 1 min, while the eutectic point of pure sucrose solution was −13·9° C. In sea-water with added sucrose, on the other hand, about 70 per cent or more egg cells could survive freezing at −20° C at least for 1 min. These observations suggest that some very drastic changes promptly take place in the freezing egg cells when they have been cooled to a dangerous temperature below the eutectic point of the surrounding medium. The freezing process of the egg cells suspended in some of these media was, therefore, observed in a special cold box.

A small amount of egg suspension, covered with silicone oil, was cooled on the stage of a remote-control inverted microscope with special heating devices. The tip of a fine thermocouple was inserted in the egg suspension for measuring the temperature. When the egg suspension was cooled to −4° C it was seeded by means of an ice-tipped pipette. In the egg cells frozen in this way a remarkable change was found, especially in the solutions of potassium salts. When the frozen suspension was cooled to a temperature slightly below the eutectic point of the medium, fine crystals of the potassium salt suddenly appeared as many pine-needle-cluster-like crystals on the surface of homogeneous ice (Fig. 1). In such a case, if the frozen suspension was re-warmed to a temperature above the eutectic point, these salt crystals rapidly disappeared leaving underlying ice crystals covered with the concentrated salt solution. Such salt crystallization at the eutectic point could be repeated many times by fluctuating the temperature of the frozen suspension. When one of such salt crystals grew to the surface of an egg cell, a pronounced darkening rapidly spread from the spot touched by the salt crystal to the whole cell. There is no doubt that in this instant a flashing[2] or an intracellular formation of very fine ice crystals occurred in the cell. In the

Table 1. PERCENTAGE SURVIVAL AFTER A SHORT PERIOD OF FREEZING IN THE EGG CELLS IN VARIOUS SINGLE SALT SOLUTIONS

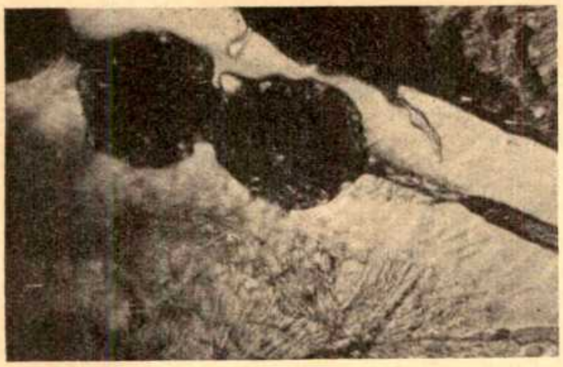

Fig. 1. Intracellularly frozen egg cells in potassium nitrate solution at the eutectic point. Fibre-like potassium nitrate crystals can be seen below on the underlying ice mass (× 180)

cells frozen with sodium chloride or magnesium chloride solution, the occurrence of an intracellular freezing at a definite low temperature was not clear; but in the process of re-warming from the critical temperature shown in Table 1 the yellow colour of the egg cells invariably turned to dark brown, showing a denaturation of the cytoplasm.

From the results described here, it is reasonable to suppose that at the eutectic point of the suspending medium or at least at a definite temperature below that point the egg cell is promptly damaged. Such damage seems to occur as a result of a destruction of protoplasmic structure of cell surface, perhaps by a very rapid change in the interactions between protoplasm surface and surrounding water, because a complete removal of water from the contacting medium suddenly occurs at the time of the formation of cryohydrate. The fact that in solutions of any single solute other than potassium salt the suspended egg cells are killed at a freezing temperature lower than the eutectic point may be explained as a consequence of easy attainment of metastable state in these solutions. This seems reasonable because in these solutions the apparent crystallizing out of the solute was scarcely observed at least at about their eutectic temperatures. The damage at the cell surface may certainly cause a decrease in the capacity of living protoplasmic membrane to serve as a barrier against ice inoculation into the cell[3]. Therefore, if freezing is rapid, an ice seeding from the injured spot into the cell may result, especially in the cells suspended in potassium salt solutions in which the eutectic temperature is high, due to which fact the cells have still a lot of easily freezable water within them. In the case of freezing cells suspended in calcium chloride solution another cause of frost injury should be considered, because the eutectic point is far lower than their danger-point temperature.

In any event, the process of occurrence of frost damage reported here is very characteristic in instantly occurring on a cell at a definite low temperature according to the kind of the suspending solution. In this respect the nature of this type of frost damage seems to be different from the hitherto known effect of increased salt concentration at the freezing[4], which is also found in freezing sea urchin egg cells even at a high sub-zero temperature if the freezing is prolonged.

MEIOSIS IN OVARIAN OOCYTES OF ADULT MAMMALS

By R. G. EDWARDS

National Institute for Medical Research, Mill Hill, London, N.W.7

MANY of the chromosomal anomalies in man and animals arise through non-disjunction or lagging chromosomes during meiosis in the oocyte. Investigations of the origin and primary incidence of such anomalies would be greatly facilitated if meiotic stages in the mammalian oocyte were easily available. Unfortunately, this has not been the case. Oocytes undergo the prophase stages of meiosis until diplotene just before or shortly after birth in the majority of mammalian species[1,2]. DNA synthesis occurs in the oocytes before birth, no further synthesis occurring in the oocyte until after fertilization[3]. The total number of oocytes per female is thus determined at birth in most species, no oocytes being formed thereafter. After diplotene, oocytes enter the dictyate stage and remain nucleated for the long period from diplotene until shortly before ovulation. In most mammalian species the stages of meiosis between diakinesis and the metaphase of the second maturation division occur in the brief period between the stimulation of the Graafian follicle by luteinizing hormone and ovulation a few hours later. Anaphase and telophase of the second meiotic division occur after penetration of the egg by the fertilizing spermatozoon. Thus, to find the early stages of meiosis, oocytes must be taken from late fœtuses or newly-born animals, for example, mouse and man[4]. The later stages of meiosis will be found in oocytes taken from adult ovaries.

Much fundamental information on non-disjunction, lagging chromosomes, crossing-over, and associations between normal and structurally altered chromosomes will be provided by studies on meiotic stages after diplotene. The present article is primarily concerned with methods designed to obtain these stages. Oocytes which are naturally in diakinesis or later stages of their meiotic divisions can be recovered from the ovaries just prior to ovulation[5,6]. But the number of such oocytes recovered is meagre, and the stage of meiosis can vary widely between different animals. Under appropriate endocrinological conditions the dictyate stage in oocytes of adult mammals can be terminated, and the resumption of meiosis can be induced. The exact stage of meiosis at a particular time can often be predicted with considerable accuracy.

In the rabbit, an injection of a luteinizing hormone or the coital stimulus initiates the resumption of meiosis, and ovulation occurs 8–9 h later[7]. In man and other species, a single or multiple injection of a luteinizing hormone, with or without previous follicular priming by a follicle-stimulating hormone, induces the maturation of many oocytes and ovulation. Hormonal treatments leading to the resumption of meiosis or to ovulation are known in the mouse[8,9], rat[8,10], cow[11], monkey[12], man[13], and many other species. The timing of each stage is very precise in the rabbit[7] and the mouse[14], and any stage of meiosis between diakinesis and the second metaphase can be obtained with precision. Such timing could presumably be extended to other species, for example, pig and sheep[15]. Metaphase of the second maturation division should be especially vulnerable for study, since in the majority of mammalian species the oocyte remains in this stage for some hours after ovulation. Anaphase and telophase of the second division will be more difficult to obtain, since they occur rapidly after sperm penetration, and anomalies at these stages could perhaps best be inferred from the examination of chromosomes at the first cleavage.

In the investigation of meiosis in human oocytes, such endocrinological techniques are obviously difficult to apply. Fortunately, there is an alternative technique which promises to supersede the endocrinological control of ovulation in most species. This is to stimulate the oocytes directly *in vitro* after their liberation from the follicle. In addition to being a most attractive technique in that it avoids the use of hormone injections *in vivo* and permits the use of small pieces of ovary, it has also proved to be an unusually simple technique when used in several species. All that is necessary is to liberate the oocytes into a simple culture medium by puncturing the follicles; many oocytes then immediately resume their maturation. Pincus and Enzmann[7] were among the first to use this technique in the rabbit. Pincus and Saunders[16] extended this work to human ovarian oocytes, and claimed that approximately 50 per cent of the oocytes displayed meiotic chromosomes or first polar bodies. Chang's[17] detailed analysis of the maturation of rabbit oocytes *in vitro* is perhaps the most extensive report. We have induced large numbers of mouse, rat and hamster oocytes to resume their maturation in this manner (Table 1). Pituitary hormones are clearly unnecessary to provide the stimulus to the oocyte; indeed, mouse oocytes resume meiosis when placed in 0·85 per cent saline or when taken from pregnant or non-pregnant animals. An inhibitory influence within the follicle rather than a factor in the oocyte evidently causes the persistence of the dictyate stage, and rupture of the follicle releases the oocyte from the inhibitor. If oocytes within their follicles are cultured *in vitro*, no evidence of maturation is found (Table 1). Mouse oocytes liberated from their follicles are excellent material for squash preparations, many of them having few or no cumulus cells attached. The rate of maturation of oocytes from the rabbit[17] and mouse is approximately the same *in vitro* and *in vivo*. Care is necessary in evaluating the stage of meiosis, for many oocytes are in metaphase of the second maturation division when liberated from their follicles (Table 1). These oocytes are usually free from corona cells, and are presumably atretic[1,18]. Although the ooplasm of rabbit oocytes matured *in vitro* differs in some respects from those stimulated *in vivo*, many of the former are capable of being fertilized after transfer to the Fallopian tubes of recipient rabbits[17]. Squash preparations of two stages in the maturation of mouse oocytes *in vitro* are shown in Figs. 1 and 2.

Unfortunately, human, baboon, monkey and dog oocytes have not responded, in our hands, as well as those of rabbits and rodents after liberation from their follicles. No chromosomes were found in 48 dog oocytes after culture for up to 12 h. It must be stressed, however, that the dog oocyte is one of the exceptions among mammalian oocytes in that its meiotic divisions are resumed after ovulation[1]. In *Cynus* monkeys 9 + 1? out of 56 living or squashed ovarian oocytes possessed chromosomes after 4–12 h in culture (Table 2). The three oocytes which were squashed appeared to be in metaphase of the second maturation division. A baboon autopsied near the time of ovulation[19] yielded 90 ovarian oocytes. They were cultured for periods up to 24 h. Altogether, 13 oocytes possessed meiotic chromosomes of the second

Table 1. PROPORTION OF MOUSE, RAT AND HAMSTER OVARIAN OOCYTES WITH CHROMOSOMES OR POLAR BODIES AFTER 6–8 H IN CULTURE

		Mouse				Rat	Hamster
Condition of animals		In œstrous cycle			2·5–8 days pregnant	In œstrous cycle	In œstrous cycle
No. of animals		10			4	3	2
Type of oocyte		With corona cells	Without corona cells	In follicle	With corona cells	With corona cells	With corona cells
Proportion of oocytes with chromosomes or polar bodies	At recovery	1/52	13*/30	0/7	0/18	0/15	0/12
	After 6–8 h in culture	68/79	29/42	0/14	27/39	19/23	11/13

*At least 11 of these oocytes were in metaphase of the second meiotic division.

Table 2. PROPORTION OF *Cynus* MONKEY AND BABOON OVARIAN OOCYTES WITH CHROMOSOMES OR POLAR BODIES AFTER VARIOUS PERIODS IN CULTURE

Species	No.	Stage of menstrual cycle	Period of culture (h)				
			0 (controls)	4–6	12	21–24	Total 4–24
Cynus	1	No cycle. Offspring weaned one week previously. Follicular. (No corpus luteum)	0/7	1/5	4/13	—	5/18
	2	Follicular phase (no corpus luteum)	0/8	0/3	2/15	—	2/18
	3	Fresh corpus luteum	0/5	1/1	1+1 ?/19	—	2+1 ?/20
Baboon	1	Recently ovulated	3/11	1/10	1/12	8/57	10/79
	2	Follicular	0/21	1/9	—	2/19	3/28
	3	Follicular	0/6	1/11	0/12	0/18	1/41
	4	Immature	2/19	0/11	—	0/17	0/28

The stage of the menstrual cycle in *Cynus* monkeys was determined from examination of the ovaries; baboons from the condition of the sex skin.

maturation division, the chromosomes appearing to be somewhat degenerate (Fig. 3). Meiosis had evidently not been induced by liberation of the oocytes from the follicles and subsequent culture, since the 13 oocytes occurred randomly in the control and culture groups (Table 2). Moreover, these oocytes had few or no corona cells attached, and at least seven of them had a polar body. These oocytes had evidently been stimulated *in vivo* before removal of the ovary, and had probably been liberated from atretic follicles. The great majority of oocytes from four baboons, one in the luteal phase, two in the follicular phase, and the fourth immature, were all nucleated at recovery or after culture for up to 24 h. Seventy-six human eggs were cultured for periods up to 20 h. Three of them appeared to contain chromosomes and two a polar body, as judged by phase-contrast microscopy of 58 living eggs, although none of the 18 that were squashed had either chromosomes or polar body. Chromosomes could not be seen in the oocytes containing polar bodies, which indicates that the 'polar bodies' were probably cytoplasmic extrusions from degenerating eggs. A difficulty with ovarian oocytes from many species is that the corona cells adhere very tightly to the oocytes. Hyaluronidase fails to remove these cells, although Shettles[20] removes them from human oocytes by culturing small pieces of the Fallopian tube with the oocytes.

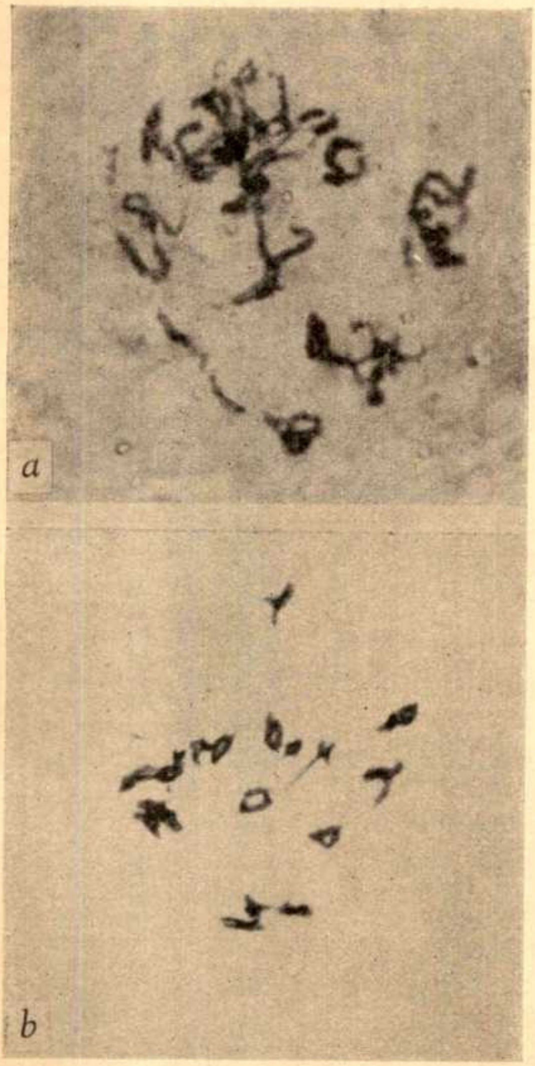

Fig. 1. Prophase of meiosis in mouse oocytes. *a*, Late diplotene, in the only oocyte so far found in this stage, after culture for 2 h (× 1,510); *b*, diakinesis-early metaphase in an oocyte cultured for 2¼ h (× 1,500)

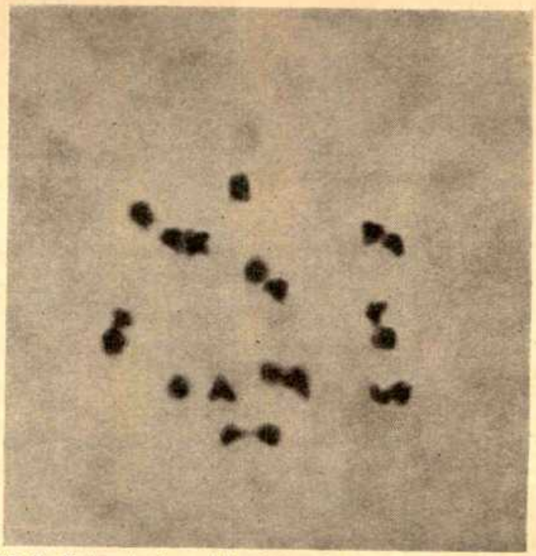

Fig. 2. Late metaphase of the first meiotic division in an oocyte cultured for 6¾ h. Colcemid (0·5 μg/ml.) added to medium during last 30 min (× 1,280)

Because the incidence of stimulated human eggs is so low it is clearly possible that the three human oocytes with chromosomes were stimulated *in vivo* before removal of the ovary. Shettles[20] observed tetrads in human ovarian oocytes in culture, but the inference from his wording is that the proportion of such oocytes was also low. Our results conflict with those of Pincus and Saunders[16]. We suspect that the oocytes classified by them as "with polar body" were either degenerate or had been stimulated *in vivo*, for they found some of these after only one or two hours in culture. Such a brief interval between dictyate and polar body extrusion appears to be improbable. Failure to stimulate the human oocyte *in vitro* might be one of the factors involved in the low incidence of fertilization *in vitro* using ovarian oocytes[21], for rabbit ovarian oocytes are fertilizable only after maturation has occurred[17,22].

The results from the baboons also indicate that the oocytes with chromosomes had been stimulated *in vivo*. On the other hand, the ratio in the *Cynus* monkeys seems to be sufficiently high to indicate some stimulation *in vitro*, although the possibility of atresia cannot be ruled out since no oocytes were seen to be actually in their first maturation division. The prospects of obtaining primate meiotic stages in the oocyte by this method thus appear to be slight. However, since oocytes from several species matured *in vitro* so easily, it might not prove too difficult to activate human and other primate oocytes. Neither the addition of gonadotrophins, steroid hormones or phytohæmagglutinin to the culture medium, nor the use of widely differing culture media, for example, various mixtures of medium 199, Gey's saline, fœtal calf serum, autologous (not human) and homologous serum, has so far induced the resumption of meiosis in human, monkey or baboon oocytes. Most of the human ovaries used in the work reported here were taken from women near to their menopause or from

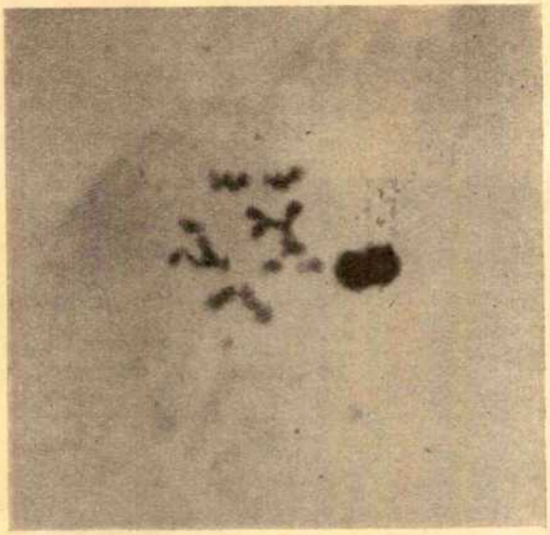

Fig. 3. Chromosomes in a baboon oocyte after 24 h in culture (× 1,050)

patients with gynæcological disorders, and there was a delay of up to 1 h before the oocytes were liberated from the follicles. Oocytes from the ovaries of younger women removed near the time of ovulation might yield meiotic figures as did those from the baboon, provided that some follicular atresia also occurs in man at ovulation[1,19]; but the value of such atretic oocytes in the analysis of chromosome behaviour is debatable.

Alternative techniques may be necessary to obtain meiotic stages in human ovarian oocytes. One alternative method is to cannulate the ovarian artery in patients undergoing surgery, and then perfuse the ovary with hormones after removal. Such a direct endocrinological stimulus in the absence of pituitary secretions might induce maturation of the oocytes in the excised ovary; in the intact mouse, for example, a single intraperitoneal injection of human chorionic gonadotrophin in various stages of the œstrous cycle or pregnancy will induce ovulation *in vivo*[23]. Moreover, many oocytes in secondary follicles, in addition to those in Graafian follicles, are found in meiosis[24]. So far, however, we have found no meiotic stages in human ovarian oocytes after the excised ovaries had been perfused for 4 h with H.C.G.[25] though the perfusion technique was not good in that the arteries were cannulated after removal of the ovaries. It may be necessary to perfuse a priming hormone in man, since luteinizing hormones alone evidently fail to induce ovulation[13]. Another alternative technique for stimulating the ovarian oocyte is to inject hormone directly into the follicle. Moricard[26] claims that this technique is successful in the rabbit. One suspects, however, that puncture of the follicle has released or diluted the inhibitor discussed above[17], and that the hormones played little or no part in stimulating the oocytes.

Some preliminary observations have been made in the present work. Large numbers of oocytes can be recovered from mammals; we obtained 38 from one human ovary, and 90 from both ovaries of a baboon. In living mouse oocytes, a close association can be seen in early metaphase between the nucleolus and some of the meiotic chromosomes[14]. Elucidation of these associations might yield information on the relationship between trisomy and the chromosomes with nucleolus organizers[27]. No evidence has so far been seen of precocious terminalization of chiasmata during the dictyate stage in the mouse; all 25 oocytes examined in detail have possessed 20 tetrads (see also refs. 6 and 8). We have observed the result of secondary non-disjunction in mouse oocytes. Three secondary oocytes were recovered after induced ovulation from a mouse classified genetically as *XO*. One oocyte possessed only 19 chromosomes (Fig. 4), the others possessing 20 ($2n=40$). This observation should be considered *sub judice*, since the mitotic complement of the donor female was not analysed and can only be inferred from the genetic evidence and from previous cytological examination of similar types of mouse[28]. It would obviously be of great

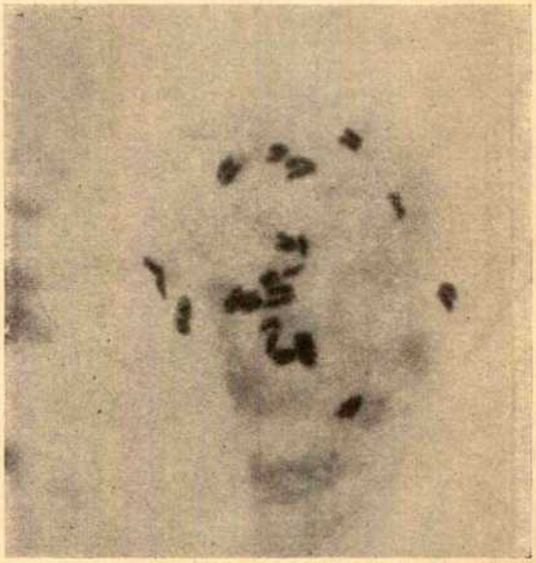

Fig. 4. Nineteen chromosomes after secondary non-disjunction in a secondary oocyte of an *XO* mouse. Ovulation induced by gonadotrophins. Mouse injected with 0·5 ml. of 'Colcemid' (1/50,000 w/v) 2 h before autopsy; cumulus cells removed by hyaluronidase (× 1,500)

interest to study the behaviour of this chromosome during the first meiotic division. In many oocytes, the meiotic chromosomes in the first polar body persist for a length of time and can be seen clearly (Fig. 5), despite the smallness of this polar body. Direct studies of the reciprocal products of the first meiotic division should be feasible. The clear separation of the chromosomes in the first polar body may be due to the absence of a spindle in many of them.

GLUTAMIC AND ALANINE DEHYDROGENASE DETERMINED BY ONE GENE IN *NEUROSPORA CRASSA*

By R. R. BÜRK and DR. J. A. PATEMAN

Department of Genetics, University of Cambridge

IT has been shown that crystalline beef L-glutamic dehydrogenase possesses L-alanine dehydrogenase activity[1,2]. Experiments are reported here which show that the triphosphopyridine nucleotide (TPN)-specific glutamic dehydrogenase of *Neurospora crassa*, which is determined by a single gene[3], also has alanine dehydrogenase activity. The two reactions catalysed by the enzyme are:

$$\text{L-glutamate} + TPN^{+} + H_2O \rightleftharpoons \alpha\text{-ketoglutarate} + NH_4^{+} + TPNH + H^{+}$$

and

$$\text{L-alanine} + TPN^{+} + H_2O \rightleftharpoons \text{pyruvate} + NH_4^{+} + TPNH + H^{+}$$

All the experiments described in this communication refer to the TPN-specific glutamic dehydrogenase and not the DPN-linked enzyme that also occurs in *Neurospora*.

Amination deficient, *am*, mutants of *N. crassa* lack the TPN-specific glutamic dehydrogenase which can be demonstrated in wild-type, am^{+}, strains. Cell-free extracts of am^{+} and *am* strains were assayed for both alanine and glutamic dehydrogenase activity. The enzyme activity was measured by following the oxidation of reduced TPN (TPNH), in the presence of appropriate substrates, by optical density measurements at 340 mμ. A series of results obtained from such enzyme assays is given in Table 1. The results show that wild-type *N. crassa* possesses both glutamic and alanine dehydrogenase. The *am* strains do not possess either normal glutamic or alanine dehydrogenase activity since their specific activities (Table 1) are not significantly different from zero.

Table 1

Strain	Specific glutamic dehydrogenase activity	Specific alanine dehydrogenase activity
am+	2,176	200
am-1	11	9
am-2	8	6
am-3	22	4

The unit of specific enzyme activity is: change in optical density at 340 mμ/min × 10^3/mg protein.

In addition the alanine dehydrogenase activity of cell free extracts of *am* and am^{+} strains was measured by their ability to synthesize alanine when incubated with pyruvate, ammonia and TPNH. The presence of alanine in the reaction mixtures was shown by paper chromatography. Incubation of am^{+} extracts with the complete system resulted in the formation of alanine; alanine was not formed if any one of the substrates was omitted. Incubation of *am* extracts with the complete system did not result in the formation of alanine. Since the *am* mutants are known to be the result of mutation in a single gene locus[3] it is evident that this locus also determines the production of alanine dehydrogenase in *N. crassa*.

The glutamic dehydrogenase of an am^{+} strain of *N. crassa* was purified by the method given by Fincham[4]. The method consists essentially of ammonium sulphate fractionation, adsorption on calcium phosphate gel and finally fractionation on a diethylaminoethyl cellulose (DEAE) column. During the final stage, 5-ml. fractions were collected from the DEAE column. Each of the fractions was assayed for glutamic and alanine dehydrogenase activity and the optical density at 280 mμ taken as a measure of the protein concentration. The results of the enzyme

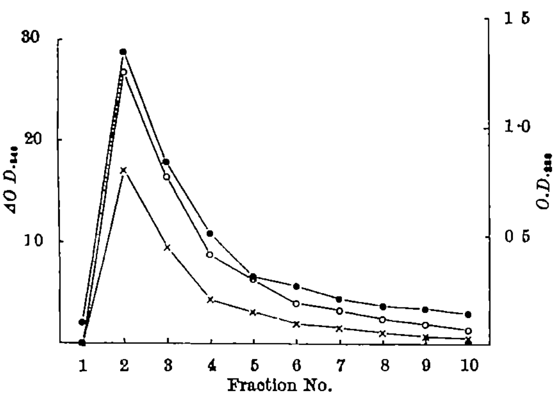

Fig. 1. DEAE chromatography of glutamic and alanine dehydrogenase. After initial purification 875 ml of enzyme extract in 0·02 M phosphate buffer pH 7·4 containing 0·001 M EDTA was applied to a 3-cm column of diethylaminoethyl cellulose. The column was eluted with 0·05 M phosphate buffer pH 7·4 and 5 ml. fractions collected.

The standard substrate mixture for glutamic dehydrogenase assay by glutamate deamination was 0·066 M sodium L-glutamate, $1·7 \times 10^{-4}$ M TPN and 0·1 M pH 8·3 *tris*-HCl buffer. The standard substrate mixture for alanine dehydrogenase assay by pyruvate amination was 0·008 M sodium pyruvate, 0·04 M ammonium chloride, $2·0 \times 10^{-4}$ M TPNH, and 0·1 M pH 8·6 *tris*-HCl buffer. Glutamate deamination (○) is expressed as $\Delta O.D._{340}$/min/μl. of column effluent. Pyruvate amination (×) is expressed as $\Delta O.D._{340}$/min/10 μl. of column effluent. (●) shows protein concentration as measured by $O.D._{280}$

assays of the various fractions are shown in Fig. 1. The ratio of the two specific enzyme activities is similar in all the fractions. The parallel behaviour of the two enzymes during DEAE chromatography is strong evidence that the same protein molecule is responsible for both glutamic and alanine dehydrogenase activity in *N. crassa*.

The best enzyme fractions obtained after DEAE cellulose column chromatography showed a 30–40-fold increase in specific activity compared with the initial cell-free extracts. They were used for a preliminary investigation of the properties of the alanine dehydrogenase. The enzyme is TPN specific and has a pH optimum of 8·8 in 0·1 M *tris*-HCl buffer at 35° C with respect to pyruvate amination. The Michaelis constants for the various components of the pyruvate amination reaction were estimated at pH 8·8 in 0·1 M *tris*-HCl buffer at 35° C. They were 29 mM for NH_4^+; 14 mM for pyruvate and 14 μM for TPNH. A comparison of the maximum rate of the α-ketoglutarate amination at pH 8·3 with the maximum rate of pyruvate amination at pH 8·8 showed that pyruvate was aminated about 3 per cent as rapidly as α-ketoglutarate by the enzyme. The incubation of the enzyme with L-alanine and TPN resulted in the reduction of the TPN as shown by an increase in optical density at 340 mμ. The maximum rate of L-alanine oxidation was about 0·4 per cent of the maximum rate of glutamate oxidation.

The current state of knowledge concerning the determination of protein specificity suggests that a single structural gene determines the specificity of a single polypeptide chain. The amination deficient mutants are known to be due to mutation within such a single structural gene, the *am* locus. Therefore the fact that the *am* mutants are deficient in both glutamic and alanine dehydrogenase activities suggests that a single protein mediates both catalytic activities. The parallel behaviour of both enzyme activities on purification also indicates that a single protein is involved. Therefore on the basis of both lines of evidence it is concluded that in *N. crassa* a single protein, determined by a single gene, is responsible for both TPN linked L-glutamic dehydrogenase and TPN linked L-alanine dehydrogenase.

The most thoroughly investigated glutamic dehydrogenase is the crystalline enzyme from beef liver[1,2,5]. The *N. crassa* glutamic dehydrogenase is like the beef enzyme in that the same protein shows both glutamic and alanine dehydrogenase activities to a similar degree and at a similar pH. In beef liver the two enzyme activities depend on the degree of association of the protein which is affected by certain agents, notably some steroid hormones[1,4]. The glutamic dehydrogenase of *N. crassa* probably consists of a number of polypeptide units, but the molecular weight is about 200,000 compared with about 1,000,000 for the beef enzyme[1,4]. It will be of interest to see if any of the agents mentioned differentiate between the two enzyme activities of the *Neurospora* protein.

USE OF THE TENTACLES, SWIMMING AND BUOYANCY CONTROL IN THE PEARLY NAUTILUS

By Dr. ANNA M. BIDDER
Department of Zoology, University of Cambridge

THE pearly nautilus has been an object of interest to zoologists since the descriptions of the eighteenth-century naturalist Rumphius[1] and of Owen[2]. The only accounts of the living animal apart from those of Rumphius were given by Bashford Dean[3] and Willey[4]: all three observers were restricted to observations made, either from a canoe, or on a dying animal in a pail or small tank.

During a recent visit to the West Pacific under a grant from the Nuffield Foundation, I was able to make some relevant observations on living *Nautilus*. Most of these were made on *Nautilus macromphalus* Sowerby, while I enjoyed for three months the hospitality of Dr. Catala-Stucki's aquarium at Noumea in New Caledonia, and valuable observations were also made on a specimen of *Nautilus pompilius* L. immediately after it was brought to the surface from about 100 fathoms in Rabaul, New Britain, where I received assistance from the Department of Agriculture, Stock and Fisheries of the Australian Government.

In Noumea, *Nautilus* was caught on the outside of the Barrier Reef, in 60–100 m, in traps of lobster-pot type, baited with dead fish and set on the bottom. The laborious work of setting and hauling up the traps was carried out by Madame Catala-Stucki and Dr. L. Merlet. Thanks to their efforts, about 40 animals were made available, many of which lived for up to 8 weeks in the aquarium. The repeated observations thus made possible produced a mass of interesting information out of which three topics are here selected: the use of the tentacles, the method of swimming, and the buoyancy-control.

The Tentacles

Since Owen's[2] classical description of *Nautilus pompilius* L., it has been known that the pearly nautilus has numerous tentacles which can be divided into 3 groups: (1) pre- and post-optic tentacles, one in front of and one behind each eye; (2) 19 pairs of digital tentacles and, within these, (3) a close-set circle of numerous buccal tentacles (the 'labials' of Owen) which, as their name implies, surround the powerful beak and buccal mass, and some of which are modified, in both the male and the female, to form secondary sexual organs.

Each of the optic and digital tentacles can be completely retracted into a muscular sheath; the buccal tentacles are carried on two lateral and one ventral pad, and are less fully retractile[4]. The tentacles carry no suckers or hooks, but are ridged, particularly on the inner side, and the ridges of both digital and buccal tentacles are adhesive: Willey[4] describes adhesive powers so strong that a tentacle attached to an object can be torn from its base and remain attached to the object.

From observations made on the animals at rest, swimming, and feeding, it emerged that there were not only marked differences in the reactions of the three types of tentacles already enumerated, but also that three groups of digital tentacles could also be distinguished by the different circumstances in which they were extended.

When the animal was at rest or quietly swimming, all tentacles were withdrawn into their sheaths, although the tips were sometimes visible. When the animal was in some way alerted, the pre- and post-optic tentacles and the four most lateral digital tentacles on each side might be extended, but there was considerable variation in the degree of extension and in the number of tentacles involved. The pre-optic and the second and third lateral digitals appeared to be more readily extended than either the post-optic or the dorsal and ventral lateral pairs.

When food (lumps of fish or crab) was brought within a certain distance, a further group of median lateral digitals, together with any of the four pairs of outer laterals not already extended, would be simultaneously thrust out to form a spreading 'cone of search' and would be held, so extended, while the animal circled round, forwards or backwards, until the food was found. The cone of search might also be formed when the animal was hungry and searching for food, or when it was exploring a new environment.

As soon as a tentacle of the cone of search touched food, an inner ring of digital tentacles, consisting of the innermost lateral and the dorsal digitals, would be extended, grasp the food and draw it under the hood, while the tentacles of search generally let go of the food. The buccal tentacles were rarely seen extending beyond the hood, but apparently held the food while the beak was biting. The three groups of digital tentacles may thus be differentiated functionally into an 'alert', a 'search' and a 'feeding' group.

A pre-optic tentacle and an outer lateral have each been drawn out by a piece of food held near, but not touching, the tentacles, showing a direct chemosensory response; the post-optics were never induced to extend in this way. The inner ring of digitals seem never to be extended during the search for food, but only when food is touched; they can also be stimulated to extend by lightly brushing the front of the hood. When an animal was held by the shell, under water, the optics and all the digitals would quickly be extended, but still in the order already described: first the pre- and post-optics and the outer laterals, then the median laterals and lastly the inner ring of laterals and dorsals. During the day the animal would often rest, attached by some of the tentacles to the glass of the tank. Sometimes only two or three tentacles were used for this, sometimes a dozen. Despite the functional differentiation already described, any combination of digital tentacles might be used for attachment, which was sometimes at the tip, sometimes by a point mid-way along the length, and which sometimes involved only one ridge, sometimes a number.

The most striking feature of a nautilus swimming with extended tentacles, whether the 'alert' or 'search' group, was the constant angle at which the tentacles were held, regardless of the direction of movement. This was well described by Moseley[5] in his account of the single living *Nautilus* dredged up during the *Challenger* Expedition.

The animals were never seen to use the tentacles in creeping or crawling, either along the bottom or over the glass of the tank.

Swimming and Respiratory Movements

Nautilus is a swimmer, and swims by jet-propulsion; but the method of propulsion differs from that of other living cephalopods (Coleoidea). In these, the shell is internal and reduced, or totally lost, and the mantle has become strongly muscular; its contractions drive the water from the mantle-cavity through the funnel, the narrow dimensions of which produce the jet. The funnel is passive in this propulsion; its muscles serve largely to anchor it against the force of the jet: it is also capable of turning the jet in various directions. In *Nautilus*, the shell is external, the mantle lines and secretes it, is only slightly muscular, and plays no part in locomotion, the muscular force for which is provided by the funnel alone. The funnel is not a tube, but a triangular muscular sheet, massively muscular in the middle, thinner at the margins, which roll over and overlap at the narrow anterior end; this can project beyond the margin of the shell, and forms, effectively, a tube. Within the mantle-cavity, the two halves of the funnel diverge so as to include the gills and only overlap when contracted together. Within the tip of the tubular portion is a valve, resembling that of the squids and cuttlefishes (Decapoda).

The funnel valve was first described by Rumphius[1] and the non-muscular character of the mantle by Owen[2], but Owen regarded the funnel simply as a vent for waste-products. Valenciennes[6] was the first to recognize that *Nautilus* is a jet-swimmer, and to perceive that the funnel was an organ of propulsion and that the ventral wrap-over, in contradistinction to the closed tube of the Coleoidea, played a vital part in this distinctive habit of funnel jet-propulsion. This intelligent reconstruction appears to have been overlooked or forgotten, and Griffin[7] thought the funnel insufficiently muscular to be used in vigorous swimming and postulated withdrawal of the head into the shell as the propulsive force, a view which has since been frequently quoted. Moseley[5], Bashford Dean[3] and Willey[4] all actually observed *Nautilus* swimming, and implied that it swam by jet-propulsion, but none of them, not even Willey, who described and figured the funnel, gave consideration to the mechanism involved.

In captivity, *Nautilus* swims chiefly at night and spends most of the day at rest on the bottom, poised on the outer curve of the living chamber with the tip of the funnel projecting 1–2 cm beyond the rim of the shell. The respiratory jet may be sufficient to rock the animal gently, or it may be so slight that there is no detectable movement except that of the posterior wings of the funnel. These may be seen flapping gently just inside the inhalent aperture, that is, the posterior angle of the shell aperture, close to the umbilicus of the shell on each side. The resting animal is partly withdrawn into the shell, with the pupil of the eye just clear of the optic notch, and only withdraws completely when handled or otherwise disturbed. When an animal hangs on to the glass of the tank, it is often possible to look straight down the funnel and watch the two pairs of gills waving to and fro in the respiratory current.

From time to time during the day an animal becomes restless and swims about until a new resting-place is found. When the animal is swimming the head is held clear of the shell; the funnel projects freely below it. Normally the animal swims backwards with the curve of the shell leading, but the tip of the funnel is very flexible, and can direct the jet so that the animal can turn about and swim in any direction. In slow swimming, the rhythmic ejections of water by the funnel are reflected in an undulating swimming movement which largely disappears when the animal swims fast.

The roll-over of the flap can change, in the same animal, from right-over-left, to left-over-right; the actual change was not observed. The funnel-valve could occasionally be seen, but always pressed against the dorsal wall of the funnel; it was never observed to project across the lumen, either at rest or in swimming Its function is thus a matter for conjecture : it may play a part in the rapid swimming which I have not seen.

A peculiar feature of the jet-propulsion of a cephalopod with an external shell is due to the fact that, when the animal is swimming with the head held steady, the capacity of the mantle cavity is constant, unlike the situation in, say, *Sepia*, in which the muscular mantle drives out water by contraction and thus diminishes the mantle-cavity's capacity. Inhalation takes place as the mantle expands again. In *Nautilus*, it is the internal volume of the funnel which changes : when the two halves of the funnel separate, water is drawn into the funnel from the surrounding mantle-cavity; when they come together and expel this water through the funnel tip, the water expelled must be simultaneously replaced and is drawn into the mantle-cavity, as already described, through the posterior angle of the shell. Expiration and inhalation are thus achieved by one and the same movement The roll-over form of the funnel allows the water to pass in readily as the two halves separate. Water is ejected by a broad band of transverse muscles, the 'compressors' of Owen[2]; the musculature of the funnel is complex, and the mechanism by which the two halves are drawn apart is not yet clear. The compressor muscles appear to consist of two layers, and it is possible that the funnel is closed by a contraction of the inner, opened by a contraction of the outer layer; a mechanism comparable to that of the decapod fin. A lightly anæsthetized animal, removed from its shell, showed vigorous flapping movements of the funnel, too rapid for their mechanism to be analysed.

In the restricted water of the tank, *Nautilus* never swims fast, but a Fijian woman told me that she had seen it in a lagoon swim 'as fast as a fish'.

Buoyancy Control

The chambered shell of *Nautilus* has long been a subject of interest to both zoologists and palæontologists, and speculation has especially been focused on the nature and condition of the contents of the enclosed chambers, and on the manner of buoyancy control. The recent work of Denton and Gilpin-Brown[8–11] on the buoyancy mechanism of *Sepia officinalis* L. has added point to these speculations.

The only existing record of the gaseous nature of the shell-contents is an oft-quoted statement by Vrolik[12] that the gas contained a higher proportion of nitrogen than is found in atmospheric air. This statement was based on tests made on an animal caught in the Bay of Amboina, preserved in alcohol, brought back to Holland by sea to the Academy of Sciences at Haarlem where gas from the chambers was examined. Oxygen is not mentioned; no trace of 'carbonaceous gas' was found. The technique used in examining this rather ancient material is not specified.

In the aquarium, healthy animals were near neutral buoyancy, and, when observed during the day, were usually slightly heavier than water, resting easily on the bottom. Changes in buoyancy were observed in individual animals. Newly captured animals were sometimes of positive, sometimes of negative buoyancy, but the light animals (positive buoyancy) would usually become heavy in a few hours.

A change in buoyancy was also observed several times on animals which were resting attached to the glass of the tank: such an animal might at one moment be seen to hang down from its tentacles, and be found, an hour or two later, straining up from them like a captive balloon. More than once, an animal was seen resting 'on the bottom' with clear water between the base of its shell and the bottom of the tank. At a later stage of captivity, the power to adjust buoyancy diminished, and the animal became permanently light, cruising round in the surface waters of the tank with the shell breaking surface. It is not known yet whether the diurnal changes in activity already described are related, as in *Sepia*, to diurnal changes in buoyancy[9].

The chambers contained both liquid and gas. X-ray photographs of a living animal, and samples drawn from the shells of live and newly-killed animals both showed a much greater volume of liquid in the newest chambers than in any other. The X-ray photographs showed that the chambers next to the newest, those which have, in fact, an apical position in life, contained little or no fluid, but that small amounts were present in the chambers overhanging the back of the hood. The floating animal, whether dead or alive, has stable equilibrium, which would seem consistent with this distribution. It is closely comparable with that found by Denton and Gilpin-Brown[11] for fluid in the cuttlebone of *Sepia*. The fact that the quantity of fluid changes with age in each chamber suggests that liquid can move out of, and probably also into, the chambers; this is also consistent with the situation in *Sepia*. The control of liquid in *Sepia* is through the 'siphuncular membrane', which closes the chambers; in *Nautilus* it must be through the siphuncule, which is drawn out from the mantle, contains a vein and an artery[4] and runs through the siphuncular tube in the shell. This tube is formed of calcareous spicules[13] which surround a 'horny' sheath (the nature of which has not been determined) secreted by the siphuncle itself: there is thus a considerable barrier between the gas and liquid in the chamber, and the blood of the siphuncle. The histology of the siphuncular epithelium closely resembles but does not appear to be exactly the same as that of *Sepia*, suggesting rather a condition from which the *Sepia* membrane could have evolved.

The buoyancy mechanism must be closely similar to that in *Sepia*, but, even if the physiology of the two siphuncular membranes proves to be the same, and an 'osmotic pump' similar to that found in *Sepia* is found[10], there are mechanical differences between the two animals. On one hand, the cuttle-bone is a small fraction only of the total weight, whereas nearly the whole of the buoyancy of *Nautilus* is utilized in supporting the shell. On the other hand, the chambers of the *Nautilus* shell are much larger than those of the cuttle-bone, and the last 6 or 8 chambers make up a large proportion of the shell's capacity, so that changes in the contents of one of these chambers would have a greater effect on the buoyancy than would be the case for a single chamber of the cuttle-bone.

The examination of the liquid from the chambers was inconclusive ; the small quantity of fluid found in the older chambers tended to be viscous ; the liquid contains organic material as well as dissolved salts.

The gas appeared to be at a pressure of about 1 atmosphere, both in an animal which had lived for some time in the aquarium, and in the animal brought up, at Rabaul, in 6–8 min from about 100 fathoms (180 m). In each case, when the shell was punctured under water, no gas emerged until the meniscus within the hole was pricked with a needle, when one small bubble sluggishly emerged. Two samples of gas from a single animal were scanned, through the kindness of Prof. Odell, in the mass-spectrograph in the Chemistry Department of the University of Auckland. The scannings suggested that the proportion of oxygen to carbon dioxide changes, as might be expected, with the physiological condition of the animal, but showed that the proportion of argon to nitrogen, in each sample, was three times that of the atmospheric air of Auckland, scanned at the same time.

Speculations on the buoyancy of fossil cephalopods have sometimes included the hypothesis of 'pre-septal' gas between the body of the animal and the newest septum. No evidence was obtained in support of this hypothesis.

It should be noted that the animal is at all times found firmly fixed in its shell, and the possibility of either air or sea-water being included in a new-formed chamber must be rejected.

In conclusion, it may be said that *Nautilus* does indeed conform to the cephalopod pattern known in the Coleoidea in that it is a predatory animal, catching food by prehensile tentacles which surround beak-like jaws and swimming by jet propulsion ; yet the form and use of the tentacles and the manner of jet-propulsion are basically different from the coleoid pattern. The difference in the swimming mechanism and the special problems of buoyancy control are intimately associated with the presence of an external shell, but the peculiar form of the tentacles must be taken as evidence of the plasticity of this region and allows free speculation about the form of the tentacles in other shelled cephalopods.

TEMPERATURE AND LIFE-SPAN IN POIKILOTHERMOUS ANIMALS

By PROF. RICHARD F. SHAW and BEAUREGARD L. BERCAW*

University of Virginia School of Medicine, Charlottesville

ALTHOUGH ageing is a complex phenomenon physiologically, it may stem from a relatively simple physico-chemical one. Many theories of the past have supposed it to result from the accumulation of toxic substances.

A more modern hypothesis is that the accumulation of nuclear damage is responsible. DNA is particularly suspect as the crucial substance as it controls all metabolism. A theory of damage to DNA, phrased more in terms of somatic mutation, has been elaborated by Szilard[1].

The purpose of this article is to consider the effect of temperature on life-span in poikilothermous animals. This bears on the question of whether ageing may be reasonably interpreted as due to a single or simple molecular process.

Rates of chemical reactions are described by an equation of the type:

$$-\frac{dy}{dt} = ky^n \qquad (1)$$

where y = concentration of substance, = time, and n, called the order of the reaction, generally refers to the number of species of molecules participating.

If death is assumed to be due to a longevity substance being reduced to some final value y_f, then t at the time of death may be represented by l, the life-span.

---

* Supported as a Summer Fellow by Lederle Laboratories, 1960.

If one plots log $1/l$ against reciprocal of absolute temperature, T, of certain invertebrate animals some surprising approximations to straight lines are obtained. This is shown in Figs. 1, 2 and 3. The organisms are respectively *Daphnia*, *Drosophila* and *Moina*. The sources are MacArthur and Baillie[2], Loeb and Northrop[3], Terao and Tanaka[4]. The only points that are very far off occur at extreme temperatures which may be unphysiological for the organism.

Such plots are equivalent to the Arrhenius plot, which yields a straight line when the logarithm of reaction rate constant is plotted against reciprocal of absolute temperature. The $1/l$ in the ageing plots corresponds to the rate constant k in the Arrhenius plot. That k is proportional to $1/l$ can readily be seen for the zero order equation. If y_f is the value of y at $t = l$, $y_f = c - kl$, so $k \propto 1/l$.

Also for first order $y_f = e^{c-kl}$

$$\ln y_f = c - kl$$
$$k \propto 1/l$$

This proportionality holds for higher orders.

Not only does the Arrhenius relationship appear to hold for ageing, but temperature-change experiments with *Drosophila* give results compatible with the idea that ageing can be represented by the reaction rate equation (1).

What will be the life-span of a fly kept for a while at 25° C and then for the rest of its life at 29°? Let us at first suppose that the process responsible for ageing and death is describable by a function $f_1(t)$ at 25° and a function $f_2(t)$ at 29°. We will not say for the moment what the function is, but it is represented by smooth curves in A and B of Fig. 4. For reasons which will appear shortly, a function $t = g_2(y)$ is also given there. This is $f_2(t)$ expressed with t as the dependent variable.

Diagram C shows the compound curve obtained if the change in temperature is made at time $t = x$. The life-span for a fly treated in this way will be l_3 rather than the l_1 or l_2 corresponding to the two temperatures used separately.

The question on which the experiment hinges is this: If the time of change, x, is varied in the experiment, how will a plot of l_3 against x appear? We will take the hypothesis that functions $f_1(t)$ and $f_2(t)$ in Fig. 4 correspond to an integral form of the rate equation (1). They differ only in the rate constant, which is k_1 at temperature 1 and k_2 at temperature 2.

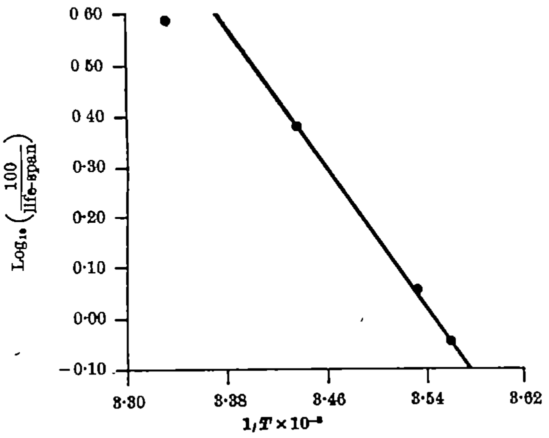

Fig. 1. Arrhenius plot on *Daphnia* from MacArthur and Baillie

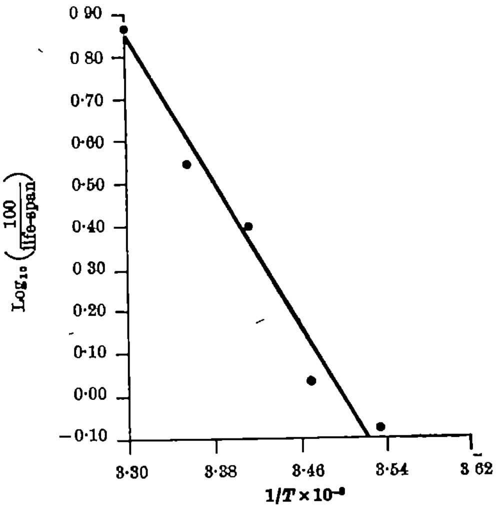

Fig. 2. Arrhenius plot of data on *Drosophila* from Loeb and Northrop

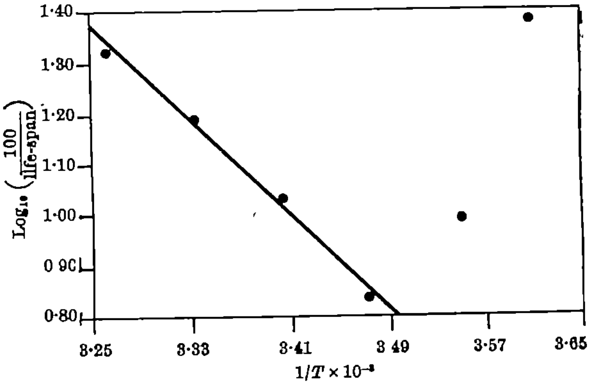

Fig. 3. Arrhenius plot of data on *Moina* from Terao and Tanaka

Under these conditions l_3 and x have a straight-line relationship as shown in D of Fig. 4.

The reason is as follows. As shown in C, the predicted value of l_3 for any x is given by x plus the distance from x to l_3. This distance is called Δt and appears in diagram B. It can be seen there to equal l_2 minus an initial amount of time given by $g_2(y_x)$.

$$\text{Thus } l_3 = x + \Delta t$$
$$= x + l_2 - g_2(y_x)$$

Since y_x is given by $f_1(t)$ when $t = x_1$ the above equation becomes

$$l_3 = x + l_2 - g_2[f_1(x)] \qquad (2)$$

It now becomes possible to demonstrate the linear relationship of l_3 and x for reactions described by equation (1).

For a first-order reaction $f_1(t) = y = e^{-k_1 t - c}$, and when $t = x$:

$$y_x = e^{-k_1 x - c}$$

Since it can be shown that $g_2(y) = -\frac{\ln y - c}{k_2}$, it follows that $g_2(y_x) = -\frac{\ln y_x - c}{k_2}$

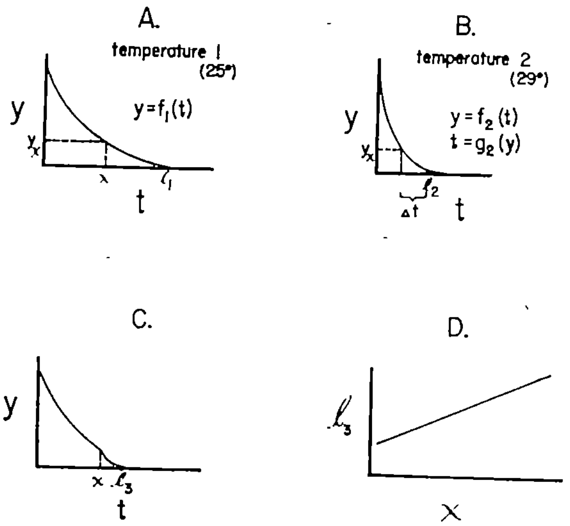

Fig. 4. The hypothesis being tested in the experiment on temperature change with *Drosophila*. *A*, Physiological age-state, *y*, of the organism is given as a function of time. At time x the age-state is y_x. At time l_1 the fly dies; *B*, time function of the age-state at a higher temperature. The life span is shorter; *C*, time function of the age-state for a fly kept at first at temperature 1 and later at temperature 2. The temperature is changed at time $t = x$. The curve is a composite of *A* and *B*; *D*, relationship of life-span to time of temperature change. It is shown in the text that if the ageing process follows the rate equation of chemical kinetics the relationship must be linear

If we substitute $y_x = e^{-k_1 x - c}$ in the above, the expression simplifies to give $g_2(y_x) = \dfrac{k_1 x}{k_2}$.

It is shown earlier that k is proportional to the reciprocal of l. So $g_2(y_x) = \dfrac{l_2 x}{l_1}$.

Substituting this in equation (2) yields:

$$\begin{aligned} l_3 &= x + l_2 - \frac{l_2 x}{l_1} \\ &= l_2 + x\left(1 - \frac{l_2}{l_1}\right) \end{aligned}$$

so demonstrating the linear relationship.

For $n \neq 1$ the general integral of the rate equation (1) is $\dfrac{y^{1-n}}{1-n} = -kt - c$.

We again evaluate $g_2\,[f_1(x)]$ in order to substitute in equation (2).

Solving for y allows us to write $f_1(t)$ as:

$$f_1(t) = y = [(1-n)\ (-k_1 t - c)]^{1/1-n}$$

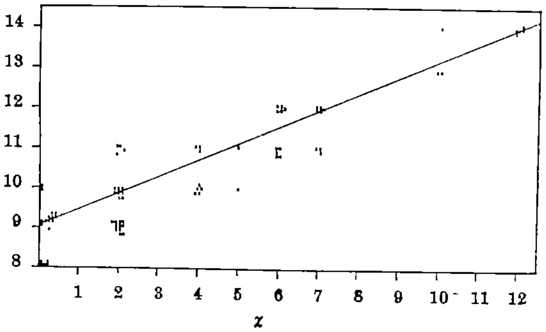

Fig. 5. Findings of the *Drosophila* experiment. A straight line appears to fit the points better than any other simple curve

Alternatively solving the general integral for t allows us to write $g_2(y)$ as $g_2(y) = t = -\dfrac{1}{k_2}\left[\dfrac{y^{1-n}}{1-n} + c\right]$.

When $t = x$:

$$f_1(x) = y_x = [(1-n)\ (-k_1 x - c)]^{1/1-n}$$

$$\text{and } g_2(y_x) = x = -\frac{1}{k_2}\left[\frac{y_x^{1-n}}{1-n} + c\right]$$

Substituting the expression for y_x into the above equation gives:

$$\begin{aligned} g_2[f_1(x)] &= -\frac{1}{k_2}\left[\frac{\left[(1-n)\ (-k_1 x - c)\right]^{\frac{1-n}{1-n}}}{1-n} + c\right] \\ &= \frac{k_1 x}{k_2} \end{aligned}$$

As before this is the same as: $g_2[f_1(x)] = \dfrac{l_2 x}{l_1}$. Substitution into equation (2) gives the same linear relationship as was found in the first-order process.

The experiment was carried out on newly emerged males of stock Oregon-*R* raised to adulthood at 25° C. The flies were put into shell vials with corn meal, agar, and molasses medium. They were observed every three and one-half days when transferred to fresh food. The life-span measured is in fact the life-span of the imago. It was also found convenient to put twelve flies in each vial. The experimental unit was thus a dozen flies rather than the individual. The measure of life-span was the time required for a dozen to be reduced to four.

The results were obtained in two different experiments done at different times. The slopes and intercepts of these were calculated by the method of least squares. The slopes of the two plots were the same as judged by t test ($P > 0.05$). But the intercepts differed by 1·05. This was probably because of a slight difference in thermostat adjustment from one experiment to the next in one or both incubators.

Since it did not appear that pooling the data could introduce any bias favouring the hypothesis, the results of the two experiments were pooled after being adjusted to the same intercept. They are presented together in Fig. 5. The line shown there was also fitted by least squares.

For the degree of variability around the regression line a better approximation to linearity could not be expected. It must be concluded that the result is that predicted by the hypothesis—the hypothesis being that ageing has a simple time function and so perhaps has a correspondingly simple molecular basis.

The results from the Arrhenius plots are also compatible with this conclusion. Some years ago there was a large school of biologists led by Crozier who supposed that a straight-line Arrhenius plot, when found for physiological processes, indicated the dominance of a single, simple, rate-limiting chemical reaction. The criticism of Burton[5] shows that the Arrhenius plot is not so powerful a tool as those workers thought, and that they may have often been misled.

It is interesting, however, that the method has, to our knowledge, never been applied to ageing except recently by Strehler[6]. The results of Figs. 1, 2, and 3 do approximate linearity. Strehler found the same for *Drosophila*. The findings are thus compatible with the view of determination of life-span by a simple rate-limiting reaction. But they are far from adequate to prove the presence of such a reaction However, by even the most sceptical view they have some significance. The nature of the ageing process is not known and the form that these plots would take could not have been predicted.

HETEROGENEITY OF THE PRODUCTS OF TOBACCO MOSAIC VIRUS BIOSYNTHESIS

By Prof. BARRY COMMONER and GEORGIA B. SHEARER

Henry Shaw School of Botany and Adolphus Busch III Laboratory of Molecular Biology,
Washington University, St. Louis, Missouri

THE characteristics of intermediate stages in virus biosynthesis are descriptive of the mechanism of replication. For example, some investigators[1-4] propose that in tobacco mosaic virus (TMV) replication the virus ribonucleic acid (RNA) fibre serves as a germinal component, providing a structural model (or 'template') which governs the specificity of new RNA biosynthesis. According to this view the resultant product is a replica of the germinal RNA fibre, which in turn regulates the specificity of subsequent protein biosynthesis, yielding thereby the characteristic protein sub-units of the virus.

Intermediates expected from such a course of events are free entire RNA fibres, free protein sub-units, and, possibly, intermediate stages in the subsequent assembly of the virus ribonucleoprotein rod from the former. Since TMV contains a single RNA fibre, but some 2,000 protein sub-units, intermediates that consist of virus RNA and protein in the proportions characteristic of the final TMV rod would appear to be specifically excluded from this scheme. A contrasting view is that TMV replication is indirect[5,6], the entering inoculum instigating a sequence of processes in which an exact replica of the virus or of its component parts appears only in the final product, the fully formed TMV ribonucleoprotein rod. This view admits of the possible occurrence of a wider range of products of TMV biosynthesis, including, for example, ribonucleoproteins which contain an incomplete RNA fibre.

These considerations suggest the importance of investigating the heterogeneity of the ribonucleoprotein products of TMV biosynthesis. There is some evidence that forms of TMV which differ from the predominant product of infection—a ribonucleoprotein rod about 3000 Å long—occur in infected leaf. Bawden and Pirie[7] have directed attention to the presence of rods of various lengths in all virus preparations. A small concentration of a specific form of the virus which, unlike the bulk virus, is closely associated with buffer-insoluble leaf components has been reported from this laboratory[8]. Zeitlin and Boardman[9] find, following incorporation of aspartic acid labelled with carbon-14 into infected tobacco leaf for periods of 2–67 h, that a form of the virus closely associated with the chloroplast exhibits a significantly higher specific activity than does ordinary TMV.

In order to investigate the heterogeneity of TMV biosynthesis we have analysed the incorporation of carbon-14, introduced into TMV-infected leaf by brief periods of photosynthesis in the presence of $^{14}CO_2$, into fractions of TMV which are separable on a chromatographic column. Leaf-blade tissue from 7-day infected plants of *N. tabacum* was exposed to $^{14}CO_2$ (150 μc. of carbon-14; 0·07 per cent carbon dioxide in air) under illumination for 3–20 min periods. The leaf chamber was then flushed with 5 per cent unlabelled carbon dioxide in air for 1 min, the tissue removed and frozen in liquid nitrogen. TMV was purified from the frozen tissue by a standard procedure which has been described elsewhere[10]. The purified virus was fractionated on an 'Ecteola' column (see legend for Fig. 1 for details) and the separate fractions analysed for carbon-14 content, protein content, infectivity, serological reactivity and ribonucleotide composition by methods given elsewhere[10].

Fig. 1 summarizes the results of a typical chromatographic separation of purified TMV isolated from infected leaf after a 20-min period of $^{14}CO_2$ incorporation. The elution pattern is similar to one observed previously on the basis of a discontinuous process[11]. An extremely small amount of ultra-violet-absorbing material is eluted at concentrations of less than 0·025 M sodium chloride. This appears to represent free virus protein sub-units which tend to become dissociated from TMV rods during purification procedures. This material does not precipitate on ultracentrifugation; its ultra-violet spectrum is that of an RNA-free protein; it forms a specific precipitate with anti-TMV serum; it is uninfectious.

Beginning at a concentration of about 0·025 M sodium chloride, increasing amounts of ultra-violet-absorbing material appear in the eluted fractions, reaching a peak in fraction 13 (about 0·06 M sodium chloride). The curve then declines gradually and measurable amounts of material are eluted up to a concentration of 0·3 M sodium chloride (fraction 60). About 90 per cent of the total material placed on the column is eluted up to this point. The remainder is removed from the column by elution with 2 M sodium chloride, followed by 0·5 M sodium hydroxide. In all fractions between 13 and 35 the ratio of absorbancies at 260 and 280 mμ is 1·20, the value characteristic of highly purified TMV. The ratios exhibited by later fractions tend to increase somewhat, and approach 1·30; however, the accuracy of the latter values is necessarily limited by the relatively low total concentrations of material in these fractions. Similar relationships are shown by the ratios of the Folin values and absorption at 260 mμ, which are also diagnostic of the ribonucleoprotein composition of TMV.

Fig. 1 shows that the fractions past No. 8 exhibit substantial infectivity toward two test plants,

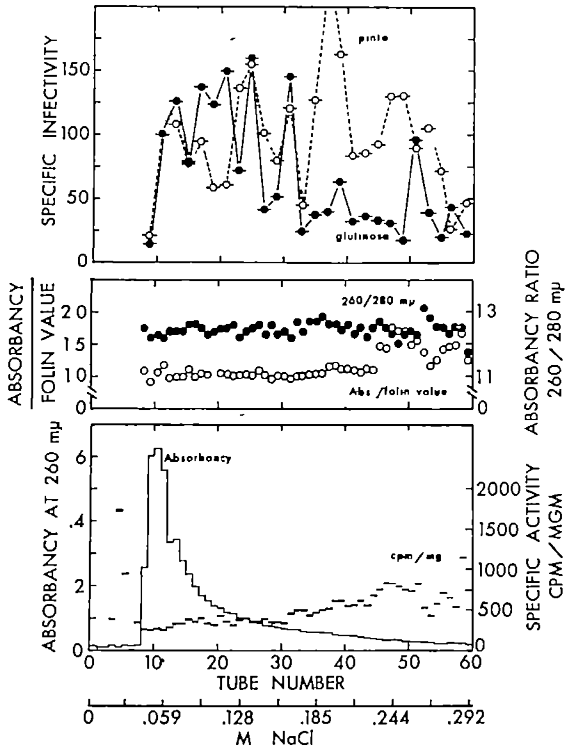

Fig. 1. Results of typical chromatographic fractionation of ^{14}C-labelled TMV on an 'Ecteola' column. The TMV was labelled by incorporating $^{14}CO_2$ photosynthetically into infected tobacco leaf (7 days after inoculation) for a 20-min period, followed by a 1-min period of unlabelled carbon dioxide. The virus was isolated from the leaf and purified by standard procedures before being applied to the chromatographic column. Successive 4-ml. fractions were collected during elution with a continuous gradient of increasing concentrations of sodium chloride. Specific activities were determined on mixtures of two successive fractions. The half-leaf method was used to determine specific infectivities, the values being expressed as per cent of the lesion count due to an equal concentration of standard unfractionated TMV.

N. glutinosa and pinto bean. The specific infectivities toward pinto bean (that is, relative number of lesions produced per unit mass of inoculum as compared with lesions yielded by a standard TMV preparation inoculated on the opposite leaf-halves) are equal to that of bulk TMV for most fractions between 10 and 50. Infectivity toward *N. glutinosa* is about equivalent to the infectivity of ordinary TMV in fractions 10–30, and declines somewhat in later fractions. The infectivity of the first 2 fractions in the leading edge of the main TMV peak is relatively low.

Specific activity is constant only in the first few fractions of the main TMV peak (fractions 10–13). Specific activity rises gradually in succeeding fractions; the carbon-14 levels in fractions 30–33 are about 75 per cent greater than those observed in fractions 10–13. Larger but more variable increases in specific activity are observed in fractions 40–55. These effects reflect the carbon-14 content of the virus protein which comprises 95 per cent of the preparation.

In order to obtain comparable data regarding the virus RNA a series of pooled chromatographic fractions were formed from material eluted from the chromatographic column between 0·10 and 0·14 M sodium chloride. RNA nucleotides were isolated from these preparations by the methods described earlier[10], and their carbon-14 specific activities determined. The results of this analysis are given in Table 1 in the form of the average values for material eluted with 0·10–0·13 and 0·13–0·14 M sodium chloride respectively. The nucleotide compositions of the RNA components from both of the composite TMV fractions are nearly identical, and correspond to the RNA composition observed in bulk TMV. The specific activities of the RNA nucleotides from fraction 2 are higher than those derived from fraction 1, and the difference is proportional to that observed in the virus protein. These results show that the substance responsible for the difference in carbon-14 levels between these successive chromatographic fractions consists of a ribonucleoprotein with the RNA composition characteristic of TMV.

Table 1. CARBON-14 SPECIFIC ACTIVITIES IN VIRUS PROTEIN AND IN VIRUS RNA RIBONUCLEOTIDES FROM SUCCESSIVE CHROMATOGRAPHIC FRACTIONS OF TMV*

Component	Fraction 1 (0·10–0·13 M NaCl)			Fraction 2 (0·13–0·14 M NaCl)		
	Molar ratio	Specific activity c.p.m./mg	% of TMV specific activity	Molar ratio	Specific activity c.p.m./mg	% of TMV specific activity
Cytidylic	0·74	†	—	0·76	†	—
Adenylic	1·12	97	43	1·12	109	41
Guanylic	1·00	25	11	0·97	34	13
Uridylic	1·16	30	13	1·16	36	14
TMV (protein)	—	223	—	—	266	—

* The values given represent averages of 2 successive 4 ml. chromatographic fractions in the case of fraction 1, and of 3 such fractions in the case of fraction 2. RNA was isolated by heating in 0·13 M NaCl; it was then hydrolysed in alkali, purified on charcoal and the ribonucleotides separated by paper electrophoresis.

† Carbon-14 content too low for accurate determination. The cytidylic acid content of TMV RNA is relatively low and the free ribonucleotide achieves relatively low levels of carbon-14 in the plant (ref. 10).

To determine whether the isotope effect is due to specific TMV protein, the serological analyses reported in Table 2 were carried out. Column fractions were pooled into two groups representing the 0·06 M–0·10 M sodium chloride and the 0·22 M–0·27 M sodium chloride eluates respectively, the specific activity of the group of late fractions being significantly greater than that of the earlier fractions. The carbon-14 recovered in the precipitate formed by treating the earlier fractions with anti-TMV serum represented 97 per cent of the carbon-14 content of the starting material. In the second group of fractions, about 87 per cent of the carbon-14 in the starting material was recovered in the antiserum precipitate. Thus, nearly all the excess carbon-14 present in the later chromatographic fraction is precipitable by anti-TMV serum, and is therefore associated with a component that contains TMV protein.

Table 2. PRECIPITATION OF CHROMATOGRAPHIC FRACTIONS WITH ANTI-TMV SERUM

	Early fractions (0·06 M–0·1 M NaCl)	Late fractions (0·22 M–0·27 M NaCl)
Amount of antigen (μg)	43	46
^{14}C in antigen (c.p.m.)	72	146
^{14}C in antigen–antibody precipitate (c.p.m.)	70	127
Per cent of original ^{14}C recovered	97	87

To evaluate the kinetic behaviour of the various chromatographic fractions relative to isotope incorporation from $^{14}CO_2$, a series of experiments similar to that described in Fig. 1 were carried out in which the time of $^{14}CO_2$ incorporation was varied between 3 and 20 min. In each case the virus found in successive fractions between 10 and 30 exhibited the gradual increase in specific activity shown in Fig. 1.

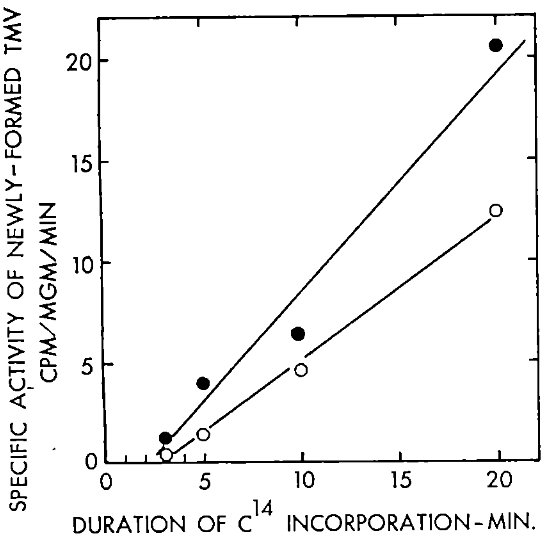

Fig. 2. Relative carbon-14 specific activity of newly formed TMV (specific activity of preparation/duration of $^{14}CO_2$ incorporation) in two groups of 'Ecteola' chromatographic fractions after various periods of $^{14}CO_2$ incorporation. Open circles: fractions eluted with 0·050 M–0·065 M sodium chloride. Closed circles: fractions eluted with 0·165 M–0·175 M sodium chloride

In such experiments the relative specific activity of the TMV newly formed during the period of isotope incorporation is given by $A/\Delta t$, where A is the specific activity of the TMV isolated from the leaf and Δt is the duration of incorporation of carbon-14. This is evident from equation (3), it being noted that V, the total amount of TMV, is so large compared with the amount synthesized during the brief experimental period (ΔV) as to be essentially invariant, and that the latter value is proportional to Δt (see also ref. 10). If $A/\Delta t$ is plotted against Δt, the intercept on the time axis represents the least time required for ^{14}C introduced as $^{14}CO_2$ to become incorporated into virus substance.

Fig. 2 shows this relationship for the TMV present in two different chromatographic fractions. The relative specific activity of newly formed TMV in the later fraction is consistently greater than that of the earlier fraction. In both cases the specific activity of the newly formed virus increases with the time of incorporation of $^{14}CO_2$, and both intercepts indicate a transit time of carbon-14 of 2–3 min for passage of carbon-14 from $^{14}CO_2$ to virus substance.

This result shows that the two chromatographic fractions represent forms of the virus that are synthesized concurrently from metabolic precursors. Their consistently different specific activities show that they are not identical materials. The increase in this difference with time of incorporation of carbon-14 suggests that the two fractions are not in the relation of precursor and final product.

Apart from the foregoing observations, there is some evidence in our experiments that purified preparations of TMV labelled with carbon-14 are associated with extremely small amounts of material that is rather high in specific activity. In the experiments described here it was found that the specific activity of unfractionated TMV remained constant when the purification process was increased from the standard 3 stage procedure to 6 stages. Nevertheless, although more than 90 per cent of the ultra-violet-absorbing material placed on the columns was recovered in the eluted fractions, the total recovery of carbon-14 was only 30–50 per cent. The remaining carbon-14 is bound to the column but can be eluted from it by extensive washing with 0·25 M sodium chloride. In the chromatographic procedure described in Fig. 1, the relative amount of carbon-14 eluted with 0·25 M sodium chloride, while quite variable from run to run, tends to be relatively high, especially when the preparation has been exposed to $^{14}CO_2$ for 5 min or less. The chromatographic fractions that exhibit this effect (40–55) tend to be moderately infectious toward pinto bean, but rather uninfectious toward *N. glutinosa*. Although this suggests a possible connexion between the high carbon-14 levels and a component related to the virus, this is by no means certain. The amounts of material involved are extremely small, and the effects rather variable. More detailed studies are required before any possible association of these effects with the process of TMV biosynthesis can be elucidated.

The foregoing experiments show that TMV preparations can be separated chromatographically into fractions that are composed of serologically specific TMV protein, that exhibit an RNA content and ribonucleotide composition characteristic of TMV, and that possess the infectivity associated with the virus. Despite these similarities the fractions do differ in carbon-14 specific activity, proportional differences being observed in the protein and in the separate RNA nucleotides of the virus. These results are evidence of heterogeneity in the ribonucleoprotein products of TMV biosynthesis. In what follows we consider the possible origins of this heterogeneity.

In these experiments all the carbon-14 found in the TMV isolated from the labelled leaf must be present in virus newly synthesized during the course of $^{14}CO_2$ incorporation, since pre-existing virus is metabolically inert. The specific activity of the newly formed virus ($A_{\Delta V}$) is given by:

$$A_{\Delta V} = \frac{C}{\Delta V} \qquad (1)$$

where C is the carbon-14 content of the newly-formed virus, the amount of which is given by ΔV. The observed specific activity of the total isolated virus, A, is given by:

$$A = \frac{C}{V} \qquad (2)$$

where V is the total amount of TMV isolated from the leaf.

Hence:

$$A = A_{\Delta V} \cdot \frac{\Delta V}{V} \qquad (3)$$

The observed differences in specific activity of carbon-14 between the TMV fractions that are separated on the chromatographic column (that is, the value of A for each fraction) must be due to corresponding variations in one or more of the foregoing parameters. The possibility that the quotient $\Delta V/V$ is significantly different for the various chromatographic fractions of TMV seems rather limited. The value of ΔV is proportional to the duration of incorporation of carbon-14, and to the rate at which the virus is synthesized from its metabolite precursors. As we have shown previously[10] this rate is reflected by the intercept on the time axis, of the line relating the specific activity of newly-formed TMV to the time of incorporation of carbon-14, since the intercept represents the minimum time required to convert $^{14}CO_2$ into TMV substance. Fig. 2 shows that two chromatographic fractions of TMV that differ

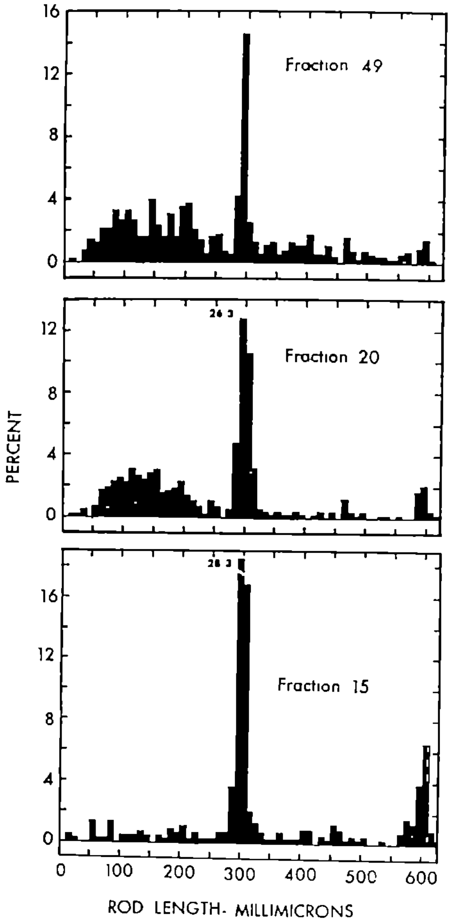

Fig. 3. Frequency distribution of the lengths of rods observed in electron micrographs prepared from several chromatographic fractions of TMV obtained by elution from an 'Ecteola' column with a continuous gradient of increasing concentrations of sodium chloride. Fraction 15 was eluted at 0·045 M NaCl; fraction 20 at 0·060 M NaCl and fraction 49 at 0·160 M NaCl Per cent of rods shorter than 3000 Å ± 300 Å: fraction 15, 13 per cent; fraction 20, 39 per cent; fraction 30 (eluted at 0·095 M NaCl, but not shown above), 43 per cent; fraction 49, 52 per cent Rods longer than the predominant 3000 Å class result from end-to-end polymerization during purification

significantly in specific activity of carbon-14 exhibit essentially identical intercepts. This result appears to preclude the possibility that the observed differences in specific activity are due to comparable variations in the rates of synthesis of different TMV fractions. The total virus content of the leaf, *V*, is essentially equal to the amount of pre-existing unlabelled virus, for the time during which labelled virus is synthesized is very short (3–20 min) compared with the time during which the pre-existing unlabelled virus is formed (7 days). Since the value of *V* for successive chromatographic fractions is a function of the relative rates of synthesis of the different fractions, this factor is also an unlikely source of the observed differences in the values of *A*. It is therefore unlikely that the observed variations in the specific activities of successive chromatographic fractions of TMV are due to corresponding differences in the ratio of newly formed virus to total virus $(\Delta V/V)$ in these fractions.

These considerations indicate that the levels of carbon-14 observed in our experiments are the result of differences, among successive chromatographic fractions, in the specific activity of the virus particles that are newly synthesized during the course of isotope incorporation ($A_{\Delta V}$). A possible explanation of these differences is that the various fractions of TMV are formed from separate metabolite pools which maintain unlike specific activities of carbon-14. Such an effect might, for example, result from variable rates of $^{14}CO_2$ incorporation into the metabolic pools of different classes of infected cells in the tobacco leaf. However, this would also require that the TMV formed in various types of infected cells be sufficiently unlike in physico-chemical properties to be distinguishable on a chromatographic column. There is no evidence in the relevant literature to support such a conclusion.

If it is assumed that the separable fractions of TMV are formed from the same metabolite pool at the same overall rate of synthesis, then the observed variations in specific activity can only mean that these fractions differ with respect to the relationship, within newly formed virus particles, between the amounts of non-isotopic carbon and of carbon-14. The simplest example of such an effect would be the addition of equal amounts of carbon-14 to the ends of pre-existing rods of TMV which differ significantly in length. In this case the specific activity of a TMV rod would be expected to vary inversely with the mass and therefore with the length of the TMV rod.

As a preliminary test of the possible association of the specific activity of TMV fractions with rod-length, we have determined the frequency distribution of rod lengths observed in electron micrographs prepared from a series of 'Ecteola' fractions of TMV. The results, which are illustrated in Fig. 3, show that the proportion of rods shorter than the predominant length of 3000 Å increases significantly in the later chromatographic fractions. Since TMV specific activity also increases in successively later fractions (Fig. 1), the empirical relationship between specific activity and rod-length corresponds to that suggested by the foregoing considerations.

Experiments designed to elucidate in detail the relationship between TMV biosynthesis and the lengths of the resultant ribonucleoprotein rods have been carried out and are to be reported elsewhere. These support the conclusion, proposed earlier on theoretical grounds[6,12], that the TMV rod is formed by a process of linear growth, and that ribonucleoprotein rods of various lengths are alternative products of TMV biosynthesis.

We thank Mrs. Clarice Phillips, Mrs. Ellen E. Richman and Mr. Dilworth Cannon for assistance in carrying out these experiments, and Mr. Mas Yamada for preparing electron micrographs.

LETTERS TO THE EDITOR

ASTRONOMY

Orbits of Natural Satellites

Bode's law, a three-parameter formula giving the distances of the planets from the Sun, is well known. In a recent communication, Woolfson[1] discussed whether Bode-type laws also applied to the innermost satellites of Jupiter, Saturn and Uranus and arrived at the conclusion that agreement was then less precise. It is the object of this communication to point out that the distances of all known satellites from the centre of the parent body can be given reasonably accurately by a simple two-parameter formula, subject to the assumption that vacant positions sometimes occur.

Fig. 1 shows a plot of the logarithm of the orbit radius of the five known satellites of Uranus against the satellite number; these five points are nearly colinear, as shown, indicating that the orbit radii of the satellites follow an exponential relationship reasonably accurately.

Consider now the satellites of Jupiter in similar manner. The four points corresponding to the satellites discovered by Galileo are effectively colinear (Fig. 2). The seven satellites exterior to these are very much smaller in size and fall into two asteroid-like groups at around 12 million and 23 million km orbit radius, respectively. These two groups then fit well the projected line through the Galilean satellites provided three positions (at about 3·1, 4·8 and 7·7 million km) are regarded as vacant. Similarly, the innermost satellite of Jupiter can be accommo-

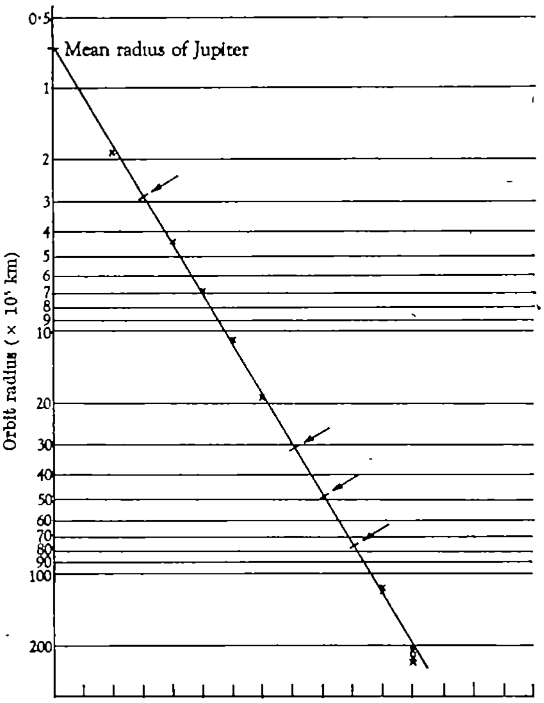

Fig. 2. Satellites of Jupiter. ×, Known satellite; arrow indicates vacant position

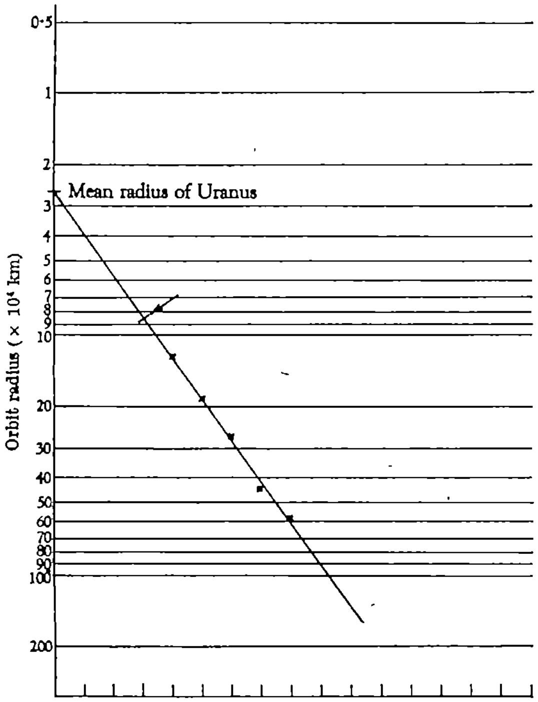

Fig. 1. Satellites of Uranus. ×, Known satellite, arrow indicates vacant position

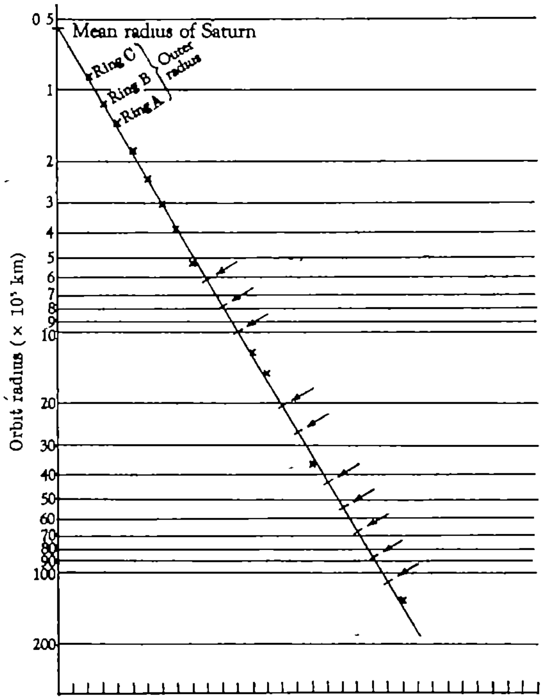

Fig. 3. Satellites of Saturn. ×, Known satellite; arrow indicates vacant position

dated provided a vacant position at 0·29 million km is allowable.

Fig. 3 shows a possible way of accommodating the satellites of Saturn according to the exponential law. It is seen that the exponential relationship is obeyed quite well by the five innermost satellites—by the innermost four in particular. As these satellites are, relatively speaking, closer together the number of vacant positions is more open to conjecture, but would seem to be larger than in the case of Jupiter; 10 vacant positions are shown in Fig. 3. It might be noted that the outer radii of Saturn's three rings lie close to vacant positions within the Roche limit while the problematical 10th satellite of Saturn, Themis, announced by Pickering in 1904 and the existence of which is now usually rejected, does not correspond to one of the vacant positions.

Possible further evidence for an exponential relationship between the orbit radii is the fact that from Mars to Uranus inclusive (including the mean asteroid) the orbit radii of the planets accurately follow such a relationship, with no vacant positions.

It is now suggested that some, in any event, of the vacant positions noted in the cases of the satellite orbits are filled either by one satellite or by asteroid-like groups of satellites. In the cases of both Jupiter and Saturn there are no vacant positions between the innermost known satellite and the Roche limit, whereas there is one such position in the case of Uranus—at about 85,000 km orbit radius. In the absence of any limit to the maximum possible orbit radius for a satellite with respect to a given central body one might also speculate on the possibility of the occupation of apparently vacant positions exterior to the outermost known satellites. Indeed, in the case of Mars this would seem to be the only possibility for the existence of additional satellites—the first available exterior position occurring at about 63,000 km orbit radius.

ASTROPHYSICS

A New Estimate of the Strength of the Magnetic Field of the Planet Venus

IN some earlier publications[1], attention was directed to the behaviour of the geomagnetic activity around the dates of lower conjunction of Venus. It appeared that, especially at times of weak solar activity and with conjunctions, where Venus passed the Sun at a small angular distance, seen from the Earth, a screening effect of Venus on the solar corpuscula was found from 6 days before up to 1 day after the date of conjunction. An estimate of the strength of the magnetic field of Venus met with difficulties.

Since 1956 the effect has been further and more quantitatively examined by us, the results of which will shortly be published in more detail. First it was found that the screening effect can be considered as statistically significant. Secondly, the relation between the amount of screening and the geocentric latitude of Venus β(♀) was investigated. The result is given in Fig. 1, in which the geomagnetic activity during the period of 6 days before up to 1 day after conjunction with respect to the mean activity over a longer period has been plotted against the angle β(♀). In this graph all lower conjunctions of Venus, since 1890, have been included which occurred in a period where the yearly sunspot-relative-number (Wolff number) was smaller than 50. The difference in position of the points at β(♀) < 4·5° and β(♀) > 4·5° is striking. At the small angles all conjunctions show a decrease of the geomagnetic activity, whereas at the bigger angles deficiencies and surpluses show up equally; the change at β(♀) = 4·5° is rather sharp. This effect seems to indicate that also in a direction perpendicular to the orbit of Venus, an estimate of the extent of the screening can be made.

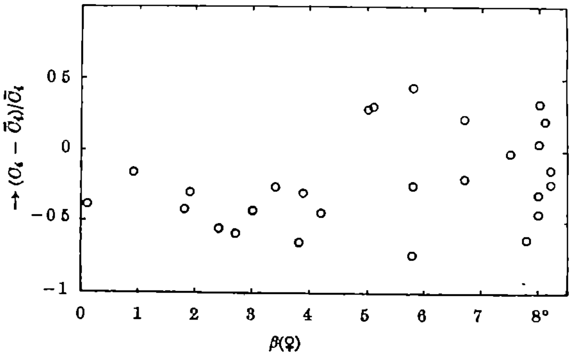

Fig. 1. Geomagnetic activity in the period of 8 days around conjunction date for 27 inferior conjunctions of Venus, plotted against geocentric latitude of Venus at the moment of conjunction

The period of 8 days in the direction of the orbit gives an extensiveness of the perturbing part of the Venus orbit, which is seen from the Earth under an angle of 8 × 0·63° = 5°. In a direction perpendicular to the orbit one finds from Fig. 1 an angle of 9°. A larger extension of the screening in this direction has to be expected, if the magnetic axis of Venus is more or less perpendicular to the orbital plane (for a dipole the difference amounts to a factor 1·26 = $\sqrt[3]{2}$).

For a calculation of the strength of the magnetic field of Venus from the distance over which the screening is active, a knowledge of the nature and velocity of the corpuscular stream seems necessary. Assuming that the screening action is equal to that on free protons, which are ejected from the Sun with a speed of 500 km/sec, it has previously[1] been calculated that the magnetic field of Venus is about 5 times as strong as that of the Earth. In case the corpuscula come from the Sun in electrically neutral clouds (which seems much more plausible and which would result, as was already remarked, in a much larger strength of the magnetic field of Venus) computational difficulties prevented a calculation at the time.

It may be said, however, that the screening of Venus will extend to where the dipole field of Venus has the same strength as the interplanetary magnetic field, of which we now know, thanks to space research, that in the neighbourhood of the Earth it has a value of 1–10 × 10^{-5} oersted[2,3].

If we assume a value of 3 × 10^{-5} oersted for the strength of this field in the neighbourhood of Venus, this would then be also the strength of the dipole field of Venus, in the direction of the poles at a distance of

$$\frac{7\cdot5^{\circ}\ \text{(average of polar dimension of screening)}}{1'\ \text{(geoc. diam. of Venus)}} = 450\ \text{Venus radii} = 2\cdot5\ \text{million km}$$

With a space probe a well-measurable field strength could be shown, therefore, to be present at a distance of 1 million km from Venus.

It follows that for the magnetic field strength at the surface of Venus near the poles we might expect a value of $450^3 \times 3 \times 10^{-5}$ oersted = 3×10^3 oersted; this is 5,000 times that of the geomagnetic field.

Errors in the Measurement of the Temperature of the Moon

Measurement of the temperature of the Moon is generally done by absolute radiometry assuming the emissivity of the lunar surface to be independent of wave-length and to be that of a 'black-body', namely, ε = 1·00, and calculating the temperature from Stefan's law[1]. This 'black-body' assumption is based on the 1930 interpretations of Pettit and Nicholson[2] of radiometric data they obtained with crude filter monochromators. The basis of these deductions was that the ratio of the radiant energy between 8–10μ to the radiant energy between 8–14μ observed was nearly identical to the ratio calculated for a 'black-body' at 400° K. The temperature of the sub-solar point (400° K) was calculated in the usual manner (assuming the emissivity to be unity) after relating all the measurements to the radiometric magnitude of a comparison star. From these paradoxical assumptions they concluded that the emissivity of the lunar surface in the region 8–10μ is unity and is unaffected by the restrahlen of any silica content it may have; this is contrary to observations made on the emissivity of silica or silicates[3,4]. In order to reconcile this dissimilarity with their original conclusion Pettit and Nicholson decided the lunar crust was finely divided, like sand, or porous, like pumice, and that its radiating properties would therefore be nearly those of a 'black-body'.

Considering the technology and knowledge of the Moon and Earth's atmosphere in 1930 Pettit and Nicholson's work was truly classic. However, in the past few years, with refined instrumentation, the radiative and transmissive characteristics of the Earth's atmosphere have been clearly defined and reveal that there is sufficient ozone in the atmosphere to absorb 25 per cent of the radiant energy in the 8–10μ region[5]. The fact that Pettit and Nicholson did not observe ozone in the atmosphere makes us sceptical of the validity of their work. Even if they had had modern instrumentation and observed this phenomenon, they would not have been able to come to any conclusions concerning the nature of the lunar crust from these measurements because the low emissivity from silicates occurs in a wave-length range in which all Earth-bound instruments are not responsive because of total absorption by ozone. Needless to say, significant temperature measurements and compositional assignments of the lunar crust can be made only from above the Earth's atmosphere; from high-altitude balloon investigations, or better yet from an orbiting lunar vehicle.

To aid in interpretation of results to be obtained above the Earth's atmosphere, we have investigated the effect of composition on the emissivity of several smooth surfaces as a function of wave-length and have calculated the emittance, $\mathfrak{R}(\lambda, T)$, at several temperatures. For these calculations:

$$\mathfrak{R}(\lambda, T) = \epsilon(\lambda) W(\lambda, T)$$

where $\epsilon(\lambda)$ is the emissivity of the surface which is dependent on wave-length, and $W(\lambda, T)$ is the energy of a black-body at wave-length, λ, and temperature, T. The $\epsilon(\lambda)$ curve was obtained indirectly from reflectance measurements on polished, opaque specimens. In this manner $\epsilon(\lambda)$ was calculated readily without having to make absolute radiometric measurements; the polished and opaque requirements negate diffusely reflected (scattered) radiation and make the transmittance negligible, respectively, hence:

$$\rho(\lambda) + \alpha(\lambda) = 1$$

where $\rho(\lambda)$ is the reflectivity and $\alpha(\lambda)$ is the absorp-

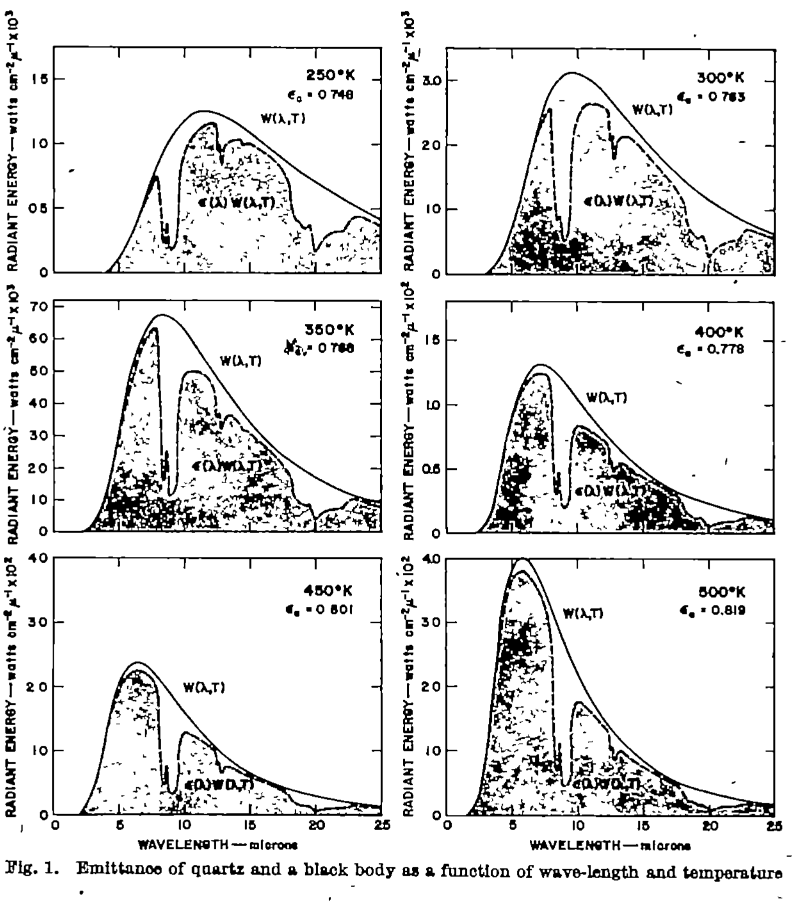

Fig. 1. Emittance of quartz and a black body as a function of wave-length and temperature

tivity. At thermal equilibrium, the absorptivity equals the emissivity, hence:

$$\varepsilon(\lambda) = 1 - \rho(\lambda)$$

Comparisons of $\Re(\lambda, T)$ curves of quartz with the corresponding $W(\lambda, T)$ curves at six temperatures are shown in Fig. 1. These curves dramatically demonstrate why the wave-length of maximum energy, λ_m, cannot be used to evaluate the temperature from the Wien law:

$$\lambda_m T = 0{\cdot}2896 \text{ cm } ^\circ \text{ K},$$

for at 300° K an error of about − 45° K would result.

Temperature determination by absolute radiometric measurements will also be in error when the emissivity is a function of wave-length. A prerequisite for the applicability of this method is that the average emissivity, ε_a, is independent of temperature; however, because of its dependence on wave-length, it is also a function of temperature.

The average emissivity, ε_a, over the wave-length interval 2–25μ is defined as:

$$\varepsilon_a = \frac{\int_2^{25} \varepsilon(\lambda)\, W(\lambda, T)\mathrm{d}\lambda}{\int_2^{25} W(\lambda, T)\mathrm{d}\lambda}$$

for any temperature, T.

It can be shown that the dependence of ε_a on temperature is a second order effect, hence measuring temperature changes of the same material by radiometric methods is valid. On the other hand, absolute values of the temperature can be significantly in error.

Because of the predominance of the strong Si–O vibrational bands near 9–10μ for most minerals, it is reasonable to conclude that a situation similar to that presented for quartz would exist for lunar surfaces. Table 1 lists ε_a for typical proposed lunar materials—granite, obsidian, dunite, and chondritic meteorite—at 350° K. Details of these measurements will be published elsewhere[6]. A variation in ε_a of about 10 per cent is obtained between granite and dunite, which would correspond to an error of about 9° K at 350° K when the temperature was calculated by use of Stefan's law. Hence, the lunar temperature changes reported by Shorthill and Saari[7] could instead be caused entirely, or in part, by compositional changes.

Table 1. AVERAGE EMISSIVITY OF TYPICAL LUNAR MATERIALS AT 350° K

Material	ε_a
Granite	0·86
Obsidian	0·83
Meteorite 'Haven' (19-13) chondrite	0·81
Dunite	0·78

If the surface of the Moon is finely divided or porous, the deviation of the emissivity curve from ideality may not be as dramatic as that obtained from our reflectance measurements on polished surfaces. On the other hand, Bell has obtained such deviations from absolute radiometric measurements of gypsum sand at White Sands, New Mexico[8], and quartz in the beach sands at Cocoa Beach, Florida[9]. Because the exact nature of the surface of the Moon is uncertain and may indeed be a slag-type material, the proposed application of lunar infra-red radiation spectrometry for compositional identification and precision temperature estimation cannot be ruled out at this time.

We are at present conducting investigations along these lines to further establish the validity of approach.

RADIOPHYSICS

Apparent Relation between Solar Activity and the 440-Mc/s Radar Distance of Venus

A CURIOUS correlation (Fig. 1) has been found between the systematic variations in the astronomical unit, as derived from radar observations of Venus at 440 Mc/s (68 cm)[1], and the solar 20-cm flux as measured at the Heinrich Hertz Institut in Berlin-Adlershof[2]. The 20-cm flux is known to be a good indicator of solar activity, and there is evidence that solar decimetre radiation (slowly varying component) is related to both the solar extreme ultra-violet flux and the solar wind intensity[3,4].

From a first glance at Fig. 1 one would suppose that the systematic variations in the radar data are due to changes in the group velocity or ray path curvature of the radar signals caused by variations in the solar wind electron density between Venus and the Earth. But the correlation is in antiphase and therefore cannot offer an immediate explanation for the observed

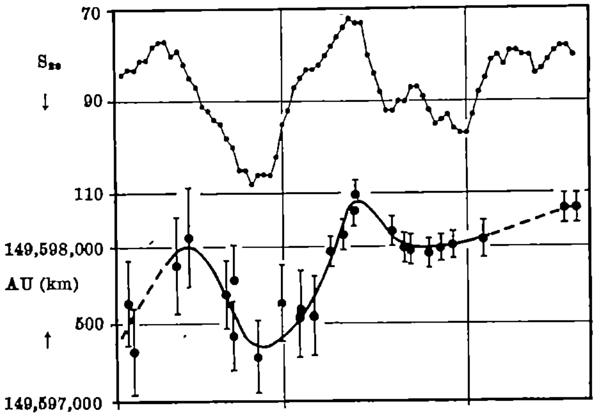

Fig. 1. Astronomical unit (AU) as derived from Venus radar measurements at 440 Mc/s reduced with Duncombe's orbit (lower part of the figure) and solar 20-cm flux (upper part) in units of $10^{-22} \frac{\text{W}}{\text{m}^2\text{c/s}}$. In order to demonstrate the inverse relation between both quantities the ordinate scale of the 20-cm flux has been drawn increasing downwards

variations in the radar distance of Venus. Furthermore, the interplanetary electron density required for this explanation is, however, of the order of 5×10^4 cm^{-3}, with variation of up to 2×10^4 cm^{-3}. These figures are unacceptably high[5,6].

A possible explanation for the correlation might be that Venus has an ionosphere with electron densities of the order of 10^9 cm^{-3}. If so, the 440 Mc/s radar signal would be reflected from this ionosphere. Then the correlation in Fig. 1 would be explained by a further assumption that the height of the Venus ionosphere changes with solar activity in a manner similar to that found for the terrestrial upper atmosphere. The scale must be somewhat larger, however, with maximum height variations of about 100 km. This figure is derived from the maximum amplitude of 600 km in Fig. 1, divided by 2, accounting for the reflexion of the signal, and reduced by a factor of 0·35, the ratio of the mean distance of Venus during the measurements to the astronomical unit.

An electron density of 10^9 cm^{-3} would imply difficulties in understanding the rather high intensity of the reflected radar signal observed at 2388 Mc/s (12·5 cm)[7,8]. Assuming an equivalent thickness of 30 km for a peak electron density of 10^9 cm^{-3} the ionosphere would have an optical thickness τ of the order of 1 at this frequency. Therefore at 12·5-cm wavelength we would have to account for an attenuation factor of $e^{-2\tau} \approx 0{\cdot}14$ in the signal reflected from the surface of Venus.

This difficulty could be removed by assuming inhomogeneities in the ionosphere, where the required peak electron density of the order of 10^9 cm^{-3} occurs only in regions small compared with the entire surface. In this case the 12·5-cm radar signal will pass the ionosphere with an appreciably smaller attenuation, whereas the 68-cm signal would be reflected from the dense regions.

The difference of 650 km between the mean value of the astronomical unit obtained by the Jet Propulsion Laboratory group at 12·5 cm : 149,598,500 ± 500 km, and the value obtained by the Massachusetts Institute of Technology group at 68 cm : 149,597,850 ± 400 km, is compatible with the assumption that the latter wave-length is reflected from an ionosphere in an altitude of about 200 km above the surface of Venus. The above difference and its entire range of uncertainty yield a value of 110 ± 150 km.

In our calculations we used the following crude model of an ionosphere: a layer with an electron density of 5×10^8 cm^{-3} containing 'clouds' with electron densities of 2×10^9 cm^{-3} which cover one quarter of the surface. The temperature was assumed to be 800° K and the equivalent thickness 5×10^6 cm, yielding an attenuation factor of 0·25 for the radar signal at 12·5-cm wave-length.

The model is in satisfactory agreement with the observed radio spectrum of Venus in the wave-length-range 0·4–21 cm (refs. 9–11), since it yields the following brightness temperatures: 470°, 590° and 730° K at 3·3-, 10- and 20-cm wave-length, respectively, if we take additionally to the model already mentioned a surface temperature of Venus of 400° K (ref. 12).

A second, but remote, possibility would be that the correlation is completely fortuitous and that the variations in the derived values for the astronomical unit are due to remaining cosine terms in Duncombe's orbit calculation, causing a spurious 30-day period; but it seems unlikely that the errors in the periodic terms can be responsible alone for the observed residuals (R. L. Duncombe, private communication).

The striking correlation between the variations in the observed value of the astronomical unit and the solar 20-cm flux urgently needs proof or disproof by further measurements, especially at 440 Mc/s, before any definite conclusion can be made.

We thank Drs. Albert Arking and Alan T. Moffet for helpful discussions. We also thank Drs. R. L. Duncombe and J. V. Evans for their communications.

METEOROLOGY

A Cyclic Change in Possibilities of Precipitation at the Plateau Rosa Meteorological Station, and the Subjacent Valtournanche Valley

One of us has recently shown[1] that although necessary temperature conditions for a transition of phase from liquid water to ice often existed in southern, cloud-bearing air masses at the Plateau Rosa in the Italian Alps, the actual periods of precipitation did not appear to follow such conditions in a concomitant manner, if considered on an annual basis. This was further substantiated by extending the analysis from the original period of 5 years to the interval covering 1952–61 inclusive[2].

Data on annual volumes of precipitation, collected during the years 1926–43 inclusive, at about 765 rain-gauge stations distributed throughout Italy south of Rome, as well as in Sardinia and Sicily, appear, on the other hand, to indicate the existence of a phenomenon cyclic with time which governs the precipitation there. Anomalies of precipitation which were computed individually for 5 different categories of station altitudes (ranging between 0 and 1,200 m in elevation) are consistently indicative of a periodic phenomenon which lags about 1–3 years behind the sunspot cycle, as monitored by the average annual Zurich sunspot numbers[3].

Since it was pointed out recently[4] that short-wave radiation may have bearing on the activation towards nucleation of water of some components of atmospheric aerosol, the possibility of correlating the 'alpine supersaturation' data quoted here with the sunspot cycle appeared to be of immediate interest. Data on total possible percentage 'precipitation increments' associated with the southern air-flow

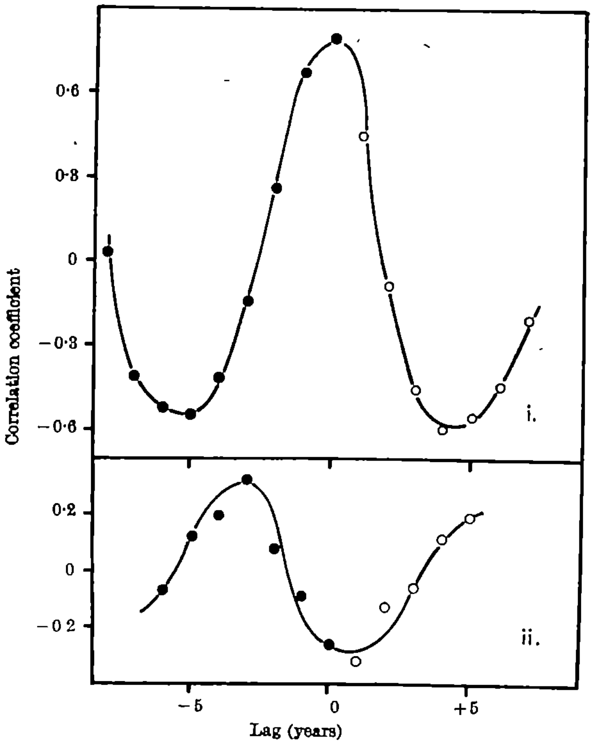

Fig. 1. Plot of linear correlation coefficients between: (i) relative percentage of possible precipitation (h); (ii) precipitation occurred (h); and the relative Zurich annual average sunspot number, against the phase, in years, by which the sunspot numbers used were shifted with respect to the year of computation. Open circles stand for interpolated Zurich numbers

were taken from refs. 1 and 2 while data on Zürich annual sunspot numbers until 1961 inclusive were obtained from pertinent Zurich publications[5]. Tentative Wolf numbers for the years 1962–68 were calculated assuming approximate minimum and maximum values of solar activity for the years 1964 and 1968 respectively, and interpolating the data in proportion and on the basis of the 2 previous cycles. Table 1 illustrates the data tentatively used for this period of time, while Table 2 gives data both on effective precipitation and the 'total probable precipitation increments' in the Plateau Rosa zone.

Linear correlation coefficients between 'possible relative percentage increments of precipitation' and the Zurich sunspot values were computed following the well-known technique of phase lagging. Results obtained on the basis of this calculation are shown in Fig. 1. A pronounced cyclic pattern of precipitation possibilities can be seen, while actual precipitation values seem to follow an opposite trend, with indications of a maximum at about 3 years behind the maximum of sunspots, and in line with more extensive data previously obtained[3]. Since the curve dealing with situations favourable towards precipitation appears to indicate reasonably encouraging consistency, especially as compared with the actual precipitation diagram, it is thought that the technique used may be profitably applied, wherever necessary data are available, to gain better understanding of natural precipitation phenomena in zones of interest for this type of study, and to indicate suitable timings of artificial cloud-nucleation.

PHYSICS

Pre-freezing Effects in Ionic Aqueous Solutions

VARIOUS workers have reported that for some liquids the dependence on temperature of certain physical properties have special features in the neighbourhood of the normal melting points. We have begun an investigation of phenomena of this type, which are potentially important for the molecular physics of liquids, and in exploratory work have found a somewhat similar effect in the electrical conductivity of an ionic aqueous solution.

Some authors, working with pure compounds, have reported instances in which a plot of the logarithm of the viscosity against the reciprocal absolute temperature appears to take the form of two straight lines which intersect at the normal melting point. Analogous effects have been reported for the dielectric constant and ultrasonic velocity of some organic liquids and the electrical conductivity of some non-aqueous liquids. Greenwood and Martin[1] reviewed this work and directed attention to some unsuspected further cases in published data. More recently, Urazovskii and Chernyavskii[2] have reported similar effects at the melting points of metastable crystal forms of the solid as well as the normal melting point. The results of Parthasarathy and Bindal[3], which show discontinuous ultrasonic velocity values at the melting point, require confirmation. Some of the foregoing results are marginally significant, and could be just as well represented by smooth curves as by curves with a discontinuity in the slope.

On the other hand, Hunter[4,5], working with three organic liquids for which discontinuities of slope in the logarithmic-viscosity and dielectric constant curves had already been reported, found that ultrasonic absorption increased rapidly but smoothly as the melting point was approached from above. McLaughlin and Ubbelohde[6,7] found analogous smooth effects in the viscosities of an organic substance and

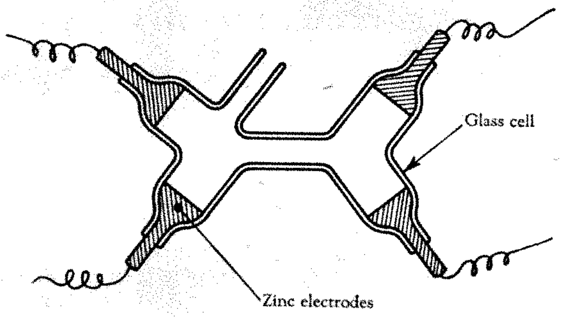

Fig. 1

two metals. They assumed clustering was involved and made deductions about the amount of clustering, using the theory of the viscosity of suspensions.

The reports of discontinuities in slope are remarkable, for they suggest a change in the structure of the liquid occurring or beginning abruptly at the melting point, even though this point is defined by equality of the thermodynamic potentials of the liquid and normal solid phases, and so depends on the structure of both. On the other hand, the rapidly increasing, smooth deviations of the second group of results have the general character of 'pre-transition' effects[8].

The true forms of the temperature plots in the neighbourhood of the melting point must be regarded as rather uncertain at present, especially for liquids for which discontinuities of slope have been claimed. A need exists for measurements of higher accuracy on highly pure liquids, of which the most amenable to preparation with high purity include water and dilute aqueous solutions.

We have obtained accurate exploratory data for the ionic conductivity of dilute aqueous solutions of potassium chloride using a four-terminal cell with platinum black electrodes, and of zinc chloride using both a similar cell and one with zinc electrodes. In one case the phenomenon observed was as follows.

A solution containing approximately 1 per cent by weight of the salt (anhydrous) was prepared from zinc of 99·99 per cent purity. Resistance measurements were made to an accuracy of 3 parts in 100,000 at a frequency of 170 c/s using the cell with four zinc electrodes (Fig. 1). A special double-bridge circuit was used. The temperature was held constant to ±0·001° C at each point, and measured by platinum resistance thermometry. Two sets of data are shown in Fig. 2, plotted as deviations from a relationship of the form:

$$\log_{10} R/R_0 = -A + B/(C+T)$$

where R/R_0 is the ratio of the resistance at T° C to the value at 0° C, and the values of B and C are approximately 144° and 104° C respectively. Fig. 2 shows a smooth deviation of approximately exponential form, rising to significance below the freezing point (−0·36° C). There is no suggestion of any sort of discontinuity.

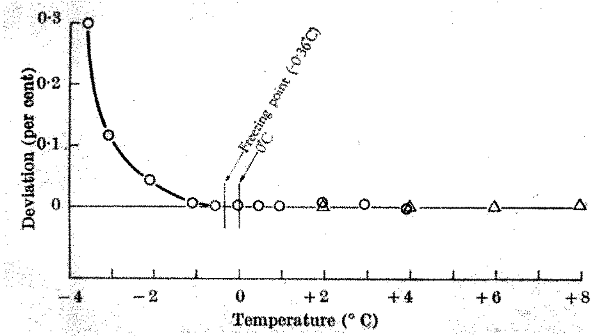

Fig. 2. Percentage deviation of the electrical conductivity of a 1 per cent aqueous solution of zinc chloride from an empirical equation relating conductivity and temperature

In our other experiments, including one made with zinc chloride solution under apparently identical conditions, no significant deviation from the above equation was found down to −3·5° C, the lowest temperature used. The root-mean-square deviations of the results from smooth curves approximate 4 parts in 100,000.

The close proximity of the phenomenon of Fig. 2 to the freezing point suggests that the normal-ice structure is involved. This view is reinforced by the results of Urazovskii and Chernyavskii showing effects corresponding to the melting points of metastable as well as stable solid forms. However, our experiments show no evidence that a change in the structure of the basic liquid develops below the normal freezing point. The phenomenon of Fig. 2 appears to be a manifestation of suspended heterogeneous phase nucleation.

As well as continuing these measurements we are obtaining accurate results for the viscosities of the solutions and for pure water.

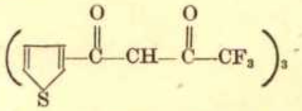
Fluorescent Properties of Rare Earth Chelates in Vinylic Hosts

Both single crystals and glasses[1] have been successfully used as hosts for rare earth laser materials. We wish to report the observation of sharp line fluorescence of f^n orbital transitions resulting from rare earth chelates dissolved in organic vinylic monomers which were polymerized to solid solutions. These materials are more easily and accurately doped than either glasses or single crystals. The simplicity of preparation and workability of these materials make them particularly attractive for possible laser applications. The observed sharp fluorescent lines may be attributed to uniform distribution and equivalent surroundings of the rare earth ion as found in single crystals.

A large number of organic chelates, co-ordinative compounds and organic salts of the rare earth elements such as neodymium, samarium, gadolinium, dysprosium and holmium have been synthesized. Four β-diketone chelates of 1,1,1-trifluoroacetylacetone; 1,3-diphenyl-1,3 propanedione; 1-phenyl-1,3-butanedione and 4,4,4-trifluoro-1,2-thienyl-1,3 butanedione have been selected out of many other chelates investigated because they satisfy the solubility requirement in monomers and polymers, and in addition exhibit good optical properties and stability. They were prepared from the hydroxides or chlorides of the rare earths and the chelating agent in boiling toluene or xylene. Monomers and comonomers such as methyl methacrylate, styrene and acrylonitrile giving macromolecular materials with known optical transparency have been used. Polymerization with peroxides as catalysts and/or thermal or ultra-violet radiation has been accomplished at normal or high pressures, under inert atmosphere. The method is general and offers a reliable procedure to obtain clear, solid solutions of individually isolated atoms of rare earths, of controllable concentrations.

Rare earth salts or chelates have also been dissolved in vinylpyridine type monomers or co-monomers with styrene and methyl methacrylate, followed by polymerization in absence of oxygen. Other olefinic monomers capable of forming co-ordinative bonds with transition elements are now being investigated in order to test the feasibility of bonding the metal atom directly to the polymeric chain.

In the case of



samarium in polymethyl methacrylate, fluorescent lines were found at 645 mμ, 598 mμ, and 562 mμ at both 300° K and 77° K with excitation into a broad absorption band centred at approximately 360 mμ. These results are in good agreement with those calculated by Wybourne[2] and observed by others[3,4]. The fluorescent lines are respectively attributable to the $A \rightarrow Z$, $A \rightarrow Y$, and $A \rightarrow X$ transitions as designated by Magno[3] and suggested by Crosswhite[5] for anhydrous samarium chloride-doped lanthanum chloride. They also coincide to within 50 Å of those observed by Adams and Millichamp[6], who investigated the electro-fluorescence of samarium-doped α-aluminium-oxide. However, they attributed the spectra to the presence of divalent samarium ion rather than the trivalent ion. The three lines exhibited widths of approximately 15 Å at 300° K for concentrations of 0·02 g/cm^3 samarium chelate in methyl methacrylate. Temperature-dependent line-widths are being investigated.

Broad band luminescence centred at 5200 Å from all the β-diketone chelates in polymethylmethacrylate was excited at an absorption band centred at 4100 Å. This luminescence is attributed to the resonating chelated rings.

Thorough spectroscopic analyses of various rare earth chelate combinations in plastic hosts are being made at liquid helium temperatures.

CRYSTALLOGRAPHY

Structure of Graphitic Oxide

GRAPHITIC oxide is the pale, non-conducting product formed in treating graphite in suspension with strong oxidizing reagents. The composition is not well defined but is usually given as approximately $C_4O(OH)$ for the most highly oxidized form. The structural information which can be obtained by X-ray methods is limited because the structure is heavily disordered. One strong ring in X-ray patterns indicates an inter-layer *c*-spacing of about 6·2 Å for the dehydrated compound. Two or three weak *hk* bands may be interpreted to indicate a hexagonal structure of the layers with a spacing of 2·45 Å. This and some chemical evidence have suggested that the layers are made up of puckered graphite-like sheets. The various proposals which have been made concerning the bonding of oxygen and OH groups are summarized in recent reviews by Hennig[1] and Croft[2].

The only prospect for obtaining further structural information appears to be offered by electron diffraction techniques; in particular, the electron microprobe diffraction techniques developed in this laboratory and successfully applied to several substances of comparable disorder[3-5]. By this means we obtained single crystal patterns, such as shown in Fig. 1, from small flat platelets of graphitic oxide (diameter 1μ: thickness < 50 Å). This indicates a hexagonal layer structure with spacing ($a_0 = 2{\cdot}43$ Å) and intensities not very different from those of graphite ($a_0 = 2{\cdot}455$ Å). Single-crystal and ring patterns from tilted specimens show that no appreciable ordering exists in the stacking of the layers.

The intensities of the spot patterns and of ring patterns were measured photographically and by the electronic method of Goodman[6]. The structure was investigated by Fourier methods. Fig. 2 is a difference Fourier map of the projected layer structure obtained after subtraction of carbon atoms, at the points indicated, in a hexagonal net. Since the absence of any indication of a superlattice implies

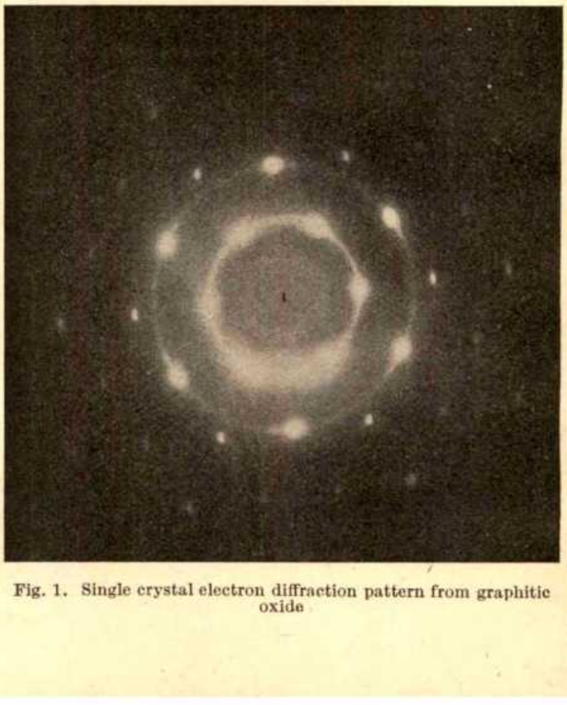

Fig. 1. Single crystal electron diffraction pattern from graphitic oxide

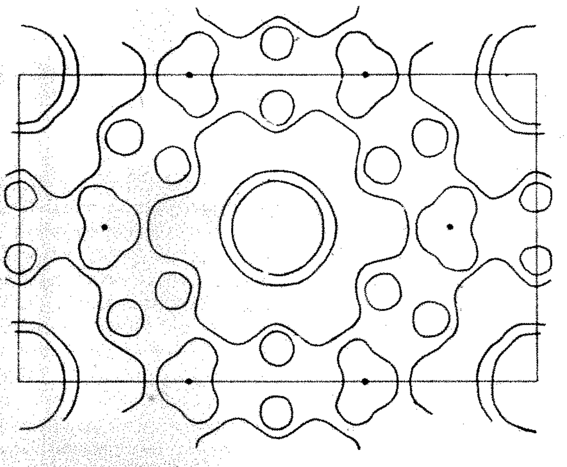

Fig. 2. Difference Fourier map of graphitic oxide layer structure after subtraction of carbon atoms at the points indicated by dots

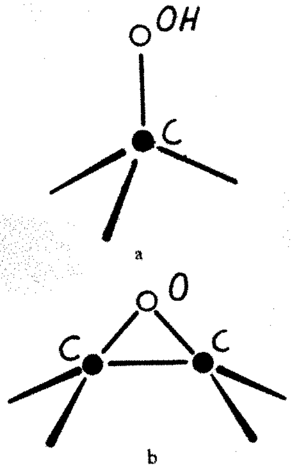

Fig. 3 *a* and *b*. The types of oxygen-bonding deduced from Fig. 2

that the oxygen positions show no long-range ordering, this map indicates the averaged distribution of oxygen atoms in the unit cells. It is seen that, in the projection, the oxygen peaks lie almost at the carbon positions or else half-way between adjacent carbon positions. It is implied that the oxygen atoms are present either as OH groups attached to single carbon atoms with the C–OH bond almost perpendicular to the plane of the layer, as in Fig. 3*a*, or else as oxygen atoms forming a bridge between adjacent carbon atoms, as in Fig. 3*b*.

Fig. 3*a* and 3*b* represent ideal symmetrical cases in which all bonds in equivalent positions relative to the oxygen atom make the same angle with the plane of the layer. This will not necessarily apply in practice because of the lack of order in the layer structure. As a result the C–O bonds will often be tilted relative to these ideal configurations, and the oxygen peaks will be spread out, as observed.

Weak broad maxima occur in Fig. 2 at positions near the centre of the carbon hexagon. These may represent some slight tendency for ordering between adjacent layers, or they may indicate the positions of occasional absorbed water molecules.

The absence of any peak in Fig. 2 on the lines joining alternate carbon atoms suggests that no appreciable fraction of the oxygen atoms is involved in ether linkages between carbon atoms in meta positions, as in the structures proposed by Ruess[7] or by Hofmann *et al.*[8]. The epoxy linkage between adjacent carbon atoms suggested in Fig. 3*b* is not ruled out by chemical evidence and does seem to be favoured by the results of infra-red spectroscopic studies[1,2], although the interpretation of these results is uncertain.

A similar electron diffraction study has been made in methylated graphitic oxide. The single-crystal and ring patterns were almost identical with those of graphitic oxide, the only difference being a weakening of the innermost ring or set of spots. The corresponding difference made to Fig. 2 is a considerable increase in the strength of the peak at the centre or the hexagonal carbon array. This suggests that when a C–OH linkage is replaced by a C–O–CH_3 side-chain, the CH_3 group tends to take up a position above or below the centre of the carbon ring.

Diamond Replication of Freezing Metal Structures

Manufactured diamond exhibits a wide variety of surface detail which permanently preserves an impression of the immediate environment during the last moments of diamond growth.

In particular, diamonds grown within a molten metal sheath, surrounded by graphite[1], show the freezing pattern of the metal on the diamond faces[2]. These patterns are particularly strong on the diamond cube faces. Fig. 1 illustrates the topography seen on the (100) faces of diamond grown within a nickel–iron alloy catalyst sheath. Examination of similar diamond surfaces in an interference microscope indicates that the main stems of the dendritic pattern are round-bottomed grooves about 1500 Å deep, while the side stems are less deep. The irregular lines separating the dendrites are about 1500 Å above the average surface.

It is suggested that this surface topography is formed as follows. When a diamond-growing experiment is terminated by switching off the heating power to the diamond-growing cell (press force remains unchanged), the metal catalyst sheath cools and eventually freezes. During the metal-freezing process, diamond growth continues in those areas where molten metal remains. The dendrite main stems freeze first, stopping growth locally and hence form the deepest grooves in the diamond surface. Diamond growth continues in other areas until stopped by the freezing of the dendrite side-stems and, finally, by the metal solidification in the dendrite boundaries. This mechanism is consistent with the observed surface contours.

The crystal axis orientation of the diamond determines the dendrite direction and, I presume, crystal orientation in the metal sheath. Dendrite orientation is parallel with the diamond crystallographic axes. In Fig. 1 the diamond crystal sides are at 45° to the long edges of the (100) face photographed. Inclusions in the diamond surface will interfere locally with the dendrite orientation.

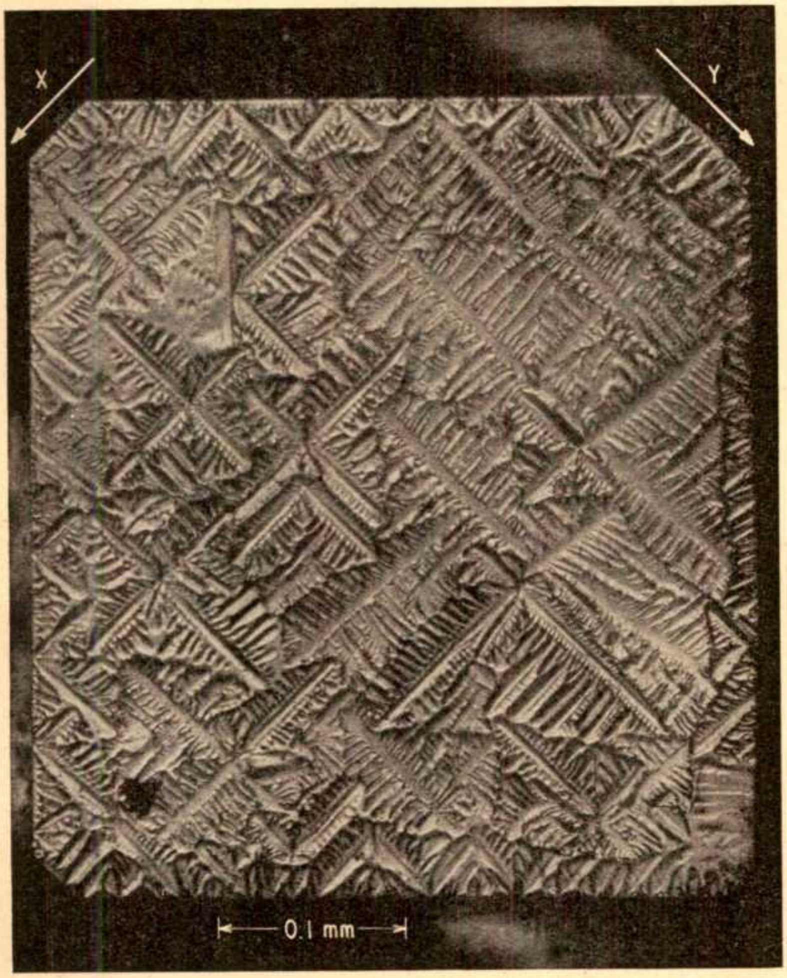

Fig. 1. Dendrite replication on diamond (100) face. Two cubic axes of the diamond are shown

The dendritic pattern is not intrinsic to diamond. When a diamond showing this pattern on a cube-face is etched in a mixture of hot sodium carbonate and nitrate, the surface dendrite pattern disappears. Square etch pits oriented parallel to or at 45° to the crystal axes are formed at the new surface.

The diamond shown was grown by K. A. Darrow of this Laboratory.

CHEMISTRY

Explosive Sensitivity of Cobalt Ammine Azides

THE correlation of the explosive sensitivity of simple metal azides with the metal's ionization potential has been related to the control of the azide's electrons by the metal and a consequent influence on the activation energy of the decomposition reaction[1]. Gray has stressed the importance of both kinetic and thermodynamic factors in the problem of sensitivity, and pointed out that, in addition to influencing the activation energy, the ionization potential is a major factor in determining the heat of formation of simple metal azides[2]. Thus a correlation with sensitivity may be predicted on both kinetic and thermodynamic grounds and no simple indication of the importance of electron control is possible.

Co-ordination compounds permit some insight into this problem. Very energetic compounds[3] exist with the azides bonded either directly to the metal, $Co(NH_3)_3(N_3)_3$, or isolated from it by the ligand sphere, $[Co(NH_3)_6](N_3)_3$. In the latter the metal cannot directly influence the azide ion's electrons. The azides are distinguishable, the co-ordinated azides having the asymmetric character of covalent azides (HN_3, CH_3N_3) while the ionic azides are symmetric as in simple metal azides[4,5].

Impact testing, despite well-recognized drawbacks, can indicate relative labilities. Our tests used a 2-kg falling hammer and 25 mg samples loosely coned on sand-paper. Crystalline samples (crystal sizes of about 0·1 mm) and powder (0·1–10μ) were prepared as previously reported[6,7]. The 50 per cent points (the drop height which on the basis of 20 tests produces ignition in 50 per cent of the samples) are reported for independent preparations.

The triammine, with only co-ordinated azides, is a very sensitive explosive as expected on both

Table 1. IMPACT SENSITIVITIES OF COBALT AMMINE AZIDES

Compound	50 per cent points (cm)	Character of ignition
$[Co(NH_3)_6](N_3)_3$	22 25 35 33*	Weak to moderate, 5–75 per cent of sample consumed in explosion
$[Co(NH_3)_5N_3](N_3)_2$	17 21 34 18*	Violent. 90–100 per cent complete
trans$[Co(NH_3)_4(N_3)_2]N_3$	13 22 41	Violent, complete
cis$[Co(NH_3)_4(N_3)_2]N_3$	7 43 55	Violent, complete
$Co(NH_3)_3(N_3)_3$	2·8* 3·2*	Violent, complete

* Powders.

thermodynamic grounds and arguments on the control of electrons. The tetraammines and pentaammine show a considerable range of 50 per cent points. It is suspected that the 7-cm *cis*-tetraammine preparation may have been sensitized by contamination with the triammine.) It is possibly of interest that these compounds are less sensitive than the triammine and comparable with the hexaammine despite the presence of co-ordinated azides.

The hexaammine with only ionic azides is particularly important. This compound does ignite at a low drop height, thus establishing that an azide may be quite sensitive even though the metal is isolated from the azide ion. Presumably, reaction begins in impact generated hotspots and by means of a high heat of reaction propagates to visible proportions in spite of an apparently unfavourable structure.

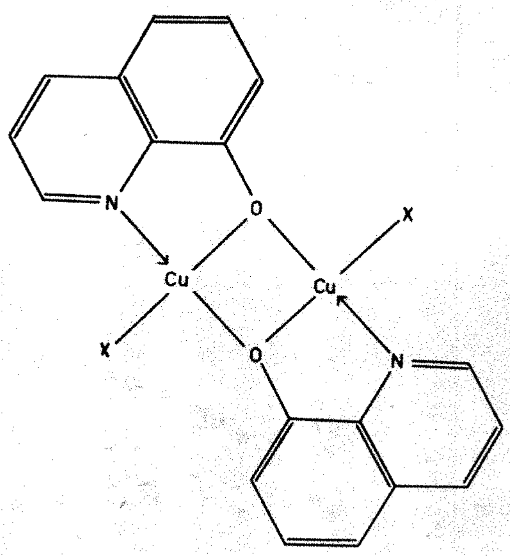
Anomalous Paramagnetism and Binuclear Structure of some Copper(II) Complexes of 8-Hydroxyquinoline

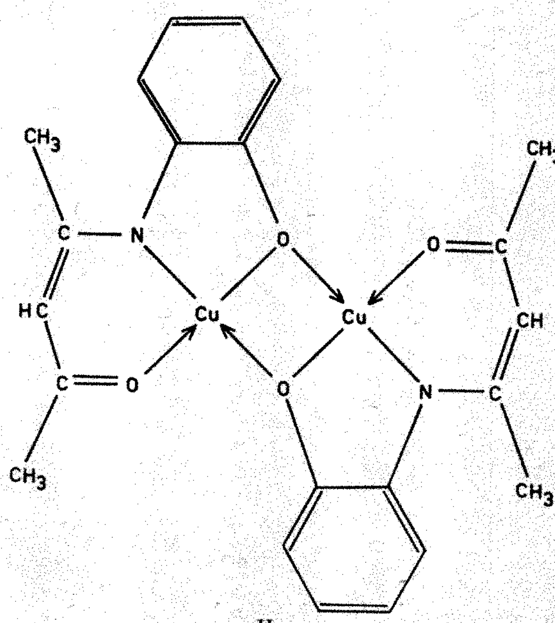
Fanning and Jonassen[1] reported that the reaction of copper(II) halide with 8-hydroxyquinoline in methanol or acetone yields compounds of the empirical formula $Cu(C_9H_6NO)X$ ($X = Cl, Br$) which possess magnetic moments in the range 1·0–1·1 Bohr magnetons at room temperature. They proposed an unusual tetrameric structure to explain the properties of these compounds and suggested that their anomalous paramagnetism and the presence of an absorption band at ~ 375 mμ in their reflectance spectra are indicative of 'δ bonds' between copper atoms.

We have synthesized the chloro-complex (found: C, 44·1; H, 2·5; N, 6·0; Cu, 25·9 per cent. Calc. for $C_9H_6ONCl\ Cu$: C, 44·4; H, 2·5; N, 5·8; Cu, 26·1 per cent) by reacting copper(II) chloride with *bis*-(8-hydroxyquinolinato)copper(II) in boiling ethanol and have confirmed its low magnetic moment (see table). The reaction of excess copper(II) nitrate with 8-hydroxyquinoline in warm 98 per cent ethanol has been found to produce the reddish-brown nitrato-complex $Cu(C_9H_6NO)NO_3.H_2O$ (found: C, 37·9; H, 3·0; N, 9·9; Cu, 21·9 per cent. $C_9H_8O_5N_2Cu$ requires C, 37·6; H, 2·8; N, 9·7; Cu, 22·1 per cent). This compound is a non-electrolyte in nitrobenzene solution and possesses a room temperature magnetic moment (see table) which is less than the 'spin-only' value for one unpaired electron.

The anomalously low paramagnetism of these complexes may be interpreted in terms of the binuclear oxygen-bridged structure I ($X = Cl, Br, NO_3$) in which electron-exchange demagnetization occurs between pairs of oxygen-bridged copper(II) atoms. This type of electron exchange occurs in the copper(II) complex of acetylacetone-mono-(*o*-hydroxyanil). This compound possesses the binuclear oxygen-bridged structure II and its magnetic properties are similar to those of binuclear copper(II) acetate[2].



I



II

Such a structure precludes the possibility of 'δ-bond' interactions between the pairs of copper atoms. Electron exchange demagnetization between pairs of oxygen-bridged copper(II) atoms has also been recently observed in the pyridine- and quinoline-N-oxide complexes $Cu(C_5H_5NO)X_2$ and $Cu(C_9H_6NO)X_2$ ($X = Cl, Br$)[3].

The postulate of a binuclear structure such as I for the complex of copper(II) nitrate with 8-hydroxyquinoline is supported by magnetic susceptibility measurements of the nitrato-complex over the temperature range of 95°–363° K. The μ–T and χ_M–T curves (Fig. 1) are in agreement with those calculated from Bleaney and Bowers's[4] expression:

$$\chi_M = \frac{g^2N\beta^2}{3kT}[1 + 1/3 \exp (J/kT)]^{-1} + N\alpha$$

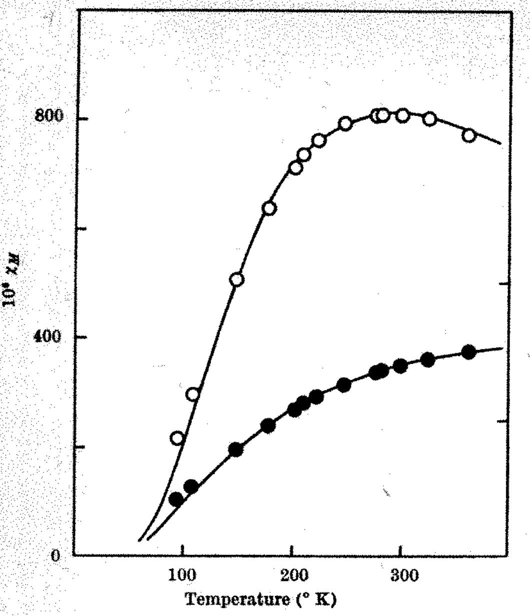


Fig. 1. ○, χ_M observed; ●, μ observed ; —, curves calculated from Bleaney and Bowers's expression:

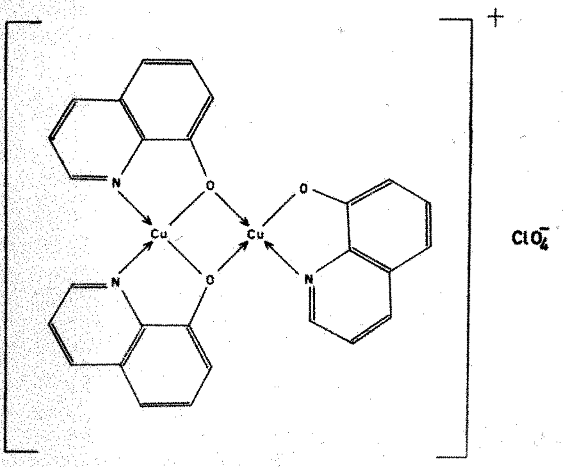
$$\chi_M = \frac{g^2 N\beta^2}{3kT}\,[1 + \tfrac{1}{3}\exp(J/kT)]^{-1} + N\alpha$$

and closely resemble those for copper(II) acetate[5] and compound II (ref. 2).

The presence of an absorption band at ~375 mμ together with its Z-axis polarization property has been associated with the binuclear copper(II) acetate type of structure[6]. However, the occurrence of a band at ~375 mμ in the above chloro- and bromo-complexes[1] is not diagnostic of the presence of either anomalous paramagnetism or a copper(II) acetate type of structure since it is known to occur in compounds such as *bis*(acetylacetonato)copper(II)[7] which are monomeric and possess normal magnetic moments.

The reaction of *bis*(8-hydroxyquinolinato)copper(II) with hexaquo-copper(II) perchlorate in ethanol gives brown crystals of the perchlorate $[Cu_2(C_9H_6NO)_3]$-$ClO_4.0{\cdot}5C_2H_5OH$ (found: C, 49·7 ; H, 3·3 ; N, 6·2 ; Cu, 18·5 per cent. $C_{27}H_{18}O_7N_3ClCu.0{\cdot}5C_2H_5OH$ requires C, 49·3 ; H, 3·1 ; N, 6·2 ; Cu, 18·6 per cent). This compound has a molecular conductivity of 24·2 mho in $3{\cdot}3 \times 10^{-4}$ M nitrobenzene solution and undoubtedly possesses the oxygen-bridged structure (III) in keeping with its low magnetic moment (see Table 1).

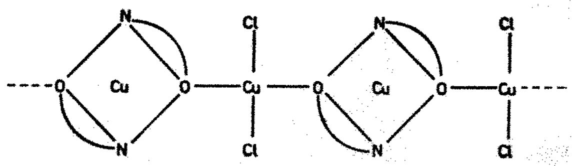


III

Table 1. MAGNETIC MOMENTS OF SOME 8-HYDROXYQUINOLINE (C_9H_6NOH) COMPLEXES OF BIVALENT COPPER

Compound	Temp. (°K)	Magnetic moment per Cu atom (in Bohr magnetons)
$Cu(C_9H_6NO)_2$	300	1·89
$Cu(C_9H_6NO)_2.2H_2O$	297	1·92
$Cu(C_9H_6NO)Cl$	293	1·14
$Cu(C_9H_6NO)NO_3.H_2O$	296	1·39
$[Cu_2(C_9H_6NO)_3]ClO_4$	295	1·60

The magnetic moment of the chloro-complex $Cu(C_9H_6NO)Cl$ was found to vary from 0·5 Bohr magnetons at 113° K to 1·4 Bohr magnetons at 372° K. However, it was not possible to fit its susceptibility curve to one calculated from Bleaney and Bowers's expression (see foregoing). It is possible that this compound possesses the polymeric structure IV rather than a dimeric one similar to I.



IV

Such a structure is compatible with the compound's preparation from *bis*(8-hydroxyquinolinato)copper(II) since in this compound the oxygen atoms would occupy trans-positions in a planar arrangement about the copper atom.

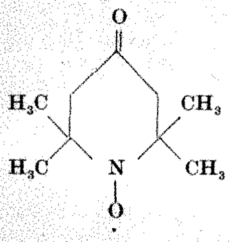
Free Radical Reactions involving no Unpaired Electrons

REACTIONS between free radicals and molecules have been extensively investigated. These involve numerous reactions of hydrogen abstraction and substitution with the contribution of unpaired electrons[1-3]:

$$A\cdot + BH = AH + B\cdot$$

In studying the effect of various factors on the stability and reactivity of free radicals, we first succeeded in observing a fundamentally new type of radical reactions with persisting free valence of the initial radical.

Investigations involved a very stable nitrogen oxide of triacetoneamine, the stability of which is accounted for by purely steric factors:



This stable free radical of tetravalent nitrogen may be readily obtained by careful oxidation of triacetoneamine with hydrogen peroxide in the presence of a tungsten, molybdenum or vanadium salt. By chromatographic separation of reaction products on aluminium oxide, we succeeded in obtaining an individual free radical of tetravalent nitrogen.

The triacetoamine-*N*-oxide is a crystalline paramagnetic substance melting at 36° C, soluble in water and ether to form red-coloured solutions.

Anal. calc. for $C_9H_{16}NO_2$: C, 63·49; H, 9·47, N, 8·23; spin/mole 6·2 × 10^{23}. Found: C, 63·53; H, 9·60; N, 8·25, spin/mole, 6·1 × 10^{23}.

The solid substance displays electron spin resonance singlet. On dissolving the substance in benzene it becomes a triplet with 13·3 gauss splitting and a *g*-factor of 2·0064 (Fig. 1). The triplet nature of the spectrum due to coupling of the unpaired electron magnetic moment with that of the nitrogen nucleus is evidence that considerable spin density is localized on nitrogen.

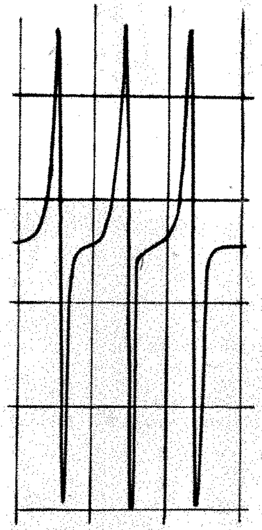


Fig. 1. Electron spin resonance spectrum of triacetone nitrogen oxide in benzene solution

On one hand, catalytic reduction of the radical in the presence of palladium on barium sulphate yields a diamagnetic hydroxylamine derivative identical to that obtained from phoron and hydroxylamine[4] (I).

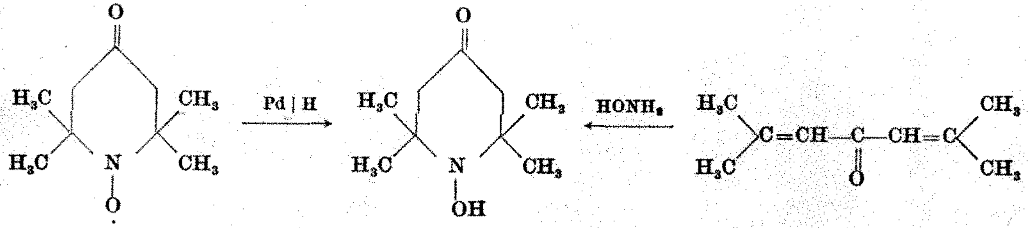
On the other hand, due to considerable steric hindrance close to the heteroatom carrying the free valence, this radical may enter into characteristic reactions with respect to the carbonyl group, without affecting the free valence. For example, the oxime radical (II) is formed by interaction between triacetoneamine-*N*-oxide and hydroxylamine.

On recrystallization from alcohol this oxime radical is in the form of well-defined rose-coloured crystals with a melting point of 155° C, readily soluble in water and yielding red-coloured solutions.

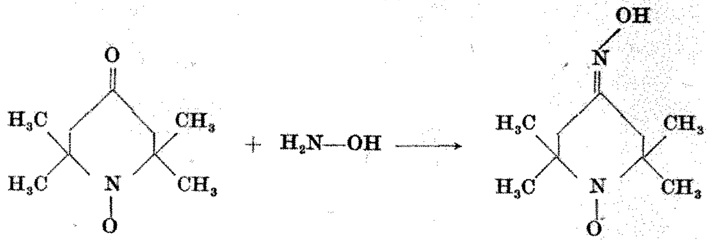
Anal. calc. for $C_9H_{17}N_2O_2$: C, 58·51; H, 9·25; N, 15·12; spin/mole, 6·2 × 10^{23}. Found: C, 58·45; H, 9·37; N, 15·25; spin/mole, 6·0 × 10^{23}.

The reactions of this radical with semicarbazide and 2·4-dinitrophenylhydrazine are similar. A yellow semicarbazone radical and an orange 2,4-dinitro-

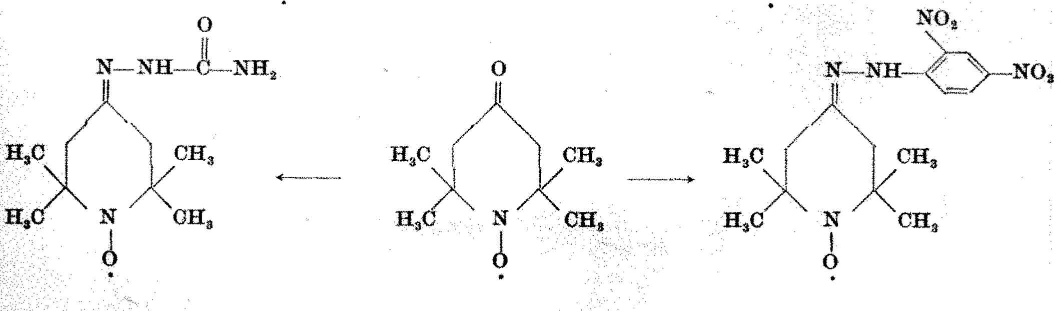
(I)



(II)



(III)



phenylhydrazone radical (III) are formed by these reactions.

On dissolving in benzene, electron spin resonance singlets displayed by solid radicals become triplets similar to that of the initial ketone radical.

Triboelectricity in Polymers

It must be emphasized that the reality of a triboelectric series implies a single determinant property acting at both donor and acceptor surfaces. An 'abundance effect'[1], if real, may be a cause of minor anomalies, but it cannot be dominant since metals, which may be inserted in the series, contain incomparably more conduction electrons than do insulators. The Frenkel mechanism[2] of thermal excitation alone is inadequate, since pyrolysis would occur, in the 100 μsec suggested by Frenkel, below 500° C, at which the population of conduction electrons might well be only 100 per c.c. Since it is known that calendering may reduce the molecular weight of polymers, I suggest that free radicals, produced by mechanical stress, form a source of relatively high-energy electrons, easily excited to the conduction-level. The much-discussed charge transfer by non-rubbing contact remains improbable except between distant members of the series.

My triboelectric series of well-defined polymers shows no correlation with dielectric constant, with dipole moment, nor indeed with the colour or intensity of ultra-violet-excited luminescence, which renders unlikely the proposed role of electron traps[3]. Members tend to be grouped by chemical nature, pointing to a determinant property linked to molecular constitution, perhaps more particularly to that of the surface[4]. The Fermi-level remains the most reasonable series-determining property[5].

Complexity of Hop Oil

Progress in instrumental methods of analysis during the past 10 years, particularly in the new field of gas chromatography, has provided the chemist with powerful tools for the separation and identification of complex mixtures. Nevertheless, it is often advantageous to fractionate the mixture prior to gas chromatography analysis in order to simplify the task of isolation and identification of single components. The oil of the hop (*Humulus lupulus* L. var. Bullion) isolated by the method of Wright and Connery[1] has been fractionated as follows: hydrocarbons were selectively separated from oxygenated compounds through alumina or silica-gel columns using light petroleum ether as eluant[2]. Esters and ketones were separated from alcohols by selective elution from a neutral alumina column using absolute ether as eluant. Esters were subjected to methanolysis using mineral acid as catalyst, and the resulting methyl esters separated from the freed alcohols, as described here. Compounds having a straight chain of seven carbons or more were separated from shorter or branched chain compounds by formation of crystalline adducts with urea in methanol[3]. Carbonyls were extracted from mixtures containing other oxygenated compounds by the Girard method[4,5]. Unsaturated compounds were separated from saturated compounds by bromination in carbon tetrachloride[6]. Unsaturated compounds having a conjugated double-bond system were separated from others by the Diels–Alder reaction[7].

Mishandling of essential oils may result in the destruction of some components and the formation of artefacts. Flash-evaporation of compounds in the injection chambers of gas chromatographs has often led to the pyrolysis of some esters and the dehydration of some terpene-alcohols[8].

The following hop oil fractions were obtained.

(1) A hydrocarbon fraction representing 70 per cent of the total oil was analysed by gas chromatography and found to contain 21 and possibly 26 compounds. The three largest components isolated and identified

by mass spectral analysis were myrcene (30 per cent), caryophyllene (20 per cent), and humulene (40 per cent). The remaining 10 per cent of this fraction was tentatively identified as a mixture containing pinene, limonene, farnesene, several other terpenes, and sesquiterpenes.

(2) The total oxygenated fraction representing 30 per cent of the whole oil was found to contain a mixture of esters, carbonyls, and free alcohols.

(3) In the carbonyl fraction, methyl nonyl ketone was the main component; but the entire homologous series of methyl ketones from acetone to hexadecanone was tentatively identified. There was also strong evidence of the presence of eight-branched ketones. Several saturated, unsaturated, and branched aldehydes were tentatively identified, including citral and the homologous series of normal aldehydes from propyl to undecyl.

(4) The alcohol fraction was also found to be a complex mixture. Isoamyl alcohol and linalool represented the major constituents, followed by geraniol, nerolidol, nerol, terpineol, and many others. Tentatively identified were *n*-amyl, hexyl, heptyl, octyl, nonyl, decyl, and undecyl alcohols.

(5) The ester fraction, analysed by gas chromatography, was a mixture of compounds having a wide boiling range[6,9]. Tentatively identified were linalyl acetate, geranyl formate, geranyl acetate, and geranyl isobutyrate. Upon methanolysis and separation from the freed alcohols, the methyl esters were analysed by gas chromatography. Approximately 60 peaks were recognized. The methyl esters were then separated into three sub-fractions: (*a*) the straight-chain, saturated esters; (*b*) the branched esters; (*c*) the unsaturated esters. Thus nine straight-chain normal acids from hexanoic to tetradecanoic were identified, plus six-branched unsaturated acids, fourteen saturated branched isoacids which did not complex with urea, and two-branched acids which did form urea complexes due to the presence of straight-chains of at least seven carbons.

Of the six branched and unsaturated acids already named, two were originally present in hop oil as methyl esters. Although results are still inconclusive, we agree with Roberts's[6] suggestion that these esters probably are isometric methyl geranates.

Positive identification of the most important components of hop oil is in progress at this laboratory, using infra-red, mass and nuclear magnetic resonance spectroscopy in conjunction with gas chromatography.

This work is supported by funds from the U.S. Brewers Association, Inc., under the Committee for Hop Research.

BIOPHYSICS

Restricted-Diffusion Chromatography through Calibrated Columns of Granulated Agar Gel; a Simple Method for Particle-size Determination

RESTRICTED-DIFFUSION chromatography through columns of granulated agar gel, as introduced by Polson[1], has been used effectively for virus purification[2]. It is now proposed that the method may be satisfactory for size determination of cell components, viruses, and proteins, and will thereby supplement the existing methods of electron microscopy, sedimentation, X-ray diffraction, and light scattering. The advantage of this technique over other 'gel-filtration' methods for the fractionation and size determination of these larger particulates is based on the fact that the pores of most agar gels are so large that such particles diffuse into them[3] and become retarded as they pass through the column with the degree of retardation increasing as particle size decreases.

An accurate method for determination of the effective pore size of agar gels, described in a previous article[3], has proved very useful in selection of the proper concentration of agar to be used in columns for the fractionation of specific particles of known sizes. As we expanded our use of agar-gel columns the need for more thorough knowledge of their properties became evident. Therefore, we established, as described previously[2], standard columns (100 cm long and 1·5 cm in diameter) of 1, 2, 3, 4, 5, 6, 7, and 8 per cent agar granules and determined the volume of effluent liquid in which the peak concentration of a series of particulates of known size appears.

In these studies the samples were run at room temperature and a standard buffer (0·2 M sodium dihydrogen phosphate, 0·3 M sodium chloride adjusted to *p*H 6·8 with 5 N sodium hydroxide) was used throughout.

All columns were operated by gravity flow and were adjusted to give a flow-rate of 5–10 ml./h. A 2 ml. suspension of the desired particles was applied at the top of a column and 1·5–2 ml. samples were collected. Appearance of the particles in the eluate was followed with a recording spectrophotometer. With the information thus obtained we constructed calibration curves (Fig. 1) which show the behaviour of spherical or nearly spherical particles as they pass through the gel columns.

Particles used for calibration were:

		Approximate diameter (mμ)
(1)	Shope papilloma virus (ref. 4)	45
(2)	Southern bean mosaic virus (SBMV) (ref. 5)	28
(3)	Coliphage *f2* (ref. 6)	20
(4)	Ferritin (ref. 7)	9·4
(5)	Hæmoglobin (ref. 8)	6
(6)	Lysozyme (ref. 9) (estimated from molecular weight data)	4

Duplicate runs on identical suspensions gave readings within 2 ml. of each other. Duplicate columns gave somewhat greater variability with all points displaced in the same direction by 0–6 ml. as would be expected with slight differences in the agar gels or in the packing of columns.

Most samples were diluted approximately 10-fold on passage through each column; however, there was less spread of the smaller components on 7 and 8 per cent agar. Agar chips for all calibrated columns were between 40 and 60 mesh in size. A sample column containing 6 per cent agar, 60–80 mesh,

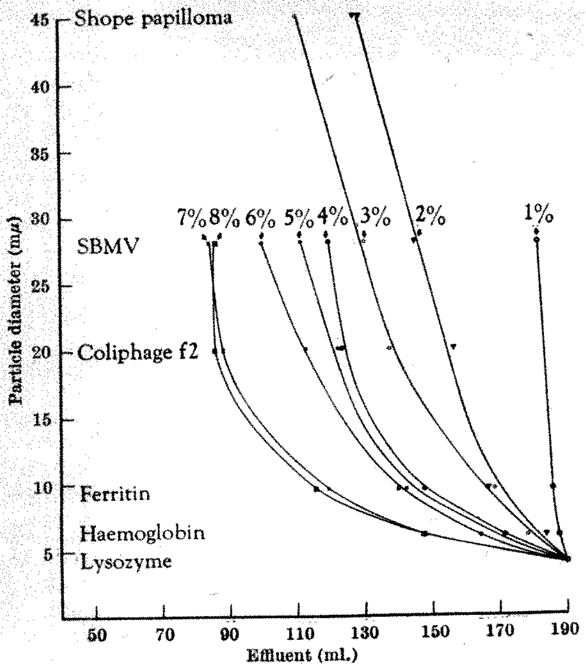

Fig. 1. Calibration curves for granulated agar columns. Note that the position of lysozyme for all curves is at 190 ml. For greater ease of comparison all curves which did not have lysozyme at this average point were shifted to right or left to make this one point coincide. Since the entire curve was shifted in each instance, relative positions of points on any one curve were retained. Each point represents the peak concentration of the component

gave nearly the same sample spread and position of points as did the corresponding column of 40–60 mesh size. Very fine agar granules were not tested for possible reduction in sample spread.

Once a column is calibrated within the proper size range it becomes a useful tool for the easy determination of particle size for unknowns. One need only introduce the test suspension at the top of the calibrated column, assay samples to determine effluent liquid volume to the peak of concentration of the test sample, and locate this point on the calibration curve. Furthermore, if a suitable assay method is available for determining the concentration of the desired particle and distinguishing it from contaminants one can even determine particle size in relatively impure preparations.

A standard buffer of *p*H 6·8 was used for the present work, but other buffers can be satisfactorily used and must be used if the columns are operated at 4° C, at which temperature our standard buffer crystallizes. We have had satisfactory separation of particulates in 0·01 M buffer and at *p*H 8, but the limitations in buffer and *p*H have not yet been throughly explored.

Our calibration curves are based on spherical or nearly spherical particulates, and any appreciable deviation from sphericity would tend to alter the position of peak concentration of a component. Thus noticeable errors in size determination could be experienced if the particulate being studied were not spherical.

Of interest are the facts that our 8 per cent agar membrane, reported earlier[3], had pore diameters of 18·6 mμ whereas the 7 per cent agar had pore diameters of 20·2 mμ, and that we have found the coliphage *f*2 particles, which are 20 mμ in diameter, to be slightly retarded in the 7 per cent agar-gel columns but not in the 8 per cent.

From a careful study of the calibration curves, one can obtain information useful in the purification and separation of large molecules, viruses, and cellular fragments. For example, one can pass a sample rapidly through 8 per cent agar and separate the large component, 20 mμ and over, from most of the smaller particulates. Agar gels with larger pore sizes can then be utilized for fractionation of these larger particles. Likewise 7 or 8 per cent agar columns can be useful in the fractionation of the smaller particulates.

The calibration curves presented in Fig. 1 are useful for determining the general properties of each gel concentration and for relating columns of one agar gel with those of another. However, one should not assume that any 100 cm × 1·5 cm column of a given per cent granulated agar gel will agree precisely with that presented here. Each column to be used for particle-size determination should be calibrated for this purpose with a series of particulates of known size and with the buffer to be utilized with the test sample.

We thank N. D. Zinder for supplying the coliphage *f*2 and C. A. Knight for supplying the Shope papilloma virus.

Effect of Adsorbed Proteins on the Wettability of Hydrophilic and Hydrophobic Solids

WHEN barium stearate or other hydrophobic powders are exposed to blood plasma they remove certain coagulation factors such as factor V[1] and fibrinogen[2], and their surface becomes hydrophilic. Barium sulphate, aluminium hydroxide and other hydrophilic particles adsorb other coagulation factors preferentially (prothrombin, factors VII, IX and X), but changes of wettability at their surface are less obvious. To indicate if one protein may have areas of less polarity by which it can attach itself to less-wettable substrates, leaving its more polar sites exposed, and vice versa, the relative wettability of thrombin and fibrinogen adsorbed on to glass and lucite was observed as follows.

A pattern of three partially overlapping rectangles was outlined on paper (Fig. 1); a ⅛-in. thick 'Lucite' plate was placed on it and covered over area *ABC* with thrombin ('Topical, Bovine', Parke, Davis and Co., Detroit; 12·5 U. per ml. 0·85 per cent sodium chloride). The plate was tilted after approximately 1 min (edge *ABCEF* pointing down), rinsed with

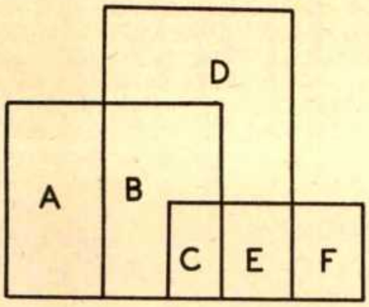

Fig. 1

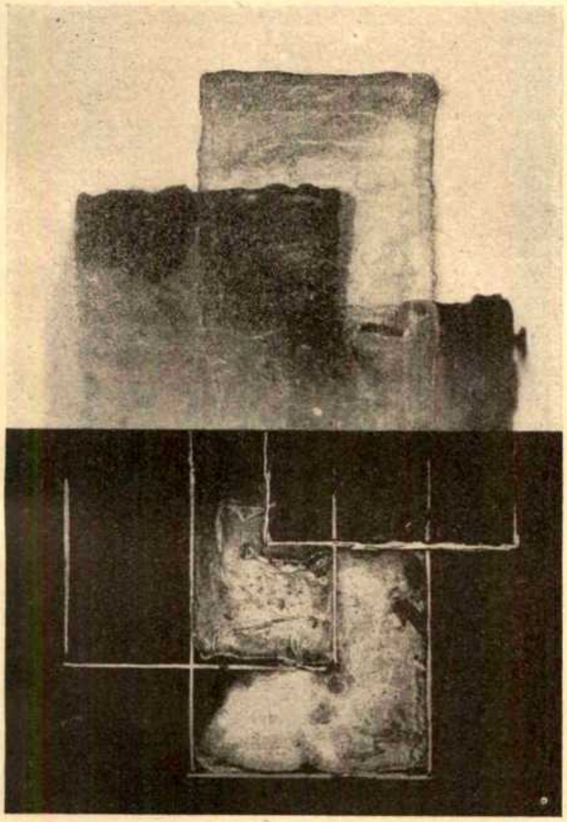

Fig. 2. Upper half, thrombin and fibrinogen pattern on lucite plate; lower half, same on glass plate with left and right position reversed to match pattern outline. Background on glass is black because water droplets (showing white on lucite background) fuse and have low contact angle. Both prints are positives

20 ml. 0·85 per cent sodium chloride followed by large amounts of cold running tap-water and finally with distilled water, and allowed to dry at room temperature. Next, area *DBCE* was covered with fibrinogen ('Human Fraction' I, Mann Res. Lab., New York; 2 mg per ml. 0·85 per cent sodium chloride) and the plate was rinsed and dried as before. Finally, area *CEF* was treated with the thrombin solution as had been area *ABC*. After drying, and cooling in a refrigerator, the plate was placed face down over a 50° C water bath; as soon as water had condensed on it sufficiently to reveal marked contrasts, the plate was held with the wet side facing, but not touching, a black velvet cloth and a photograph was taken using oblique flash. The more hydrophobic areas containing more droplets with high contact angle reflected more light.

Exactly the same procedure was followed using a ¼-in. thick plate of glass instead of 'Lucite'; wax crayon outlines were needed here to prevent random flow of reagents.

The combined photographs (Fig. 2) indicate the following: the surface of fibrinogen adsorbed either on glass or on 'Lucite' is less hydrophilic than that of adsorbed thrombin (area *D* is lighter than areas *A* and *F*). The wettability of thrombin adsorbed on to glass is lowered more after exposure to fibrinogen than is that of thrombin adsorbed on to 'Lucite' (area *B* is lighter than area *A* on glass but not on 'Lucite'. Similarly, the wettability of fibrinogen adsorbed on glass is increased more by exposure to thrombin than that of fibrinogen adsorbed on 'Lucite' (difference between areas *E* and *D* is greater on glass than on plastic).

Though fibrinogen does appear to have a less-polar surface on glass than on lucite, single observations on glass partly coated with a repellent were needed to avoid variations in technique; they confirmed our findings.

These results suggest that non-polar sites on fibrinogen will adhere to those on thrombin, and that adsorption of either molecule on an apolar substrate hinders this 'non-polar bonding'. This would be in agreement with the finding[3] that substrates are hydrolysed most by thrombin if they contain apolar side-chains.

To distinguish between change of polarity by removal of a single layer and by formation of a double layer, actual thickness measurements are needed. Ellipsometry[2,4] is used for this purpose.

BIOCHEMISTRY

A New Variant of Human Transferrin in a Venezuelan Family

THE most prolific of the hereditary variations among the human serum proteins is that of the iron-transport protein transferrin. The initial demonstration of genetically determined transferrin heterogeneity[1] has been followed by numerous reports of additional variants, until at the present time thirteen transferrins have been described: B_0 (ref. 2), B_{0-1} (ref. 3), B_1 (ref. 4), B_2 (ref. 5), B_3 (ref. 6), C, D_0 (ref. 2), D_4 (ref. 7), D_{Montreal} (ref. 8), D_{Chi} (ref. 6), D_1 (ref 9), D_2 (ref. 4), and D_3 (ref. 2). Each of the molecular species of transferrin has been identified by its characteristic mobility in starch-gel electrophoresis. Transferrin C is common in all populations; variants of more rapid mobility than transferrin C have been named B, and slower-moving variants have been labelled D. Where convenient, subscripts have been chosen to define the relative electrophoretic mobilities of variants within the fast- and slow-moving categories. In certain cases, particular transferrins appear to be restricted to specific populations; thus, transferrin B_{0-1} occurs in 8 per cent of Navajo Indians, B_2 in 1 per cent of Caucasians, D_{Chi} in 6 per cent of Chinese, and D_1 in 10 per cent of American Negroes.

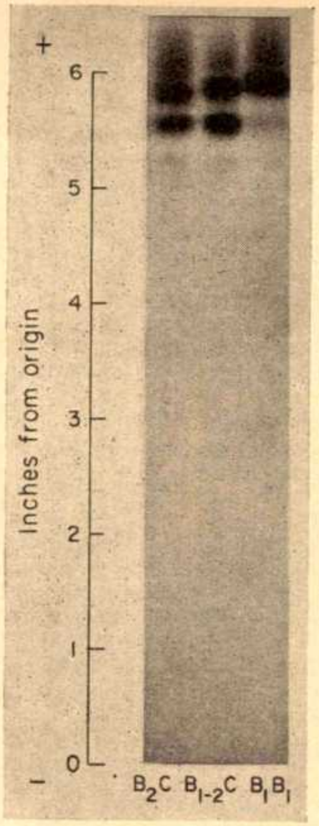

Fig. 1. Comparison by starch-gel electrophoresis of sera of transferrin phenotypes B_2C, $B_{1-2}C$, and B_1B_1. Electrophoresis for 6 h at 20 V/cm, 4° C. Faint iron-binding components migrating more rapidly and more slowly than the principal transferrins can be seen in the autoradiograph (ref. 8)

In the experiments described here, vertical starch-gel electrophoresis was carried out in the borate buffer system of Smithies[10], and transferrins were identified by autoradiography[2]. The examination of sera both from a hybrid Venezuelan individual of Italian and Negro descent and from one of her three sons revealed them to be heterozygous for transferrin C and a more rapidly migrating transferrin variant. When this variant was compared with known faster-moving transferrins by electrophoresis under conditions of high voltage and low temperature[8], it was found (Fig. 1) that this transferrin migrated slightly more rapidly than transferrin B_2 but more slowly than transferrin B_1. These electrophoretic differences were consistently observed in samples obtained from the individual at three different times over the course of two years. These experiments therefore provide evidence for the existence of another genetically determined transferrin variant, for which the name transferrin B_{1-2} is suggested. Population studies on more than one thousand Venezuelan Indians and hybrid individuals have revealed no further examples of the new transferrin.

Incubation of transferrin B_{1-2} with various concentrations of the enzyme neuraminidase[11-12] produced the characteristic stepwise pattern of four additional slower-moving components; at the highest enzyme concentrations, only the slowest-moving of these components was present. It appears, therefore, that the new variant, like the ten other transferrins which have been examined[8,12], contains four sialic acid residues accessible to the enzyme.

We thank Dr. Eloise Giblett, King County Central Blood Bank, Seattle, for providing sera of transferrin phenotypes B_2C and B_1B_1.

Regulatory Mechanisms of Glycogen Deposition in Liver of Normal and Tumour-bearing Rat, and in Novikoff Ascites Hepatoma

THE lowering of glycogen store in normal animal tissues during the growth of a transplanted hepatoma and the absence of glycogen in neoplastic tissues are commonly observed phenomena. The complex processes which result in removal of glycogen from normal tissues during the growth of a transplanted tumour are not fully understood. However, evidence is available for low glycogen formation in tumours and is based mainly on the assumption of a defective system of glycogen synthesis[1,2].

In this communication emphasis will be placed on yet another factor, that is, the site of synthesis and degradation of glycogen in the cell as a determinant in glycogen storage. The changes that occur at the intracellular level in glycogen synthesizing and degrading enzymes have been examined and the interpretation of the results provides a possible explanation of the phenomena.

In the normal liver cell, the site of glycogen synthesis is believed to be the glycogen granules, where the synthesizing enzyme, glycogen synthetase, is present bound to the glycogen particles[3]. On the other hand, the glycogen-degrading enzyme, phosphorylase, is distributed in mitochondria, endoplasmic reticulum (microsomal fraction), glycogen granules (glycogen pellet) and the soluble part of cytoplasm (supernatant fraction). The phosphorylase in the glycogen pellet is not bound to the glycogen particles[4]. Amylase, which is also capable of removing glycogen store, is present in the liver in very low though estimable concentrations and is believed to be responsible for the formation of glucosyl-oligosaccharides[5]. Amylase activity in the Novikoff ascites hepatoma is considerably lower than in liver and no saccharides have been detected in the solid form of the tumour[2].

In our experiments, Sprague–Dawley rats weighing 150–200 g received transplants of Novikoff ascites

Both liver homogenates (in sucrose–EDTA and sucrose–EDTA–sodium fluoride) were centrifuged for 10 min at 700*g*. Precipitate was discarded. The supernatant (first supernatant) was centrifuged at 5,000*g* for 10 min. The precipitate (mitochondrial fraction) was separated and the supernatant fluid recentrifuged at 25,000*g* for 10 min. After removal of the fatty layer, the upper part of the supernatant was sucked off (final supernatant), and the middle portion discarded. The suspension at the bottom was removed with the syringe (microsomal fraction) and the tube inverted to pour off the remaining microsomes. The pellet remaining at the bottom is referred to as particulate glycogen. The different precipitates were suspended in known volumes of sucrose–EDTA or sucrose–EDTA–sodium fluoride solutions for the assay of glycogen synthetase and phosphorylase activities respectively. The figures are representative of 3–6 assays each fraction.

* Microsomal fraction is usually contaminated with the final supernatant.

tumour cells. After 6–7 days, the animals were killed and the liver and ascitic tumour removed from each. The tumour cells were suspended in a wash medium described by Wu and Racker[6], sedimented by centrifugation at 80 *g* for 6 min and repeatedly washed and centrifuged at this speed to give tumour cells free of erythrocytes and most of the polymorphonuclear leucocytes. The washed tumour cells were finally centrifuged in a graduated tube at 1,200 *g* for 10 min. The tissues (liver and tumour cells, uncorrected for raffinose space) were homogenized in a Potter–Elvehjem homogenizer with a 'Teflon' pestle for 6 min at 600 r.p.m. to give a 10 per cent homogenate in 0·25 M sucrose solution containing 0·001 M ethylenediamine tetraacetic acid (EDTA) for the assay of glycogen synthetase activity. An equal volume of 10 per cent homogenate was prepared in sucrose–EDTA solution containing sodium fluoride (final concentration, 0·1 M), for the assay of phosphorylase activity. The homogenates were then subjected to the fractionation procedure as described by Leloir and Goldemberg[4].

All sedimented fractions were suspended in known volumes of sucrose–EDTA or sucrose–EDTA–sodium fluoride solutions. Normal rat livers served as control tissues, and were subjected to an identical fractionation procedure. Glycogen synthetase and phosphorylase activities were measured according to procedures described by Nigam *et al.*[2]. Protein determinations were made according to Lowry *et al.*[7], with human serum albumin (Connaught Laboratories, Toronto) serving as a reference standard. The results of the protein determinations and enzyme assays in the various fractions of normal liver, liver of tumour-bearing animals and tumour are shown in Table 1. It can be observed that in normal rat liver, glycogen synthetase and phosphorylase activities are present largely in the glycogen pellet. The synthetase activity is also present in the microsomes and mitochondria and to the least extent in the supernatant fraction. The phosphorylase activity is evenly distributed in the supernatant, mitochondrial and microsomal fractions. These results are in agreement with those reported by Leloir and Goldemberg[4]. The growth of hepatoma, however, provokes certain changes in the distribution pattern of the two enzymes. The liver of the tumour-bearing animal shows a marked loss of glycogen synthetase and phosphorylase activities from the mitochondrial and glycogen pellet fractions. This loss is not accompanied by any appreciable increase in the activity of these enzymes in the supernatant fraction. The microsomal fraction shows loss for glycogen synthetase but not for phosphorylase activity.

In the tumour cell glycogen synthetase activity is present in mitochondria, microsomes and particulate glycogen (the particulate glycogen fraction in tumour is different from liver particulate glycogen since it contains little glycogen) although it is highest in the supernatant fraction. Tumour phosphorylase is also mainly localized in the supernatant and is inactive in the particulate glycogen fraction. The tumour cell thereby resembles, to a certain extent, the liver of a tumour-bearing rat. In both these tissues the synthesizing and degrading enzymes are largely a manifestation of the soluble cytoplasmic fraction.

From these observations it is clear that, in normal liver, phosphorylase is either in an inactive form or unable to approach the glycogen molecules since it does not degrade glycogen in spite of being adsorbed on the glycogen granules. The growth of hepatoma is associated with certain changes that bring about loss of glucose and glucosyl-oligosaccharides[2]. Under such conditions it is likely that an impairment of glycolytic activity in the soluble cytoplasm occurs due to limiting amounts of substrate. This process would be followed by a release of phosphorylase and adenosine triphosphate (ATP) from the mitochondria in amounts sufficient to activate the phosphorylase, bridge its link to glycogen molecules and subsequently degrade the polymer. The absence of glucose would thus be a prerequisite for any appreciable glycogen degradation since in its presence adenine nucleotides formed during pyruvate oxidation are held inside the mitochondria and are not readily available for extra-mitochondrial phosphorylase activation or for glucose phosphorylation as observed in case of Pasteur effect[8].

The phenomenon of glycogen removal from liver during tumour growth can therefore be explained more appropriately on the assumption of an initial activation of phosphorylase due to the removal of cytoplasmic glucose, followed by degradation of the glycogen granules and loss of synthesizing capabilities of the degraded particles. The activation of phosphorylase can be ascribed to the availability of ATP, which not only phosphorylates dephosphophosphorylase but also provides 3′-5′ cyclic AMP (a co-factor for phosphorylase reaction) by the action of adenyl acylase on ATP. Such stimulation of phosphorylase activity has been shown during the administration of epinephrine and glucagon[9] and has been proposed for glycogen depletion during puromycin administration[10]. The case of tumour can be explained on lines parallel to those discussed for liver. It is proposed that in tumours the degradative apparatus is always in an active state due to a constant supply of glycolytic energy as evidenced by high rates of aerobic and anaerobic glycolysis. The formation of saccharides from UDPG in tumour homogenate supports the view that a certain amount of glycogen is synthesized in the tumour cell only to be degraded by an active phosphorylase, and perhaps a slow acting tumour or circulating blood amylase.

Characterization of some Urinary Protein Fractions in Patients with Multiple Myeloma

THE urinary protein described in 1847 by Henry Bence Jones is a diagnostic tool in multiple myeloma and has been subjected to intense and detailed biochemical investigation. The characteristics of this protein (BJP) are well established[1]. But so far the supernatant urine after precipitation of the BJP by heating (65° C) has not been thoroughly studied. Therefore, in patients with proved multiple myeloma we investigated: (1) the whole urine; (2) the BJP; (3) the supernatant urine after removal of the BJP[2]. The work was then extended to other patients with evidence of a urinary paraprotein, and to patients with macroglobulinæmia Waldenström with or without BJP.

Samples of urine were lyophilized after exhausting dialysis and dried over phosphorus pentoxide; then they could be stored indefinitely. The aforementioned three urine fractions were examined by means of paper electrophoresis for proteins, glycoproteins and reducing hydroxyl groups, by paper chromatography for carbohydrates, amino-acids and glycopeptides, by diffusion measurements according to Northrup and Anson[3] for calculation of molecular weight, and by analytical ultra-centrifugation. In addition, protein, carbohydrate, sialic acid, hexosamine and hexose content were estimated chemically. Cholesterol and phosphatide contents were determined chemically and by thin-layer chromatography.

The following results were obtained:

(1) The known characteristics of the BJP were confirmed (Table 1*A*).

Table 1. PERCENTAGE COMPOSITION AND MOLECULAR WEIGHT OF URINARY FRACTIONS FROM PATIENTS WITH POSITIVE BENCE JONES PROTEIN

	A	*B*	*C*
Protein	86	50	31
Hexose	1·2	12	22
Sialic acid	0·3	2·0	2·0
Hexosamine	0·5	4·0	9·8
Molecular weight	32,000–40,000	13,000–17,500	9,000–12,000
Sedimentation coefficient ($S_{35,w}$)	3·5	—	1·8

A, BJP; *B*, supernatant urine after removal of BJP; *C*, water-soluble glycopeptide after lipid extraction of *B*.

(2) The supernatant urine, from which the BJP had been removed by heating twice to 70° C at *p*H 6–7, contained a well-defined glycolipoprotein which is quite different from the BJP and from the uromucoids described by Tamm and Horsfall and other authors[4–6]; this urinary protein has not yet been described. Its biochemical characteristics are presented in Table 1*B*.

(3) This glycolipoprotein from the supernatant urine was further prepared by lipid extraction with methanol and methanol-chloroform. After removal of the lipid extractable material an especially interesting water-soluble and non-dialysable fraction remained, consisting of 40 per cent carbohydrate and 40 per cent protein. For characteristics of this substance see Table 1*C*.

It should be emphasized that this fraction could be recovered several times from the same patients over a period of two years, thus proving the reproducibility of the methods used for urinary preparations. This glycoprotein is homogeneous by electrophoresis and ultra-centrifugation. Investigation for the presence of reducing hydroxyl groups with silver nitrate reveals a strong positive reaction. This low molecular weight glycopeptide seems to be important in the uroprotein constellation in paraproteinæmia.

(4) Comparison with urine from myelomatous patients without typical BJP made evident that the carbohydrate concentration and the relation of carbohydrate to protein are important in the precipitation of BJP and its heat reversibility. The BJP will be negative at a carbohydrate concentration above 30 per cent or a protein–carbohydrate ratio below 2 : 1. Urine with a higher protein concentration may reveal a BJP on electrophoresis but no evidence for BJP on heating. Reversible BJP will be found at a protein–carbohydrate ratio about 11 : 1 (Table 2).

These results indicate that in patients with multiple myeloma in addition to the BJP it is possible to

Table 2. RELATIONSHIP BETWEEN BENCE JONES PROTEIN AND PROTEIN–CARBOHYDRATE RATIO

	I	II	III	IV
Protein–carbohydrate ratio	40 : 1	11 : 1	9 : 1	2 : 1

I, Irreversible BJP; II, reversible BJP; III, negative BJP, but positive urine electrophoresis; IV, negative BJP, negative urine electrophoresis.

isolate other well-characterized non-dialysable urinary fractions which seem to be typical uroproteins in paraproteinæmia. These substances possibly play an important part in the physicochemical variability of the BJP as we presume that the BJP may be present in the native urine in the form of a glycolipoprotein complex which is broken down by a mild water hydrolysis when the urine is heated to 70° C.

A detailed study, including similar urinary protein findings in macroglobulinæmia Waldenström, will be published elsewhere[7].

Inhibition of Spontaneous Splitting of γ-Globulin Preparations with ε-Amino-caproic Acid

In our previous work[1] in which changes of human γ-globulin preparations were examined during storage it was established that splitting occurs in them under the formation of two new fragments, gamma$_X$ and gamma$_Y$; this is especially marked in preparations prepared from placental extracts. Similar results were achieved by other authors[2]. Further, it has been established that a similar splitting occurs when the solution of human γ-globulin is treated with some proteolytic enzymes, for example, with plasmin, trypsin and papain[3]. It can be therefore presumed that a process of a proteolytic character occurs during storage.

The inhibition of proteolytic processes, especially of such connected with the action of plasmin by ε-amino-caproic acid, has already been described[4,5]. This is why we used this inhibitor for the stabilization of human γ-globulin preparations.

We prepared several sterile samples of 16 per cent solutions of human γ-globulin isolated from placental material in a 3 per cent ε-amino-caproic acid solution (ACA) as well as in a 2·25 per cent glycine solution, which is at present used as stabilizer of commercial γ-globulin preparations. The solutions were stored for 5 months at the temperature of 0° to + 4° C; samples were withdrawn at monthly intervals and analysed by immunoelectrophoresis, agar electrophoresis and by ultracentrifugation. Fig. 1 shows the results of immunoelectrophoresis of one of the preparations after a 5-months' storage in both kinds of solutions under precipitation with anti-human γ-globulin rabbit serum. In γ-globulin stored in glycine solution the usual products of splitting (gamma$_X$ and gamma$_Y$) were formed, while in the ACA solution the splitting was markedly inhibited. In this case only characteristic γ-globulin line precipitates, the splitting being detectable by a forking of its end at the cathode side.

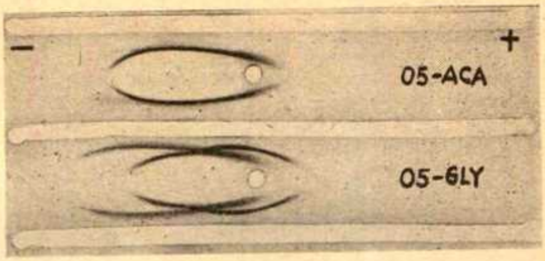

Fig. 1. Immunoelectrophoresis of placental γ-globulin preparations stored for five months in ε-aminocaproic acid and glycine

The inhibitory effect of ACA is still more definitely shown by the results of ultracentrifugation analysis (Fig. 2, Spinco model *E*, 52,000 r.p.m., time 56 min). In both samples three components appear: the lightest of S_{20} = 3·9, medium of S_{20} = 7 (unsplit γ-globulin) and the heaviest of S_{20} = 10·5 (dimer of γ-globulin, usually in preparations prepared by ethanol treatment). While in the inhibitor (ACA) containing preparation the 7*S* γ-globulin forms 92 per cent, the lighter fraction amounting to 4 per cent, in the control preparation (glycine solution) the 7*S* γ-globulin forms only 22 per cent, 78 per cent being formed by the 3·9 *S* fraction. Former analyses of isolated fractions of splitting demonstrated their very close sedimentation constants, and thus the lighter fraction can be considered a mixture of both products of splitting, gamma$_X$ and gamma$_Y$.

These results indicate that ε-amino-caproic acid is a suitable stabilizer of human γ-globulin preparations against spontaneous proteolysis. As the ε-amino-caproic acid shows no toxic or noxious effects on

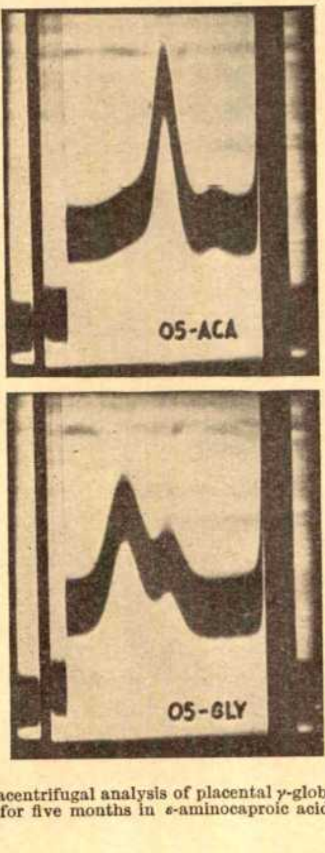

Fig. 2. Ultracentrifugal analysis of placental γ-globulin preparations stored for five months in ε-aminocaproic acid and glycine

parenteral administration[6] it appears suitable also for the production of injection γ-globulin solutions[7].

Uricolysis by Human Leucocytes

ALTHOUGH uricase is absent from the tissues of the human being, there is nevertheless evidence that uric acid is destroyed in man. Benedict, Forsham and Stetten[1] first demonstrated by intravenous injection of isotopically labelled urate that only two-thirds to three-fourths of the daily urate turn-over of the body actually appears as urinary uric acid. Furthermore, the total recovery of the injected isotopically labelled uric acid in urinary uric acid over a 7-day period is similarly reduced[2]. The missing isotope has been demonstrated in a variety of metabolites in the urine, including ammonia, urea, allantoin, allantoic acid, respiratory carbon dioxide and fæcal bacterial bodies, after intravenous administration of uric acid labelled with nitrogen-15 and uric acid-2-^{14}C (refs. 3, 4).

We were led to re-examine this problem by observing that the inflammatory response to the intra-articular injection of sodium urate crystals involves a phagocytosis of the crystals by leucocytes[5]. A similar phagocytosis of urate crystals in synovial fluid is also seen in spontaneous attacks of acute gouty arthritis[6]. Our investigations show clearly that human leucocytes are capable of degrading sodium urate.

Human leucocytes essentially free of erythrocytes were prepared according to Fallon *et al.*[7] using fibrinogen sedimentation. The leucocytes were suspended in Krebs–Ringer bicarbonate buffer with added glucose (1·5 mg/ml.) to give a leucocyte concentration of about 15,000 per mm.^{3}. Erythrocytes from the initial sedimentation were washed twice with isotonic saline, and the packed cells, essentially free of leucocytes, were diluted with 10 volumes of Krebs–Ringer bicarbonate containing added glucose. Sodium urate-6-^{14}C with a specific activity of 2·8 μc./mg was crystallized from hot neutral solution of uric acid-6-^{14}C (Isotope Specialties).

Incubations were carried out aerobically at 38° C in modified Warburg flasks. Test flasks contained 0·5 ml. of the leucocyte suspension or erythrocyte suspension and 0·5 ml. of plasma containing 100 μg of sodium urate-6-^{14}C, either as microcrystals or in supersaturated solution. All incubations were performed in duplicate, and were terminated in 2 h by adding 0·3 ml. of 60 per cent perchloric acid to the incubation mixture. The carbon dioxide evolved was collected in 0·8 ml. hyamine and counted in a Packard 'Tri-Carb' liquid scintillation counter. Sonicated leucocytes were prepared with a Mullard probe sonicator using four interrupted 30-sec cycles while the sample was chilled in ice. Uricase activity[8] was determined spectrophotometrically in a Beckman model *DU* spectrophotometer. Leucocyte peroxidase was demonstrated spectrophotometrically according to Maehly[9]. Hydrogen peroxide was generated by adding glucose and glucose oxidase (Worthington) to each cuvette.

Table 1 shows the uricolytic ability of erythrocytes as compared to leucocytes as well as a comparison of the degradation of uric acid-6-^{14}C in solution as compared to microcrystalline suspension. As might be expected since leucocytes readily ingest crystals of sodium urate, sodium urate in crystalline form resulted in greater uricolytic activity in the leucocyte suspension while sodium urate-6-^{14}C in solution provided a better substrate for uricase action. Similar results were obtained in three other experiments. The calculated rate of uricolysis in this work was 0·25 μg sodium urate/h/10^6 leucocytes. Uricolysis by intact erythrocytes was negligible.

Table 1. COMPARISON OF URICOLYTIC ACTIVITY OF HUMAN ERYTHROCYTES AND LEUCOCYTES*

	$^{14}CO_2$ production in c.p.m. from Sodium urate-6-^{14}C	
	Solution	Microcrystalline
Plasma	136	147
Plasma + uricase	204,000	136,000
Plasma + erythrocytes	173	—
Plasma + leucocytes	960	2,081

* These are the average values of duplicate determinations.

No uricase activity was detectable in the sonically disrupted leucocyte with incubations up to 2 h at 25°. However, a peroxide-dependent uricolysis was demonstrable in the leucocyte peroxidase assay when a hydrogen peroxide generating system was used and accounted for the disappearance of 0·3 microgram of uric acid per 10^6 leucocytes/h.

That the gastrointestinal tract might be a primary site for uricolysis was suggested by the finding of Geren and associates[10] that after oral administration of uric acid labelled with nitrogen-15 only 27 per cent of the nitrogen-15 could be recovered in urinary uric acid over a 3-day period, while intravenous administration resulted in a recovery of 88 per cent of the isotope. Although sulphonamide bacteriostasis of the gut failed to alter uricolysis[3], Sorensen[4] reported that treatment with a combination of drugs, which effected much superior bacteriostasis than sulphonamides alone, reduced the recovery of carbon-14 in uricolytic fragments from 22·5 per cent before bacteriostasis to 3 per cent after bacteriostasis. By contrast, the recovery of carbon-14 in urinary allantoin was lowered only slightly from 2·1 to 1·8 per cent with bacteriostasis. Sorensen concluded that the primary site of uricolysis in the human is the intestinal tract and is the result of bacterial action on uric acid contained in intestinal secretions.

Although Bien and Zucker[11] have reported that overnight incubation of whole blood was accompanied by a decrease in uric acid content, *in vitro* studies by Sorensen[4] using uric acid-6-^{14}C and a variety of human tissues, including whole blood, led him to conclude that uricolysis did not occur in any human tissue.

Despite the absence of uricase in human tissues there are a variety of enzymatic reactions which could destroy uric acid. Canellakis, Tuttle and Cohen[12] have demonstrated that the products of peroxidative destruction of uric acid in phosphate buffer are allantoin, carbon dioxide, and urea, and that a variety of peroxidases can attack uric acid, including verdoperoxidase. Verdoperoxidase accounts for 1 per cent of the dry weight[13] of human leucocytes. Howell and Wyngaarden[14] have demonstrated the peroxidative destruction of uric acid catalysed by methæmoglobin and other hæm proteins *in vitro*.

Thus, leucocytes have been shown to contain the enzymatic equipment necessary for degrading uric acid, although such a destruction by intact human leucocytes has not heretofore been reported. Canellakis[12] states that in unpublished experiments leucocytes from a sterile abscess in the rat were found capable of degrading uric acid. Soberon and Cohen[15] have demonstrated a hydrogen peroxide requirement for uricolysis using the rat leucocyte.

Although most of the uricolysis in the normal human is accounted for by the action of the bacterial flora within the intestinal tract, uricolysis might very well account for the persistent appearance of essentially the same quantities of carbon-14 in urinary allantoin before and after intestinal bacteriostasis observed by Sorensen[4].

Sialic Acid in the Bulbo-urethral Glands of the Boar

THE two bulbo-urethral glands (Cowper's glands) of the boar lie parallel to the pelvic urethra to which they are united by a heavy muscular attachment. They are normally about 15 cm long by 3–5 cm in diameter and contain a sticky, white mucin which is ejected into the pelvic urethra during ejaculation of semen. In semen freshly collected by means of an artificial vagina the mucin has lost its sticky character and appears as small gelatin-like lumps resembling tapioca. Each lump consists of a white opaque 'nucleus' surrounded by a water-clear gel. If the semen is left standing for several hours these lumps grow and coalesce into large masses of transparent elastic gel which may occupy more than 50 per cent of the semen volume. Many spermatozoa are trapped in the gel mass.

The change in the physical properties of the mucin that occurs when it mixes with the semen is induced by the secretion of the seminal vesicles[1]. Thus if a small quantity of the bulbo-urethral mucin is immersed in the fluid secretion of the seminal vesicles a transparent gel-layer forms rapidly on the surface of the mucin, and this increases in thickness until a lump of gel is obtained which closely resembles those found in freshly collected semen. Semen from which the small lumps have been removed can be used successfully for artificial insemination. Thus the role of the gel in reproduction is not understood although it is possible that it functions as a plug in the uterus of the sow and so prevents back-flow of semen.

Table 1. COMPOSITION OF THE BULBO-URETHRAL MUCIN

	Percentage of dry weight	Molar ratio
Sialic acid (N-acetylneuraminic acid)		
Before hydrolysis (Svennerholm)	26·6	(1·00)
After hydrolysis (Warren):		
With neuraminidase	24·6	
With acid	25·2	
Galactosamine		
Galactosamine standard	12·8	0·83
N-Acetylgalactosamine standard	13·3	0·87
Neutral sugars (as galactose)	4·0	0·26
Methylpentose (as fucose)	0·78	0·047
Uronic acid (as glucuronate)	$\ngtr$0·1	
Ester sulphate (SO_4^{2-})	0·52	0·054

Odin[2] found that 14·7 per cent of the dry weight of the semen gel consisted of a sialic acid which was identified as N-acetylneuraminic acid. This finding is unexpected since N-glycolylneuraminic acid is the predominant sialic acid in epithelial secretions of this species[3].

Analyses of the secretions of the reproductive tract of the boar showed that the bulbo-urethral mucin contains between 4·0 and 4·5 per cent (fresh weight) of sialic acid. The concentration of sialic acid in the seminal vesicles is less than 1 per cent of that in the bulbo-urethral mucin while the other glandular secretions contain negligible amounts. The analysis of carbohydrates in the mucin is given in Table 1. Sialic acid was determined, as N-acetylneuraminic acid, in the intact secretion by Svennerholm's resorcinol method[4]. It was also determined by Warren's method[5] after liberation of sialic acid either by incubation with neuraminidase[6] or by heating for 1 h at 80° in 0·1 N sulphuric acid. The sialic acid produced by acid hydrolysis was examined by paper chromatography[7] and shown to consist of N-acetylneuraminic acid plus a trace of the N-glycolyl derivative. Authentic samples of these acids were kindly supplied by Dr. G. Blix. Neutral sugars were determined by an orcinol method[8] and methylpentose by the method of Gibbons[9]. Hexosamine was analysed according to Rondle and Morgan[10] and has been expressed as galactosamine since the hexosamine liberated by acid hydrolysis[10] gave a single spot with R_F equal to that of galactosamine when it was examined by paper chromatography[11]. Both galactosamine and N-acetylgalactosamine have been used as standards in the Rondle and Morgan method. The standard solutions were subjected to the same hydrolysis procedure as the mucin. Uronic acid was determined according to Bitter and Ewins[12] and ester sulphate by a modification of the procedure of Heald and Robinson[13].

The predominance of sialic acid and, after acid hydrolysis, of galactosamine in approximately equimolar amounts suggests that the mucin is analogous to the submaxillary mucins of sheep and cattle. The carbohydrate in the submaxillary mucins consists mainly of disaccharide units with the structure 6-(N-acetyl-α-D-neuraminyl)-N-acetylgalactosamine[14,15]. The majority of these disaccharides are linked glycosidically to free carboxyl groups of aspartyl and glutamyl residues in a protein core[16]. For this reason N-acetylgalactosamine may be the more suitable standard for the hexosamine assay reported here[14].

Seminal plasma consists of the mixed secretions of several accessory glands in the male reproductive tract. Constituents of the plasma often originate mainly or entirely from a single gland and thus chemical analysis of seminal plasma can yield useful information on the secretory activity of the various glands[17]. In boar seminal plasma citric acid, ergothioneine and inositol are indicators for the activity of the seminal vesicles while the level of glycerylphosphophorylcholine is a measure of the contribution of the epididymal secretion to the seminal plasma. It is now clear that in boar semen the sialic acid, which is present almost entirely in the gel, can serve as a measure of the secretory activity of the bulbo-urethral glands.

Chromatographic Isolation of Leucodrin

LEUCODRIN, the dilactone $C_{15}H_{16}O_8$ (refs. 1–3), which in the past was used as a remedy for malaria[4], has been isolated from the leaves of *Leucadendron adscendens* by chromatography on a column of finely powdered 'Perlon'.

Dried, powdered *Leucadendron* leaves were extracted continuously with boiling methanol until free from bitter principle, the solvent was evaporated from the extract, the residue dissolved in water and the cold solution passed through a column of powdered 'Perlon' ('Versuchsprodukt PP. 15/Sp.'). The column was first washed with cold water until the effluent was clear and then elution with boiling water afforded, after concentration, a clean, crystalline product in 15 per cent yield. This product was identical in all respects with the product obtained from *Leucadendron* leaves by Rapson[1], who used in its purification the rather more tedious method of precipitation of impurities with lead subacetate. The product from chromatography had m.p. 212·5°–213° (lit.[1] m.p. 212°–212·5°) (Found: C, 55·3; H, 5·0 per cent. Calc. for $C_{15}H_{16}O_9$. C, 55·5; H, 5·2 per cent), $[\alpha]_D^{20}-19{\cdot}5°$ (lit.[3] $[\alpha]_D^{17}-19{\cdot}2°$). Further elution of the column with warm, absolute alcohol and evaporation of the effluent afforded the yellow pigment, rutin, which melted indefinitely at 187°–192°. By following Rapson's procedure[1] on the same batch of leaves, leucodrin was obtained in 10 per cent yield.

The influence of powdered 'Perlon' in the separation of leucodrin is undoubtedly due to the formation of hydrogen bonds between the polyamide and this phenolic natural product. In fact, polyamides have been used previously as an adsorbent in chromatography for the separation of phenols[5], flavones and their glycosides[6], chalcones and flavones[7] and methyl gallates[8]. The high yields obtained, undoubtedly due to the fact that the phenolic material is not only held back on the surface but also inside of the polyamide[5], could make chromatography on powdered 'Perlon' a very efficient technique for the large-scale separation of naturally occurring phenols.

Preliminary investigations into the structure of leucodrin appear to point to the presence of two different lactone rings in the molecule rather than the spiro-γ-lactone type system which was put forward by Rapson[3] as a possibility—the infra-red spectrum shows two distinct carbonyl bands, ν_{max} (nujol) 1,805 and 1,778 cm^{-1}, λ_{max} (in ethanol) 205 mμ (ε 7,150), 230 mμ (ε 9,660) and 277 mμ (ε 1,430). The ^{1}H nuclear magnetic resonance spectrum at 60 Mc/s, for a solution of leucodrin in trifluoroacetic acid (reference compound, tetramethylsilane), shows two bands which cannot be ascribed to either of Rapson's structures: a moderately intense band at 9·09 τ which is probably associated with a  $-\overset{|}{\underset{|}{C}}-CH_2-\overset{|}{\underset{|}{C}}-$ group reasonably far removed from an aromatic nucleus, and a very intense band at 5·43 τ which might be associated with the protons of a  $-CH_2-O-\overset{\overset{O}{\|}}{C}-$ group.

A detailed account of degradative studies will occur in due course.

Thanks are due to the BASF Laboratories, Ludwigshafen, for a gift of 1 kg 'Versuchsprodukt PP. 15/Sp.', and also to Tropical Products Institute for obtaining the leaves of *Leucadendron adscendens*.

PHYSIOLOGY

Phosphoproteins and Sodium Transport

A FAIR measure of agreement has been reached that active transport of ions and volume regulation of cells involves utilization of adenosine triphosphate (ATP). We have put forward the suggestion that the phosphorylation of phosphoprotein is the first step in this utilization of ATP.

We have shown[1,2] that phosphoprotein turn-over of liver slices is dependent on the sodium concentration of the external medium, and is sensitive to cardiac glycosides and other drugs inhibiting ion transport, such as 'Promethazine'. We now bring evidence that the phosphoprotein turn-over of liver slices is also markedly affected by external potassium ion concentration.

Liver slices can be severely depleted of potassium by first cooling and then incubating in potassium-free Ringer solution at 38° C. Intracellular sodium increases greatly in such slices. If 5–10 m.equiv. potassium is then added to the incubation medium, transport starts. There is no lag period before potassium accumulation begins; in this respect the system differs from liver slices that are recovering from cooling alone[3,4] as these have a delay of about 10 min before potassium accumulation starts. The rate of potassium uptake is between 8–12 m.equiv./min/kg dry weight, and is inhibited immediately by 'Ouabain' at 5×10^{-4} M. 'Ouabain' at 10^{-4} M has little effect until some 10 min have passed, whereupon inhibition begins and progresses. 'Promethazine' also inhibits at a concentration of 10^{-4} M.

If phosphorus-32 is included in the potassium-free medium, the slices incorporate the tracer into ATP and phosphoprotein. If potassium is added, after labelling the slices with phosphorus-32 in potassium-free medium, there is a rapid fall in the radioactivity of the phosphoprotein as transport commences. This is detectable within 15 sec and maximum at 30 sec. By 45 sec after potassium addition, the radioactivity has returned to initial levels. Table 1 illustrates such an experiment and shows that 'Ouabain' abolishes the effect of potassium. 'Promethazine' (not shown) also prevents the effect of potassium. There is little or no effect on ATP radioactivity caused either by potassium addition or by the drugs.

Table 1. EFFECT OF 'OUABAIN' AND POTASSIUM ON PHOSPHOPROTEINS OF LIVER SLICES

Exp. No.	K^+ 10 mM	'Ouabain' (5×10^{-4} M)	Specific activity of phosphoprotein c.p.m./μM P
1	—	—	16,000
	+	—	11,000
	—	+	15,500
	+	+	15,200
2*	—	—	27,000
	+	—	20,000

The slices were leached of potassium by cooling at 0° in 0·154 M sodium chloride for 30 min. They were then suspended in potassium-free Ringer, containing phosphorus-32, specific activity 3×10^6 c.p.m./μmole inorganic phosphate for Exp. 1 and 15×10^6 c.p.m./μmole inorganic phosphate for Exp. 2, for 30 min at 38°. Transport was initiated by addition of potassium chloride, 10 mM, and the experiment ended 30 sec later. 'Ouabain', when present, was added 3 min before potassium chloride. The rate of uptake of potassium was 8 m.equiv./kg dry wt./min in controls and about 1 m.equiv./kg dry wt./min in presence of ouabain.

* The figures in Exp. 2 represent the total radioactivity in phosphorylserine derived from the proteins by acid hydrolysis and subsequent chromatography.

Essentially similar results are observed in human red cells. If cells with high internal sodium are incubated with phosphorus-32 in a medium free of potassium, phosphoproteins become labelled. On addition of potassium, there is a fall in radioactivity which is blocked by 'Ouabain' (Table 2). In contrast to liver slices, the effect of potassium is to bring about a new steady state, so that phosphoprotein radioactivity in the presence of external potassium is about 67 per cent of that in its absence. Liver slices show an effect of potassium addition within a few seconds; red cells show the effect after half an hour. This slowness of response may be connected with the slow rate of ion transport found in red cells.

The fall in radioactivity is recorded as a fall in specific activity of the protein–phosphorus. The labile 10 per cent of the phosphoprotein–phosphorus contains nearly all the counts[5]; this fall in specific activity represents dephosphorylation of the labile fraction.

Table 2. EFFECT OF 'OUABAIN' AND POTASSIUM ON PHOSPHOPROTEINS OF HUMAN RED CELLS

K 25 mM	'Ouabain' 10^{-5} M	Specific activity, c.p.m./μM P in phosphorylserine
—	—	225
—	+	150
+	—	190
+	+	210

Cells were loaded with sodium by cold storage (sodium was 50 m.equiv./l. of cells). They were incubated in medium with and without external potassium or 'Ouabain' as shown in a system as described in ref. 8 containing phosphorus-32 of specific activity 16×10^6 c.p.m./μmole in organic phosphate. The phosphoprotein residue was hydrolysed in hydrochloric acid, with the prior addition of 10 μmoles of carrier phosphorylserine, which was isolated by chromatography on 'Dowex 50' as already described (ref. 1). The specific activities of ATP, not shown, were essentially the same in all systems.

Table 3. EFFECT OF 'PROMETHAZINE' ON CALCIUM

Preincubated in Ca^{2+}	Promethazine (10^{-4} M)	Specific activity, c.p.m./μM P after final incubation in 0·93 mM Ca, 10 mM Na: ATP	Specific activity, c.p.m./μM P after final incubation in 0·93 mM Ca, 10 mM Na: Phosphoprotein
2·8 mM	—	104,000	4,300
2·8 mM	+	123,000	7,200
0·93 mM	—	170,000	7,700
0·93 mM	+	200,000	9,000

Preincubation was in choline Ringer at 38° for 10 min, gas-phase 95 per cent oxygen–5 per cent carbon dioxide and 'Promethazine' as shown. For incubation, the slices were transferred to choline Ringer containing 10 mM sodium, 0·93 mM calcium and phosphorus-32, but no drug. Incubation time was 10 min. As a control, slices were preincubated in choline Ringer containing 0·93 mM calcium and transferred to the same medium as the experimental slices.

It is suggested that sodium and potassium take part in the following reactions of the phosphoproteins of liver cells and human erythrocytes:

$$\text{ATP} + \text{Protein} \xleftrightarrow{\text{Na}_i} \text{P} \sim \text{Protein} - \text{Na} + \text{ADP}$$

$$\text{P} \sim \text{Protein} - \text{Na} \xleftrightarrow{\text{K}_o} \text{P} \sim \text{Protein} - \text{K} + \text{Na}_o$$

$$\text{P} \sim \text{Protein} - \text{K} \longrightarrow \text{K}_i + \text{Protein} + \text{inorganic phosphate}$$

(Where Na_i and K_i are internal and Na_o and K_o are external.) 'Ouabain' (and also 'Promethazine') compete for the phosphoproteins with both sodium and potassium. 'Ouabain' and 'Promethazine' not only prevent the effects of addition of sodium and potassium on phosphoprotein turn-over, but also prevent certain calcium effects.

Liver slices respond to addition of sodium to the medium by increased phosphoprotein turn-over. This effect is competitively inhibited by calcium in media where osmolarity is regulated with choline chloride[2,9]. Thus 10 mM sodium is effective when calcium concentration is 0·93 mM but ineffective in the presence of 2·8 mM calcium. But slices pre-incubated with 2·8 mM calcium will not respond to a fresh medium containing 10 mM sodium and 0·93 mM calcium with stimulated rates of turn-over of phosphoprotein and ATP, whereas slices pre-incubated with 0·93 mM calcium will do so. If the prior exposure to 2·8 mM calcium was conducted in the presence of 'Ouabain' or 'Promethazine', and the slices were then removed to a fresh medium containing phosphorus-32 and 10 mM sodium these slices responded with greater activity in ATP and phosphoprotein than did untreated controls (Table 3). In other words, the drugs reduced the effect of the higher levels of calcium to that of the lower level. In liver slices, therefore, as in muscle[6,7], there is a balance between the activities of sodium, potassium and calcium, which all appear to centre around a common site or sites.

These results will be published in detail shortly[8,9].

Activities of Various Concentrations of Triamcinolone Acetonide

Blank[1] has reported that 0·01 per cent triamcinolone acetonide, applied topically, was at least comparable in clinical efficacy with 1·0 per cent hydrocortisone, although somewhat less effective than 0·1 per cent triamcinolone acetonide, the concentration usually adopted clinically. In a larger group of cases Olansky[2] found that 0·1 per cent triamcinolone acetonide was significantly more active than the 0·01 per cent concentration, but he quoted earlier studies[3] which suggested that 0·025 per cent triamcinolone acetonide was difficult to distinguish from the 0·1 per cent concentration. Since there would be economic advantages in using a reduced concentration if this could exhibit the activity of 0·1 per cent triamcinolone acetonide in most dermatitides, we have conducted experiments to compare the effects of three concentrations of triamcinolone acetonide and 1·0 per cent hydrocortisone.

Chemical irritants such as cantharidin and volatile oil of mustard were found unsatisfactory for the production of uniform inflammation, while turpentine was considered to be possibly dangerous. It was therefore decided to use the 'Cellophane' tape method described by Wells[4] to produce a standardized trauma on the flexor aspect of the forearms of volunteers. 'Cellophane' tape, 0·5 in. wide, was smoothed on to a marked area and stripped off sharply in one direction. A fresh piece of tape was applied to the same area and stripped off in the opposite direction, this process being repeated until the surface became uniformly red and glistening. Erythema was produced in this way to a length of approximately 14 cm but only the central portion of 10 cm was used for division into control and treated areas.

Lotions containing 0·01, 0·025 and 0·1 per cent triamcinolone acetonide and 1·0 per cent hydrocortisone were prepared and packed in code-labelled containers. Measured quantities of these lotions were applied at random and under double-blind conditions to marked areas of the 'stripped' skin and were spread evenly, care being taken to avoid the control areas interposed between treated areas. By marking five areas, each 2 cm in length, it was found possible to compare three preparations simultaneously. After the lotions had been applied, the areas were examined at intervals and the responses were recorded after 2 and 6 h. The preferences at 2 h were analysed sequentially[5] with $\alpha = 0{\cdot}025$, $\beta = 0{\cdot}05$ and $\theta_1 = 0{\cdot}85$, although in some instances results continued to become available after a boundary had been crossed.

Table 1. Triamcinolone Acetonide (T.A.) 0·01, 0·025 and 0·1 per cent compared with Hydrocortisone 1·0 per cent (H)

T.A. concentration (per cent)	T.A. better		H better		No difference	
	2 h	6 h	2 h	6 h	2 h	6 h
0·01	13/32	14/32	9/32	8/32	10/32	10/32
0·025	15/32	21/32	6/32	3/32	11/32	8/32
0·1	17/32	23/32	5/32	0/32	10/32	9/32

Table 2. Triamcinolone Acetonide (T.A.) 0·01 and 0·1 per cent compared with Triamcinolone Acetonide 0·025 per cent

T.A. concentration (per cent)	T.A. 0·025 per cent better		T.A. 0·01 per cent or 0·1 per cent better		No difference	
	2 h	6 h	2 h	6 h	2 h	6 h
0·01	16/32	18/32	5/32	6/32	11/32	8/32
0·1	9/32	3/32	11/32	8/32	12/32	21/32

The total results are summarized in Tables 1 and 2.

The results read at 2 h indicate that 0·025 and 0·1 per cent triamcinolone acetonide have similar activities and that both concentrations are more active than 1·0 per cent hydrocortisone, while 0·01 per cent triamcinolone acetonide is similar in activity to 1·0 per cent hydrocortisone and less active than 0·025 per cent triamcinolone acetonide.

After 6 h the preferences for both 0·025 and 0·1 per cent triamcinolone acetonide over 1·0 per cent hydrocortisone are increased, but there are still no significant differences between these two concentrations of triamcinolone acetonide.

Wells[4] found that the effects of hydrocortisone were apparent on the 'stripped' area after about 4 h and became maximal after 12 h, but he applied the drug 3 times in 24 h if the experiment was prolonged. In our experiments, the activity of all the preparations appeared to be maximal after 2–3 h following a single application and the effects of hydrocortisone were often beginning to fade at the sixth hour.

The results obtained by the 'Cellophane' tape-stripping method support the clinical evidence that 0·025 per cent triamcinolone acetonide is indistinguishable from the 0·1 per cent concentration, although the latter may be preferred in refractory dermatoses. The experimental results also suggest that 0·025 and 0·1 per cent triamcinolone acetonide have longer, as well as greater, activity than 1·0 per cent hydrocortisone.

Effect on the Plasma Citrate of Treatment of Primary Hypothyroidism with Triiodothyronine

During the course of metabolic studies on myxœdematous subjects it was noted that the plasma citrate-level was in some cases raised. In the hope that useful information might be obtained on the mode of action of thyroid hormones on tissue metabolism, the plasma citrate-level was followed during the treatment of four female patients suffering from primary myxœdema, using ordinary replacement doses of triiodothyronine. Triiodothyronine was also administered to four normal medical students, two male and two female, and their plasma citrate-levels were followed.

Plasma citrate was measured by the method of McArdle[1] on venous blood taken in the fasting state. The normal range of plasma citrate in our laboratory is 2·0–3·9 mg/100 ml. The initial basal metabolic rates in patients 1–4 were −29, −38, −35 and −13 per cent, respectively (standards of Robertson and Reid[2]), and rose to within normal limits in from 7–14 days. The total daily dose of triiodothyronine administered (orally) was as follows: case 1, 60 μg; case 2, 60 μg for 4 days, followed by 120 μg; case 3, 20 μg for 4 days, 40 μg for 6 days, followed by 60 μg; case 4, 20 μg for 8 days followed by 30 μg. The normal students received 80 μg per day.

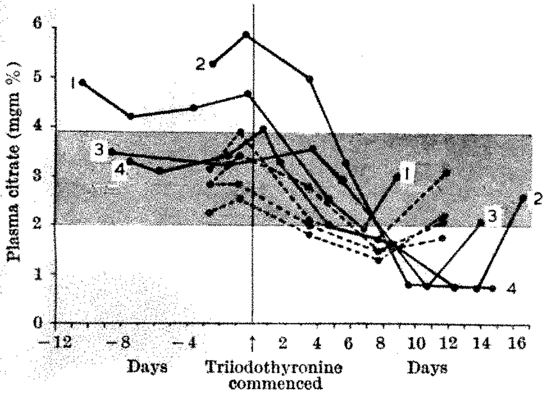

Fig. 1

The results are shown in Fig. 1; those obtained in patients are represented by solid lines, and in normals by dotted lines. Two of the hypothyroid subjects had high plasma citrate-levels initially. Triiodothyronine produced an abrupt fall in plasma citrate to subnormal levels in all subjects. The fall was on the whole greater in the hypothyroid subjects. A minimum value was reached in the controls at the eighth day; thereafter the levels began to rise again. In three out of four of the hypothyroid subjects the trough of the curve was delayed until the tenth to thirteenth day.

It seems reasonable to suppose that the initial fall in plasma citrate is in some way related to the effect of thyroid hormones in raising the metabolic rate particularly as only physiological doses have been used. It may be due either to a slowing in the rate of release of citrate into the circulation or to an increased rate of removal. It might be suggested that in the hypothyroid state the pathways involved in the oxidation of citrate are depressed, and that treatment corrects this. The subsequent return to normal in plasma citrate (Fig. 1) might be expected if the restoration of citrate synthesis took place more slowly than that of citrate catabolism. Examination of plasma-levels of other Krebs cycle intermediates might be of value in investigating the above possibilities. Relevant to these suggestions are the findings that succinoxidase activity in some mammalian tissues is depressed by thyroidectomy and increased by administration of thyroid hormone[3,4]. Pitt-Rivers and Tata[5] have, however, pointed out the difficulties in accepting that the thyroid hormones act by facilitating a rate-limiting enzyme reaction; the work of Tapley *et al.*[6–8] on the effect of thyroid hormones on mitochondrial swelling suggests that these hormones could regulate metabolism by controlling the permeability of mitochondrial membranes to enzyme substrates. The observations reported here could be equally well explained by such an effect.

I thank Prof. C. Wilson, Dr. J. M. Ledingham and Dr. A. Stuart Mason for their advice and permission to examine their patients.

HÆMATOLOGY

Common Antigen between Human Red Cell and Glomerulus

The existence of a shared antigen between the kidney and the red cell has been demonstrated by Simonsen[1] for the dog and by me[2] for the dog and the rabbit.

During the course of isolation of a soluble fraction from human glomeruli, it was observed that rabbit antisera to this material contained a hæmagglutinin of considerable titre to human red cells. While initially only group O cells were evaluated, it soon became apparent that the hæmagglutinin was capable of also agglutinating group A and group B cells.

The procedure for the isolation of the soluble fraction from human glomeruli, to be reported in detail elsewhere, consists of isolating glomeruli from pooled human kidneys by Greenspon's method[3] and subjecting the glomeruli to trypsinization for 6 h at 37° C and storage in the cold overnight. The particulate material is removed by centrifugation and the supernatant subjected to treatment with trifluorotrichloroethane as described elsewhere[4]. The aqueous phase from this treatment is dialysed against water and then lyophilized.

Fig. 1 represents a double diffusion agar analysis of rabbit antisera directed against this extracted material. As can be seen, wells 1 and 2, containing two separate rabbit sera, indicate two reacting components present in the glomerular extract which is placed in the centre well. Wells 3 and 4, which show a single line, represent the same antisera as present in wells 1 and 2 respectively except that the antisera has been absorbed with human O, Rh negative cells to remove the hæmagglutinin.

Human O_h cells (suggested by Dr. Kurt Stern, University of Illinois Medical School, and kindly supplied by Dr. Philip Levine, Ortho Pharmaceutical Corp.) were evaluated against the rabbit anti-glomerular extract sera in an effort to determine the specificity of the hæmagglutinin. While the titres of the sera were not remarkably high, nevertheless agglutination occurred. Antisera developed against whole pooled human glomeruli exhibited much higher titres against all human red cells tested.

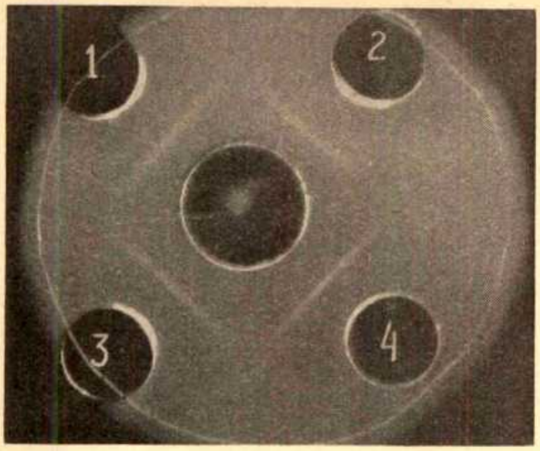

Fig. 1. No. 1. Rabbit anti-glomerular extract serum 45; No. 2, rabbit anti-glomerular extract serum 82; No. 3, rabbit anti-glomerular extract serum 45 absorbed with human O(H) Rh-negative cells; No. 4, rabbit antiglomerular extract serum 82 absorbed with human O(H) Rh-negative cells; centre well, glomerular extract 10 mg/ml.

Inasmuch as the starting material consisted of pooled kidneys, it is rather tenuous to conclude that the hæmagglutinin is directed against a component that is independent of the ABO system. Nevertheless, the hæmagglutinin can be removed by the use of any human A, B, O cell. That the hæmagglutinin may be due to contamination with red cell stroma cannot be absolutely ruled out except to point out that microscopic examination of the starting material is performed before trypsinization and also that a considerable amount of contamination would have to be present to contribute to the final, soluble extract.

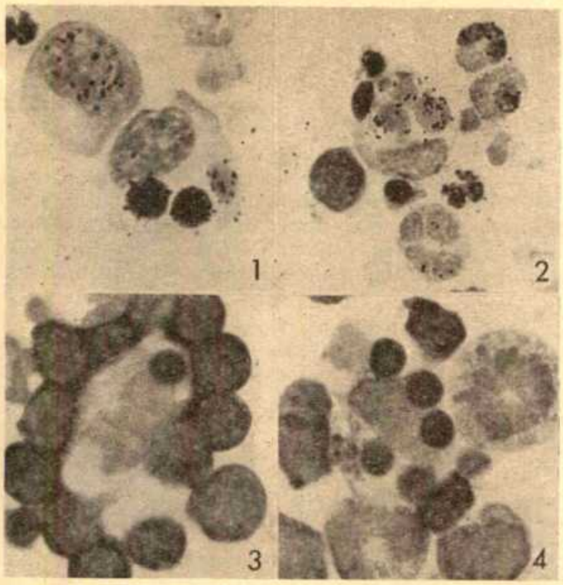
Nucleophagocytosis in Bone Marrow

INGESTED nuclear material has long been known within the reticular cells of normal lymphoid tissues and has led to the suggestion that the reticular cell may re-utilize lymphocytes and incorporate their deoxyribonucleic acid (DNA) into newly formed cells[1,2]. During autoradiographic studies of lymphocytes in the bone marrow, observations have been made on reticular cells including the ingestion of nuclear material labelled by the prior incorporation of tritium-labelled thymidine during DNA synthesis. Male Hartley guinea pigs weighing approximately 400 g were given a single, intraperitoneal dose of tritiated thymidine (1 μc./g body-weight: specific activity, 1·9 c./mM). After intervals of 25, 48 and 72 h humeral bone marrow was gently suspended in homologous serum and examined in smears. Autoradiographs of smears were prepared by coating with melted Eastman Kodak *NTB*[3] emulsion, exposing for 14 days and staining through the fixed emulsion with MacNeal's tetrachrome stain.

After each time-interval reticular cells could be found showing well-labelled bodies within their cytoplasm (Figs. 1 and 2). Even after the earliest interval some of these inclusions of labelled DNA appeared to be partially digested (Fig. 1) and, at later times, short strands of labelled material extended into the adjacent cytoplasm in some instances (Fig. 2). These appearances clearly indicate a true ingestion of nuclei which represent a population of cells with a notably short life span from DNA formation to phagocytosis. It is improbable that this phenomenon is merely a result of radiation damage as not all the nuclear inclusions were labelled. Furthermore, a special study of bone marrow preparations from healthy animals receiving no radioisotopes readily revealed a variety of reticular cells containing Feulgen-positive bodies within their cytoplasm (Figs. 2 and 3).

The precise identification of the inclusions rests, at present, on indirect morphological evidence. Some are small, round, dense bodies most readily interpreted as being the discarded pyknotic nuclei of late (orthochromatic) erythroblasts. Such nuclei, devoid of cytoplasm, may be seen in smears, both free and in the process of apparent extrusion from erythroblasts. Other inclusions stain less densely and are larger than the nuclei which normally appear to be lost by erythroblasts. These might represent the phagocytosis of earlier (polychromatic) erythroblasts *in toto*, possibly as a manifestation of 'ineffective erythropoiesis'[3], but attempts to show an association of the ingested bodies with hæmoglobin or its derivatives have been largely unsuccessful. Thus, Lepehne's reagent clearly demonstrates erythrocytes within the cytoplasm of reticular cells, but a stainable envelope around engulfed nuclei is seen only exceptionally. Moreover, no increased optical density is apparent when viewed by monochromatic light at wave-lengths approximating to that of Soret absorption of hæmoglobin (4150 Å), and the Prussian blue reaction reveals no satisfactory correlation with the presence of non-hæmoglobin iron. On the other hand, these nuclei resemble those of small lymphocytes in size and chromatin pattern where such features are not obscured by lysis. They also resemble the lymphocytic nuclei illustrated within phagocytic reticular cells in the lymphoid tissues[1,2] and it may be noted that the small lymphocyte forms a large population of cells in the bone marrow of this experimental animal[4]. If this identification is correct, it appears that certain small lymphocytes have a 'life-span' of only a few hours before being phagocytosed in the bone marrow. Labelled small lymphocytes do not appear in the thoracic duct lymph or the bone marrow until 2–4 h after tritiated thymidine, yet at 25 h they may be already partially digested within reticular cells (Fig. 1).

As individual reticular cells may contain as many as five or more ingested nuclei (Fig. 4), it is possible that the phagocytosis of lymphocytes occurs on a significant scale. The full extent of the phenomenon is difficult to determine because of the fragility of reticular cells and their characteristically uneven distribution in smears. In the single cell suspensions which are desirable for quantitative techniques[4] reticular phagocytes are infrequently seen. However, they are readily demonstrated in smears that have been carefully prepared after minimal agitation of the bone marrow suspension. Other fragile cell types, notably megakaryocytes, which are plentiful in histological sections of bone marrow but not



Figs. 1–4. Reticular cells containing ingested nuclei in bone marrow smears. (× *c.* 750.) Fig. 1. Autoradiograph, 25 h after tritiated thymidine, showing three labelled inclusions. Fig. 2, Autoradiograph, 72 h after tritiated thymidine, showing four ingested nuclei three of which are labelled and partially digested. Fig. 3. Rosette of basophilic erythroblasts. The central reticular cell contains one ingested nucleus. Fig. 4, Reticular cell containing five ingested nuclei and surrounded by erythroblasts and myelocytes

in routine smears, are also seen in greater numbers in those preparations.

The functional significance of the phagocytosis of small lymphocytes by bone marrow reticular cells is not known. It might merely represent the removal of effete or defective cells after a short and possibly functionless existence. Alternatively, the small lymphocyte may be making a specific contribution to hæmopoiesis in a manner analogous to the feed-back re-utilization theory developed for the lymphoid tissues. According to this view, lymphocytes are ingested by reticular cells which then become lymphocyte-forming cells[1,2], and, at least in antigenically stimulated tissues, the ingestion may occur after a very short life-span[5]. In the bone marrow, however, the immediate cellular relationships of the reticular cells make this less acceptable as a universal explanation. Although some phagocytic cells lie free in the bone marrow smears, many form the central cells of erythroblastic islets (Fig. 3), and others are closely related to a variety of myeloid and erythroid precursors (Fig. 4). Particularly in the case of erythroblastic islets, the relationships are so intimate that it may be difficult to discern a distinct line of junction between the cytoplasm of the reticular cell and that of the surrounding erythroblasts (Fig. 3). This no doubt contributes to the fragility of the reticular cell in smears and suggests the possibility that ingested lymphocytes may provide a source of DNA or other materials for the reticular cell, either for its own metabolism or to be passed out to the surrounding cells in a similar fashion to the ferritin transfer described by Bessis[6]. Such a mechanism might be increased in the event of a stimulus calling for an increased demand on reticular or stem cells. In recent long-term experiments Rieke[7] has noted an increased number and grain density of labelled bone marrow reticular cells in response to anæmia at a time when small lymphocytes appeared to be the only source of well labelled DNA. However, intermediate stages which might further support the hypothesis of lymphocyte incorporation have not yet been observed.

While the interpretation remains speculative, the present observations suggest that nuclear phagocytosis in the bone marrow includes a short-lived group of cells, possibly lymphocytic. If so, this would contribute to the turnover of the small lymphocyte population in normal and stimulated bone marrow.

RADIOBIOLOGY

Cæsium-134 in Man in Scandinavia

Lidén and Andersson[1] have demonstrated the presence of cæsium-134 in Laplanders from north Sweden and Finland. They suggest that a possible source of the cæsium-134 was the Windscale accident of October 1957. The activity of cæsium-134 in the Laplanders in 1961 was found to be 1·1–1·6 per cent of the activity of cæsium-137, and to attribute this to the Windscale accident it must be assumed that: (*a*) the activity emitted from Windscale contained one-third as much cæsium-134 as cæsium-137; (*b*) one-tenth of the cumulative fall-out of cæsium-137 in Scandinavia to mid-1961 was due to emissions from Windscale.

After the Windscale accident a considerable number of samples of milk, grass and soil were taken from the surrounding district and analysed by γ-spectrometry for iodine-131. Some of these samples, and others taken later, were afterwards analysed for some of the longer-lived activities, especially cæsium-137. Results of the iodine-131 and cæsium-137 surveys[2-6] show that the patterns of deposition of these two isotopes in the Windscale district were very similar. The ratio of activities of iodine-131 to cæsium-137 worked back to the time of the accident was close to 50 : 1.

Fig. 1 shows (*A*) the cæsium-137/barium-137m peak at 0·662 MeV as it appeared in a milk sample from a farm 14 km south-south-east of Windscale, and (*B*) the same peak given by a soil sample taken from a point 2 km from Windscale in the same direction. The milk was collected on November 11, 1957, and measured on December 6, 1957, by which time the ratio of iodine-131/cæsium-137 was about 1/2. On the high-energy side of the peak a small peak occurs at about 0·8 MeV, the height of which is about 2 per cent of the height of the 0·662 MeV peak. It is possible that this peak is due to cæsium-134 (major γ-rays 0·60 and 0·80 MeV; half-life 2·1 years)

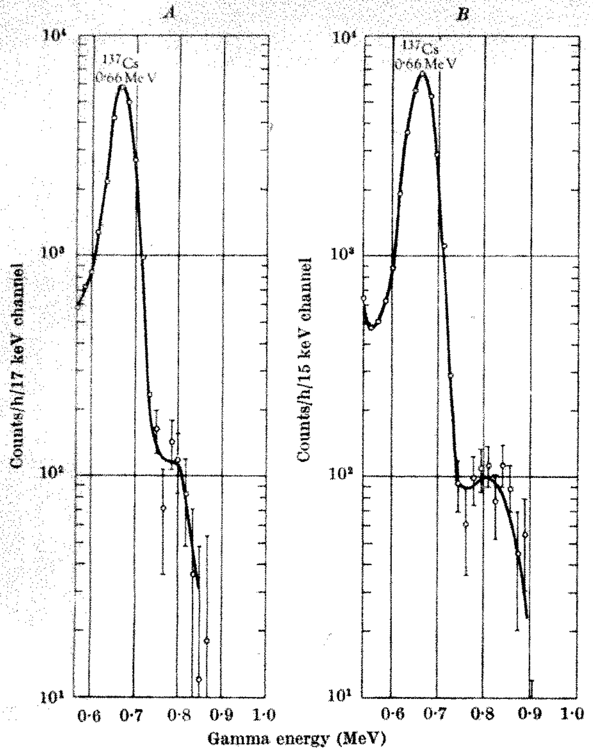

Fig. 1. *A*, Part of spectrum of 1 pint of milk collected on November 11, 1957, from a farm 14 km south-south-east of Windscale and measured on December 6, 1957. Cæsium-137 content of milk is 15 mμc/l.; *B*, part of spectrum of 3-kg sample of top soil collected in January 1961 from a site 2 km south-south-east of Windscale, and measured in June 1961. Level of cæsium-137 activity in soil is 240 mc/km^2

but this is not easy to confirm. The possible presence of the 0·60 MeV peak is masked by the 0·662 MeV peak of cæsium-137, together with a small contribution from the 0·64 MeV γ-ray of iodine-131.

The sample of top soil was collected in January 1961 and measured in June 1961; the naturally occurring activities in this sample have been subtracted from the curve using the spectrum of sub-soil from the same site, following the technique of Löw and Edvarson[7]. At the time of collection of this sample the zirconium-95/niobium-95 activity from weapon debris was very low, and did not contribute significantly to the counting-rate in the 0·76 MeV part of the spectrum. About 20 per cent of the observed cæsium-137 was due to weapon debris. Again a small peak appears in the spectrum at about 0·8 MeV, which is about 1·5 per cent of the height of the cæsium-137 peak; the accuracy of this 0·8 MeV peak is low because the statistics of the difference of these two curves are poor. Part of this peak may be due to manganese-54; but if it is all attributed to cæsium-134 deposited in 1957, back extrapolation suggests that the activity of cæsium-134 was about 4·5 per cent of that of cæsium-137.

From these two curves, which are typical of several obtained for milk and soil from the Windscale area, the activity of cæsium-134 released in the accident is known to be less than 5 per cent of the activity of cæsium-137, after correction for crystal efficiencies and γ-intensities from the recently published decay scheme[8]. It follows that the cæsium-134 found by Lidén and Andersson in Lapland cannot be attributed to Windscale, even if the assumption (*b*) above is correct.

The latter assumption is based on an interpretation by Hvinden and Lillegraven[9] of measurements of cæsium-137 deposition at Bergen; but it can be shown to be unlikely by consideration of the isopleths of cæsium-137 in soil around Windscale. The 20 mc/km^2 isopleth lay at an average distance of about 30 km from Windscale[6]. The cumulative fall-out of cæsium-137 at Bergen up to June 1961 was about 70 mc/km^2; if 7 mc/km^2 of this is attributed to Windscale it would imply that the deposition from the accident was reduced with distance by a factor of only 3 as the cloud travelled from about 30 km to 800 km.

Mutagenic Effect of X-rays on Moths

Müller *et al.*[1] conclude from their experiments on the mutagenic effect of X-rays on moths that: "If very low doses have any effect at all, then it must be much smaller than should be expected from the results of irradiation with higher doses". This is contradicted by the results they present in their Fig. 1 and Table 1.

Their regression curve based on effect proportional to square of dose, which holds at high dose-rates (their Fig. 2), extrapolates to about 40 mutations per 10^6 scales at 0 dose, so that no significant increase is found even at 40 r. However, the actual number found was 19 at 0, 22 at 10 r., so that there is a net increase of 20 at 20 r., 25 at 40 r. Calculated increases at 20 and 40 r. are 2 and 7 on their result of 202 mutations at 200 r., an effect proportional to square of dose.

The increase in mutation frequency for low doses is not less, but very much more than would be expected from the results of irradiation with higher doses.

Hugo P. Kortschak
Experiment Station,
Hawaiian Sugar Planters' Association,
Honolulu.

[1] Müller, I., Löbbecke, E. A., and Oltmanns, O., *Nature*, **194**, 78 (1962).

We certainly agree with Dr. Kortschak that there is a larger increase in mutation-frequency from 0–20 and 0–40 r. than would be expected from the dose-relationship at higher doses. But in his considerations he leaves out of account the very low, and repeatably low, value at 10 r., and the sentence quoted by him refers to these very low doses between 0 and 10 r., where only an insignificant effect was found. Somewhere between 10 and 20 r. there must be a steep increase in mutation-frequency, which might be a rather sudden step. The hypothesis is that there might be a protective mechanism, which is destroyed by doses between 10 and 20 r. However, this needs to be proved by extensive experiments and because of their hypothetical character these considerations were not included in the short communication.

BIOLOGY

Conversion in Plants of Benzoic Acid to Salicylic Acid and its βd-Glucoside

PREVIOUS investigations of the auxin metabolism in plant tissues led to the following findings of a ring hydroxylation resulting in 2-hydroxyindolyl-3-acetic acid[1,2], and a hydroxynaphthalene-1-acetic acid, which probably hydroxylated in the 8-position, and their glucosides[2]. Other known products of the auxin metabolism were the aspartic acid conjugates[3] and the βd-glucose esters[4,5] of the free auxinic acids. Analogues of the last two metabolites have also been described for benzoic acid[4,6]. In wheat coleoptiles no hydroxylation of benzoic acid could be demonstrated.

Using the method described earlier[4] etiolated *Helianthus* hypocotyls were incubated with 6×10^{-5} and 6×10^{-4} molar carboxyl-labelled benzoic acid. Hypocotyls were crushed directly on chromatographic paper '*S* and *S* 2043*b*'. The solvents used in chromatography were butanol / formic acid / water (10 : 1 : 2) for the first and isopropanol / ammonium hydroxide / water (80 : 15 : 5) for the second direction. The compounds labelled with carbon-14 were then detected by autoradiography of these paper chromatograms (Fig. 1). Besides the very large spot of the benzoyl-βd-glucose (*BGl*) and two hitherto unknown compounds (BX_1 and BX_4), it shows the free benzoic acid (*BA*), a very small spot of salicylic acid (*SA*), and a relative large spot of βd-glucosido-salicylic acid (*GlSA*). The glucoside was characterized by hydrolysis with emulsin. The hydrolysis products agreed with co-chromatographed authentic salicylic acid and glucose. The radioactivity and colour reaction with ferric chloride, and diazobenzene-sulphonic acid were in accordance with this phenolcarbonic acid.

Recently[7] gentisic and *o*-pyrocatechuic acid were found in leaves of various plants fed with salicylic acid. The same acids and *p*-hydroxybenzoic acid were formed in plants incubated with carboxyl-labelled benzoic acid[7]. Whether they did occur as free acids or as glycosides is questionable, because the investigations were carried out with acid-hydrolysed ethanol extracts of plant tissues. *Helianthus annuus* hypocotyls, *Solanum tuberosum* tubers, and *Pisum sativum* internodes and roots are able to form salicylic acid, and in much larger quantities βd-glucosidosalicylic acid from benzoic acid. No other phenolcarbonic acids or their glycosides in traceable amounts derived from benzoic acid.

In wheat coleoptiles no ortho hydroxylation of benzoic acid could be demonstrated. On the other hand, it was shown that wheat plants are capable of metabolizing salicylic acid to gentisic and *o*-pyrocatechuic acids[7]. Therefore, it seems that ortho hydroxylation of aromatic acids needs a specific reaction mechanism, while further hydroxylation appears a rather widespread and more unspecific reaction, presumably catalysed by polyphenoloxidases.

In the biosynthesis of coumarin[8] a high rate of conversion of cinnamic acid to βd-glucosido-*o*-coumaric acid was found. This glucoside has been discussed as a possible intermediate in the biosynthesis of coumarin. The same situation has been described for the synthesis of hydroxynaphthalene-1-acetic acid[2] and here of salicylic acid. But whether the glucosido-phenolcarbonic acids are intermediates or detoxification products is unknown. Due to its lactone ring, coumarin may be an exception; however, other phenolcarbonic acids are substrates for phenoloxidases. In the case of salicylic acid gentisic and pyrocatechuic acid, and possibly polyphenols, are formed. The glucosides of phenolcarbonic acids prevent this oxidation. Therefore, it seems that this property may be the general function of those phenol-glucosides. A balance favourable for this assumption is indicated by the fact that the quantitative relation between the free phenolcarbonic acids and their glucosides (about 1 : > 10) was always nearly the same, whether plants were fed with the free phenolcarbonic acids or their glucosides. The function of these glucosides is under investigation.

Antagonistic Effect of Urea and 2-Chloroethanol on the Resistance to High Salt Concentration in Wheat Seedlings

IT is considered that the ammonia produced by the hydrolysis of urea in the soil damages the roots of plants. Recently, Cooke[1] reported that at least one other factor may be operative in urea toxicity. Weber and Tanford[2] demonstrated that 2-chloroethanol strengthened the intramolecular hydrogen-bonding of ribonuclease and urea possessed the opposite character. The increase of resistance to high salt concentration by the seed treatment with dilute 2-chloroethanol solution was found by Miyamoto[3].

The present investigation deals with the antagonistic effect of urea and 2-chloroethanol on the resistance when their dilute solutions are applied to the wheat seed treatment.

Wheat seeds were soaked for 14 h at room temperature in the solutions which are indicated in Table 1. After the treatment, the seeds were spread on a filter paper and dried for 4 h. Control seeds were treated by water instead of the solution. A 200-g portion of sandy soil (*p*H 6·65) was placed in a Neubauer container and moistened by 25 ml. of water. Forty seeds were planted in the soil. At 6 days after the seeding, 3·0 or 4·0 g of ammonium nitrate in the form of 50 per cent solution was added on the surface of soil. The numbers of wilted plants were recorded and they were considered to be the criteria of the damage. Tests were replicated three times and the averages were calculated. The results are shown in Table 1.

Table 1. EFFECT OF SEED TREATMENT WITH UREA AND 2-CHLOROETHANOL ON THE RESISTANCE TO HIGH SALT CONCENTRATION IN WHEAT SEEDLINGS

Seed treatment (14 h)	Amount of applied NH_4NO_3 in g/200g soil	Wilted plants (%)		
		24*	48*	72*
0·06 % Urea	3	14·2	50·5	71·4
	4	32·9	69·3	88·6
0·08 % 2-Chloroethanol	3	0	12·9	20·4
	4	5·3	29·0	41·9
0·06 % Urea + 0·08 % 2-chloroethanol	3	7·3	28·4	38·9
	4	18·8	45·5	64·4
Control	3	6·3	27·6	40·4
	4	14·4	40·0	66·6

*Hours after the NH_4NO_3 application.

The results in Table 1 indicate that the seed treatment with 0·06 per cent urea reduces the resistance, and the effects of 0·06 per cent urea and 0·08 per cent 2-chloroethanol seed treatments are antagonistic. The seed treatment with 0·08 per cent ammonium nitrate solution did not influence the resistance, and no antagonistic effects between 0·08 per cent ammonium nitrate and 0·08 per cent 2-chloroethanol were observed. I consider that the weakening effect of urea on the intramolecular hydrogen-bonding of some macromolecular substance may be the reason for the decreasing of resistance, and it can be a factor other than ammonia in urea toxicity.

Gibberellin-like Activity of Kudzu Vine Extract

PLANTS sensitive to the application of gibberellin A_3 (gibberellic acid) respond in a number of ways; but the most characteristic one is that of elongation of the stem. This response has been demonstrated and reported by many workers[1–5].

A number of investigators have reported gibberellin-like activity in extracts from a variety of plants and plant parts[6–12]. Generally, a positive growth response of the bio-assay plant stem to the test extract has been accepted as an indicator for the presence of a gibberellin-like substance[6–9,12].

Among the plants assayed in the Merck Chemical Division laboratory in July of 1958 for the purpose of determining the occurrence of gibberellin-like activity of extracts of both flowering and non-flowering species[13] was the kudzu vine (*Pueraria thunbergiana*). This perennial plant, a member of the Leguminosae, is a very long-running, somewhat woody plant which has become established in many parts of south-eastern United States as a soil-erosion control agent and as a minor forage crop. Its rapid growth (50–100 ft. per season) suggested the possibility of its extract possessing gibberellin-like activity. The initial assay gave a positive growth response of relatively great magnitude.

The sample of kudzu vine used in preparing the extract was collected in Georgia. Only the first twelve inches of terminal stem of each runner of the vine was collected, and several pounds were sent by air mail express so as to reach the laboratory in a still succulent condition. The parts collected consisted of the stem proper, leaves and leaf petioles. Three hundred grams were prepared for extraction by maceration in a Waring blender. Distilled water was added to facilitate blending, and the amount used was noted. The *p*H of the resulting slurry was adjusted to 3·5 with 5 N hydrochloric acid. The initial extraction was conducted with ethyl acetate, added in an amount to give a 1 : 1 ratio with the water already present in the slurry. Steeping, filtering and separation of the water layer from the solvent followed. Two more extractions of the residue solids were made with ethyl acetate. The individual ethyl acetate filtrates were combined, and concentrated to 30 ml. by evaporation at room temperature. The water layer from the first extraction was similarly reduced to 30 ml. A non-ionic surfactant was added as 1 per cent of the total volume to each concentrate.

Investigations of growth activity of the extracts were initially conducted with the pinto bean seedling bio-assay method. However, the technique utilized was slightly modified from that given by Gray[14]. A volume of 0·01 ml. of each material was placed at the terminal of the seedling stem. Measurement of stem height at the inception of the test and again six days after application yielded data for comparison with measurements of control plants and of plants treated with standard potassium gibberellate solutions.

The results obtained with the ethyl acetate extract of the kudzu vine are given in Table 1.

Table 1. RESPONSE OF PINTO BEAN SEEDLING TO THE EXTRACT OF KUDZU VINE AS INDICATED BY STEM HEIGHT INCREASE

Material	Age of pinto bean seedling (days)	Vol. of solution applied (ml.)	Average increase in stem height (in.) six days after application
Check	14	—	0·56
Standard solution of potassium gibberellate, 1 p.p.m.	14	0·01	0·75
Kudzu vine extract	14	0·01	6·00
Check	20	—	1·62
Standard solution of potassium gibberellate, 1 p.p.m.	20	0·01	3·93
Kudzu vine extract	20	0·01	17·00

Additional assays with Pinto bean seedlings, dwarf pea seedlings and *dwarf*-1 maize[4] confirmed the presence of gibberellin-like activity in the extract of the kudzu vine. The water filtrate has given comparable activity.

The magnitude of the responses obtained with the extract had been exceptionally high, and a log of the concentration-height increase study indicated a gibberellic acid activity equivalency falling within a 10–100 p.p.m. range for a volume of 0·01 ml. of the initial ethyl acetate extract. This activity has not been equalled by other plant extracts showing positive growth responses.

An initial examination of the extract by chromatography developed a number of fluorescent bands, one of which paralleled the band of the chromatograph of standard gibberellin A_3 control. An eluant of the former band was assayed by means of the pinto bean seedling technique, and the resultant height increase was again indicative of a plant growth activity of a high order.

Subsequent chromatographic and biogrowth work with kudzu vine extracts confirmed the presence of a gibberellic acid-like substance. Visual comparison of the fluorescence on the chromatograms to standard gibberellic acid indicated an approximate level of 80–500 parts per billion[15].

Infection of Celery Seedlings by *Septoria* spp.

Celery seed often carries pycnidia of the fungi *Septoria apii* and *Septoria apii-graveolentis*. It is commonly assumed that spores from these pycnidia infect young seedlings, and that this is the most important way in which the diseases caused by these two fungi start each year. There are, however, the following reasons for doubting the validity of this assumption: (1) Seed treatment with fungicides does not satisfactorily prevent infection of celery seedlings, although similar treatments are effective in certain other diseases in which the fungi are seed-borne as pycnidia. (2) Infection of celery seedlings can, however, be prevented by treating infected seeds in hot water, a treatment known to be effective against certain fungi carried inside seed, for example, *Ustilago nuda* in wheat and barley.

These facts suggest that spores in pycnidia may be less important than has previously been supposed, and that seedlings become infected by parts of the fungi which are not carried superficially on the seed. We have obtained the following evidence in support of this hypothesis: (*a*) A considerable number of samples of heavily infected seed of different ages and from different sources were examined. In most of them no viable spores were found and only a few (*c*. 1 per cent) of the spores from the youngest seed, about 8 months old, germinated under optimum conditions. None of these samples had been treated in any way before it was examined. (*b*) Healthy seed were heavily contaminated with viable spores taken from young cultures of the two fungi. They were then sown in conditions favourable for infection of seedlings. None of the seedlings became infected. When seedlings of the same age, grown from uncontaminated seed, were sprayed with viable spores from cultures of the same type and age, almost all became infected. (*c*) Microscopic examination of seed carrying pycnidia showed that many contained hyphæ abundantly in the mesocarp; that in some the testa was invaded by hyphæ, and that occasionally the hyphæ had penetrated to infect the cotyledons. The hyphæ inside the seed have not yet been identified but microscopically they did not have any characteristics that would have precluded them from belonging to *S. apii* or *S. apii-graveolentis*.

Although the above facts do not preclude the possibility that seedlings become infected from the occasional spore that remains viable in infected seed, they do strongly suggest that more frequently seedlings become infected from mycelium carried within the seed.

Differential Synthesis of Nucleic Acids in Sexual Differentiation of *Allomyces*

What could well be the final expression of a fundamental, sex-determining antagonism between deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) biosynthetic pathways has found a first chemical confirmation in our recent measurements of the percentage values of the DNA/RNA ratios in the gametes of the water mould *Allomyces*[1].

As expected from the cytological data (selective multiplication of the male nuclei[2]), the DNA/RNA ratio was found to be higher in the males (12·8 per cent) than in the females (6·9 per cent)[1]. Thus, it remained to follow the evolution of this nucleic acid ratio from the initial, undifferentiated hyphæ through the progressively differentiating male and female gametangia, in an attempt to determine, chemically, the crucial point of appearance of the diverging values of the ratio.

Male and female hybrid strains of *Allomyces macrogynus* × *A. arbuscula*[3] have been grown, at 25° C, in 50 ml. of either of the modified glucose–yeast extract (*GY*) solutions[4]: G_2Y, namely that containing twice the concentration of glucose (6 g/l.) and half that of yeast extract (Difco, 0·5 g/l.), which favours quick and relatively synchronized differentiation of the gametangia; glucose–casein–yeast extract (*GCY*) solution, with normal glucose (3 g/l.) but only 0·1 g/l. yeast extract and a supplement of 3 g/l. casein hydrolysate (Difco), favourable to vegetative growth and slowing down differentiation[5]. Through continuous agitation of the cultures, each small block of inoculum (12 per flask, cut from gametophytes grown on plates of 'YpSs' Difco medium[6]) gives rise to a mycelial ball of radially disposed hyphal tips which are starting to differentiate their gametangia earlier (second day on glucose–yeast extract, G_2Y solution) or later (third day on glucose–casein–yeast extract, *GCY* solution). Improved synchronization of the last stages of gametangial differentiation could be achieved by dipping young mycelial balls in the discharge, hypotonic saline solution[7]. Finally, the balls of each sex were pooled and their developmental stage[2] controlled under the microscope before drying them between pieces of blotting paper, measuring their fresh weight and keeping them in the freezer until analysis.

For the nucleic acid analyses, we have combined the principles of the classical methods[8], according to the following procedure: (1) initial grinding of the frozen balls in cold, 10 per cent trichloroacetic acid (TCA)[9], followed by successive washings of the residue with cold, 5 per cent TCA and twice with a chloroform/ethanol mixture (1 : 3) to remove lipids (and male carotenoids); (2) hydrolysis of the dried residue in 1 N potassium hydroxide at 37° C overnight[10]; exact neutralization of the hydrolysate with HCl has preceded the precipitation of DNA and protein with 2·5 per cent TCA (final) + hydrochloric acid 0·6 N, hydrolysed RNA remaining in the supernatant; RNA was determined on an aliquot of this TCA supernatant, using the orcinol, colorimetric (660 mμ) method[11,12], against a standard curve of pure RNA (Fluka AG., Buchs, Switzerland) and each time with a renewed standard of 10 μg/ml. (3) DNA was selectively extracted from the residue (2), with 0·5 N perchloric acid[13] for 20 min at 70° C, followed by washing with cold 2 N hydrochloric acid (puriss., Merck Co.). Finally, DNA was determined at 260 mμ with a model *DU* Beckman spectrophotometer, in the perchloric acid–hydrochloric acid solution and against standards of pure DNA (Fluka AG.), dissolved in the same solvents also used as blank.

Table 1

Developmental stage of *Allomyces* (statistically predominant)	Nucleic acid ratios* DNA/RNA (per cent)		RNA/DNA	
	♂	♀	♂	♀
Vegetative hyphæ + club-like progametangia (*GCY*, 3 days)	8·5	10·5	11·8	9·5
Young gametangia† in early maturation (G_2Y, 3 days)	8·9	9·2	11·2	10·9
Mature gametangia‡ + free gametes (G_2Y, 4 days and 2 h in hypotonic saline solution)	11·9	6·1	8·4	16·4

* Average values from four experiments.
† Traces of carotenoids in the males.
‡ γ-Carotene-rich males.

As shown by the results summarized in Table 1, the final, sex differential values of the DNA/RNA ratios (per cent) in the mature gametangia (gametes liberation stage[2]) correspond closely to those previously measured in the free gametes of *Allomyces*[1], male values averaging 1·5–2 times higher than the female ones. Moreover, the origin of this final, higher value in the male gametes can now be traced back to the first maturation stage of the gametangia, characterized by the differential multiplication of the male nuclei[2,5,14].

In the female gametangia, the DNA-level can be considered as stationary, or, at the most, as slightly increasing as no, or only few, mitoses are elevating the given number of nuclei initially incorporated in the gametangial cytoplasm at the septation stage[2,14]. Consequently, the sharp drop in the DNA/RNA ratio in the female gametangia must result from an increase in the RNA-level as more clearly shown by the developmental evolution of the RNA/DNA ratios (Table 1, 2nd col.).

The sharp increase in the RNA/DNA values in the mature female gametangia provides direct, chemical evidence in favour of my previous assumption, mainly drawn from cytochemical observations[15,16], that differential, active RNA synthesis coincides with the formation of the basophilic nuclear caps in the mature gametangia. This has found additional support in my recent measurements of the increasing RNA/protein ratios in the maturing female gametangia[17].

By contrast, the RNA synthesis must be much less important in the male gametangia as shown by their final low RNA/DNA ratios and confirmed cytologically by the thinness of their gametic nuclear caps[18].

Occurrence of the Genus *Archigetes* in Britain

DURING the course of investigations into the taxonomy and ecology of aquatic Oligochaeta we have observed two species of *Archigetes*, a genus not to our knowledge previously recorded from Britain. *Archigetes appendiculatus* Mrazek, 1897 (non Ratzel, 1868) was first observed in a specimen of *Limnodrilus hoffmeisteri* Claparède, 1862 obtained from a Liverpool pet shop along with a large number of uninfected 'Tubifex' worms. The same species

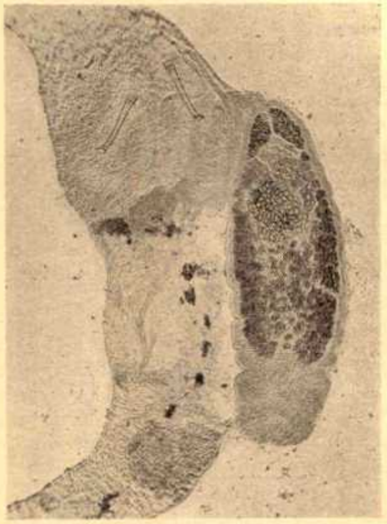

Fig. 1. *Archigetes appendiculatus* in the genital segments of *Limnodrilus hoffmeisteri*. Both host and parasite are sexually mature, eggs being clearly visible in the uterus of the parasite. Note the separation of the vitellaria into four distinct lobes. (× *c*. 17)

of parasite was later found in a pond near Fornalls Green Lane, Meols, Cheshire, on May 28, 1959. A second species *A. sieboldi* Leuckart, 1869, also from *L. hoffmeisteri*, was found from the Shropshire Union Canal near Chester on March 20, 1962. The cestodes were readily identified from recent descriptions of the genus[1,2]. In each instance the parasites were located in the genital segments of the tubificids. Both specimens of *A. appendiculatus* had eggs in the uterus (Fig. 1), while two specimens of *A. sieboldi*, from one oligochaete, contained no eggs.

At present we are collecting further data on the incidence and occurrence of *Archigetes* and other cestode parasites of Oligochaeta. We should appreciate correspondence with other workers who may find such material during the course of their studies on related fields of freshwater biology.

Presence of Istiophoridae along the South Atlantic and Mediterranean Coasts of Spain

As a result of a co-operative undertaking of the Laboratorio del Instituto de Investigaciones Pesqueras of Cadiz with the Marine Laboratory of the University of Miami, carried out by us during the years 1960 and 1961, twenty-one specimens of Istiophoridae were obtained, of which nineteen were *Tetrapturus albidus*. Two of the twenty-one specimens were not identified and are not dealt with here. Some of these fish were captured on lines operated by fishermen for the capture of the swordfish (*Xiphias gladius* L.) off the south Atlantic coast of Spain and Portugal, and in the Straits of Gibraltar. The balance of these fish were caught in the tuna-trap (Almadraba). 'Nueva Umbria', situated off the town of Isla Cristinal not far from Huelva, on the south Atlantic coast of Spain, and in the trap 'La Atunara', situated off the town of La Linea, in the Mediterranean Sea, just east of the Straits of Gibraltar. Table 1 shows the catches of the 19 specimens identified as *T. albidus*.

In October 1961 Dr. C. Richard Robins, of the Marine Laboratory of the University of Miami, confirmed, at Cadiz, the identification of nineteen of the specimens as *T. albidus* Poey (= *Makaira albida* (Poey) of some authors). Dr. Robins is investigating the other two specimens still further before identifying them.

In the Spanish literature *Tetrapturus belone* Rafinesque and *Makaira nigricans* Lacepede have been recorded from the coast of northern Spain and the Balearic Isles for the former and off the southern coast for the latter. Fernando de Buen[1] reported *M. nigricans* taken at Isla Cristina in August 1923, giving little descriptive data. Again[2] this author recorded *M. nigricans* on the south Atlantic coast of Spain and *T. belone* in the north of Spain and the Balearic Isles. Luis Lozano y Rey[3] identified the fish recorded by de Buen in the north of Spain and from Isla Cristina with *T. belone* Rafinesque.

We doubt the validity of the identification of *T. belone* Rafinesque in the above papers, with the possible exception of the listing of this species for the Balearic Isles by de Buen[2]. In fact, we agree with Robins and de Sylva[4] that a survey of all literature referring to the Istiophoridae reveals no certain record of *T. belone* from the eastern Atlantic exclusive of the Mediterranean Sea.

We believe that this is the first report in the literature of *T. albidus* from the southern Atlantic and Mediterranean coasts of Spain, with the exception of a statement in Tortonese[5] which in part reports a statement by the junior author referring to some of the above 19 specimens.

The common or vernacular names of these fish on the south Atlantic coast of Spain vary from west to east as follows: Isla Cristina, 'pez aguja'; Huelva, 'alfiler'; Barbate, 'cometa'; Algeciras, 'salton'.

We thank Mr. Antonio Solano, of the Consorcio Nacional Almadrabero, for his co-operation and the

MICROBIOLOGY

Bacterial Growth at Low Population Densities

ACCEPTING Monod's[1] formulation of the relationship between growth-rate (μ) and the concentration of the limiting substrate (s), Herbert *et al.*[2] calculated the latter for steady-state conditions in the chemostat as:

$$s = K_s \frac{D}{\mu_{\max} - D} \qquad (1)$$

where D is the dilution-rate (equal to the growth-rate), and K_s and $\mu_{\max}$ are growth constants. The concentration of cells produced (x) must be nearly proportional to the consumption of the substrate ($s_r - s$, s_r being the concentration of the growth-limiting substrate fed into the chemostat), when s is very small as compared with s_r:

$$x = y\,(s_r - s) \qquad (2)$$

or

$$x = y\left[s_r - \left(K_s \frac{D}{\mu_{\max} - D}\right)\right] \qquad (3)$$

where y is the yield coefficient which is constant at a given growth-rate. Since s is also constant at a given growth-rate and independent of s_r (ref. 3), x theoretically follows the broken curve in Fig. 1 at low values of s_r. When washout of the population occurs ($x = 0$), s_r and s become identical and can be taken as the relative threshold concentration of the limiting substrate for growth of a particular organism depending upon the growth-rate given. This was checked experimentally.

Approaching the washout of a population in the chemostat by lowering s_r at a fixed dilution-rate met with the difficulty of determining low population densities. *Spirillum serpens* did not tend to wall growth and exhibited considerable constancy of cell width and amplitude at a fixed growth-rate. With this particular organism, the calculation of cell mass after counting cell units of equal size on membrane filters has been found to yield results of sufficient accuracy down to concentrations of 10^7 cells or 0·1 mg dry weight per litre. The organism was grown in a basic mineral medium containing ammonia as the nitrogen source and lactate as the growth-limiting factor. The constants were at 20°: $\mu_{\max} = 0·34$ h^{-1}, $K_s = 2·2$ mg lactate/l., and $y = 0·42$.

When s_r was lowered stepwise at a fixed dilution-rate of $D = 0·5\ \mu_{\max}$ (where s is equal to K_s), cell concentration x adjusted to constant values according to equation (3). Below approximately 1 mM of lactate in the inflowing medium, however, the drop of x began to deviate from theoretical values as indicated by the solid curve in Fig. 1. From each point on this curve, a different value for s has been calculated by rearranging equation 2:

$$s = s_r - \frac{x}{y}$$

The lowest population that could be maintained at a constant level indicated a final washout at a threshold concentration of 12·8 mg lactate/l. (s_e). That is, about six times as high as the theoretical value.

Since the inconstancy of K_s is unlikely, it must be assumed that the growth limitation has changed. From several observations it can be concluded that growth-stimulating interrelationships between the cells occur as a consequence of the decreasing population density. If this is true, any external factor displaying the corresponding beneficial effect pertaining to growth of the population can be expected to lower the experimental threshold concentration of the growth-limiting substrate regardless of its nature. This has been demonstrated by decreasing the concentration of dissolved oxygen in a steady state culture of a microaerophilic *Spirillum*, where cells acted as reducing agents. This treatment not only

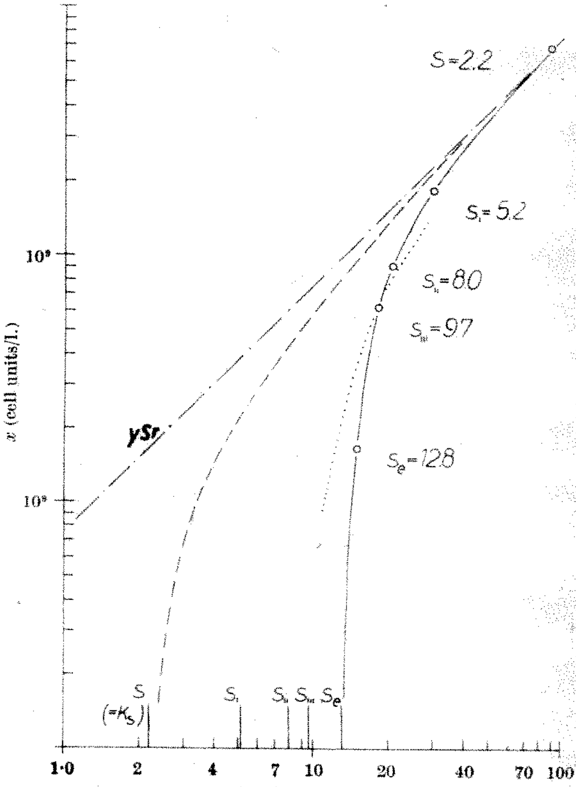

Fig. 1. Decrease of population density in the chemostat with decreasing concentration of the growth-limiting substrate in the inflowing medium. The experimental values (solid curve) deviate from the theoretical values (broken curve). From each point a specific value between s and s_e is calculated

lowered the experimental threshold concentration of the limiting substrate, but also the amount of the inoculum necessary to start growth of the population in batch culture. There are similar observations reported in the literature; for example (ref. 4), a reduced carbon dioxide production by a culture at low population densities may decrease the effectiveness of an inducer of β-galactosidase.

The determination of the experimental threshold concentration has been repeated at various dilution-rates. The deviation between theoretical and experimental values was found to increase with a decreasing growth-rate. This fact supports the concept of growth-stimulating interrelationships between cells of a bacterial population in a medium which does not meet all the requirements for growth of the single cell. This internal factor becomes growth limiting when the population density drops below a certain value. From this point of view, the existence of an *absolute* threshold concentration of the growth-limiting substrate is conceivable, below which an organism is unable to grow at any dilution-rate.

Fimbriæ and Hæmagglutinating Properties in Strains of *Proteus*

FIMBRIATION and the hæmagglutinating pattern of 21 strains of *Proteus mirabilis*, 10 of *P. vulgaris* and 20 strains each of *P. morgani* and *P. rettgeri* have been investigated. The strains of *P. hauseri* were those previously used[1] and were either in the *Y*, *W* or *R* phases[2]. The *morgani* strains comprised 12 recently isolated local strains and 8 (Nos. 232, 235, 1707, 2815, 2818, 5845, 7381 and 10041) obtained from the National Collection of Type Cultures, Colindale, London. The *P. rettgeri* consisted of N.C.T.C. strains Nos. 7475, 7476, 7477, 7478, 7479, 7480, 7481 and 8893 and 12 local strains. Methods used were those of Duguid and Gillies[3]. Broth cultures were started from stock agar slopes and incubated at 37° C and at room temperature. Erythrocytes of fowl, sheep, horse, guinea pig, rabbit, man and ox were used and the hæmagglutination pattern of 20 serial 48 h broth cultures of each strain was determined.

All strains of *P. hauseri* became hæmagglutinating after 1–3 sub-cultures in broth at both temperatures. At this stage fowl and sheep cells were strongly agglutinated. Horse and guinea pig cells weakly and rabbit, man and ox cells were scarcely ever agglutinated and then only weakly. Our results, though showing the same tendency, differed from those of Duguid and Gillies[4] and Shedden[5] in not showing such a diffuse spectrum. The former workers did, however, encounter a few strains which were inactive for rabbit, human and ox cells. With further sub-cultures the spectrum tended to become narrower, and by the 10th and subsequent examinations all strains agglutinated only fowl, sheep and horse cells. Tests with the latter cells were often only weakly positive. *Y*, *W* and *R* variants had the same hæmagglutinating properties. Shedden[5] found his *B* phase cultures (which correspond very closely to our *W* variants) to be non-hæmagglutinating. All strains of *P. morgani* became hæmagglutinating after 2 or 3 sub-cultures at both temperatures. The pattern at this stage corresponded closely to those presented for *Proteus* strains by Duguid and Gillies[4] and for *P. hauseri* by Shedden[5]. Tests with ox cells were, however, only weakly positive or negative. At about the 10th sub-culture the spectrum characteristically narrowed and tests were afterwards only positive with fowl, sheep, horse and guinea pig cells. It would appear that under the conditions of growth used, further variants of *P. hauseri* and *P. morgani* are selected which determine the final agglutinating pattern of the culture. The hæmagglutinating property of strains of *P. rettgeri* differed from those of other *Proteus* groups in that all strains developed hæmagglutinating ability earlier (2nd or 3rd sub-culture) in broth at room temperature than at 37° C (6th–10th sub-culture). Secondly, the hæmagglutinating pattern differed from the other *Proteus* groups in that erythrocytes of all 7 vertebrate species used were agglutinated to the same degree—usually fairly strongly positive—and the pattern did not vary with further sub-cultures in broth.

The hæmagglutinating activity of *P. rettgeri* and *P. morgani* was the same when tested at 4°, 22°, 37° and 55° C. The hæmagglutinins of these two groups were cell-bound and non-diffusible and were not affected by acetone or 95 per cent alcohol but were completely destroyed by boiling at 97° C for 2 min. Agglutination of red cells by *P. morgani* and *P. rettgeri* is not inhibited by D-mannose. In all these respects the hæmagglutinins of these groups resemble those of *P. hauseri*[5]. Non-hæmagglutinating variants of *P. rettgeri* could be selected by serial platings on agar incubated aerobically at 37° C. This variation has been demonstrated for strains of *P. hauseri* and *P. morgani* by Duguid and Gillies[4]. Electron microscopy showed organisms of hæmagglutinating strains of *P. morgani* and *P. rettgeri* to be perifimbriate with denser aggregations at the ends. The fimbriæ are about 0·01μ in width and 0·5–2μ in length (Fig. 1). These fimbriæ have similar distributions and dimen-

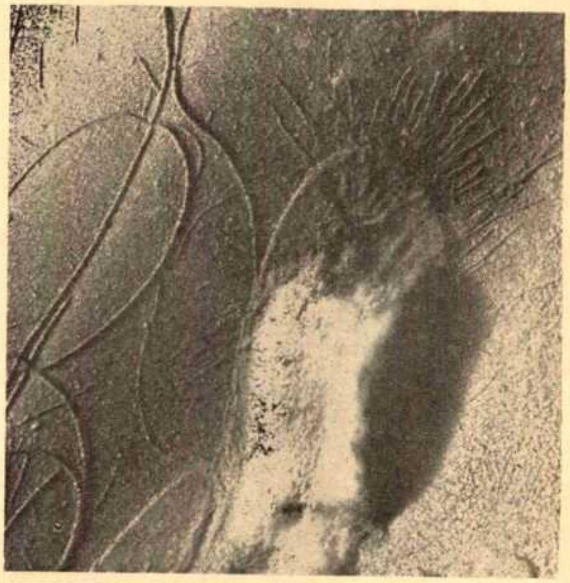

Fig. 1. Electron micrograph of *P. rettgeri* N.C.T.C. No. 7481. Numerous fimbriæ and a few flagella are present. (× *c*. 41,250)

sions to those of *P. hauseri*[5]. Non-hæmagglutinating variants of these organisms showed no fimbriæ.

P. morgani and especially *P. rettgeri* differ in many respects from *P. hauseri*. This investigation was an attempt to discover more differences and has been only partly successful. Although differences in the hæmagglutinating pattern between *P. hauseri* and especially *P. rettgeri* were demonstrated, the 3 groups of organisms were found to have hæmagglutinins with many similar physical properties.

GENETICS

Demonstration of Antigenic Difference between the American Bison (*Bison bison*) and Domestic Cattle (*Bos taurus*)

THERE are reports[1-4] demonstrating that antiserum produced against the erythrocytes of one species which react with the cells of a closely related species may be made specifically reactive with the homologous cells by absorption with cells of the related species. Hence, one might expect that this method should differentiate the cells of all, or nearly all, related species.

Stormont *et al.*[5] have demonstrated the homology of nine genetic systems of cattle blood groups with those of bison. Owen *et al.*[6] were unable to demonstrate clearly definite differences between cattle and bison blood groups by means of cross-absorptions of hetero-immune (rabbit) antisera. This communication describes a reagent which reacts specifically with bison cells and which shows no cross-reactivity for cattle cells. A brief description of this reagent has appeared elsewhere[7].

Rabbits were immunized with bison bloods obtained from Wichita Mountains Wild Life Refuge, Cache, Oklahoma, through the courtesy of Mr. E. J. Greenwalt. After appropriate absorption with cattle cells, the resulting pooled antisera were tested against the erythrocytes of cattle, bison, cattle-bison F_1 hybrids and back-cross hybrids (B_1) in which the F_1 hybrids were back-crossed to cattle. All tests indicated that this reagent was specific for bison cells. Additional evidence obtained by two other groups of workers using this reagent confirmed these data, indicating that this reagent was bison-specific in its hæmolytic reactions. The number of animals tested by these two groups and by us exceeds 2,000 cattle, all negative (including animals of both dairy and beef breeds); some 400 bison, all positive (from 2 different herds). Table 1 shows the reactions of this reagent with the cells of each of these two species as well as with those of 13 F_1, 46 B_1, a number of second-generation back-cross hybrids (B_2) and a variety of hybrids from *inter se* matings of back-cross hybrids. These bloods were made available to us by Dr. S. L. Scheinberg, who obtained them through the courtesy of Drs. Peters and McArthur, Dominion Agricultural Experimental Station, Manyberries, Alberta. The data were consistent with the supposition that this reagent detected an erythrocytic antigenic specificity, or, more probably, at least two and possibly three specificities present in bison but absent in cattle. As shown in Table 1, all F_1 hybrids reacted. Furthermore, the segregation pattern of the B_1 hybrids suggested that at least three factors were present. Of the 31 B_1 individuals tested with both dilutions (¼ and 1/16), 27 were positive with one or both dilutions and only 4 were negative with both dilutions. This is a highly significant deviation ($P = 0{\cdot}01$) from 1 : 1 segregation and is consistent with the 7 : 1 ratio expected for a three-factor segregation. Unfortunately, at the time these investigations were made, sufficient volumes of the cells of various B_1 hybrids were not available for the necessary cross-absorptions of this reagent to establish whether the antiserum could be fractionated into two or more components.

Table 1. REACTIONS OF BISON-SPECIFIC REAGENT WITH THE ERYTHROCYTES OF CATTLE, BISON AND VARIOUS HYBRIDS

Groups tested	No. per reaction type	Reaction with bison-specific reagent, diluted 1/4	Reaction with bison-specific reagent, diluted 1/16
Cattle	300	0	0
Bison	200	+	+

Inter se hybrids	2	+	+
	2	+	±
	5	0	0
	9		

Degree of hæmolytic activity: strongly reactive (+); weak but definitely reactive (±); no detectable reaction (0); not tested (nt).

The results clearly show a serological difference between cattle and bison blood group factors. Scheinberg[8], using bison-cattle hybrids, detected at least one serum protein specificity which also distinguished bison from cattle, although previous results by others were negative[9,10]. The differences in both cells and serum, however, should not affect the decision to classify these two species in the same genus as recently proposed by Stormont, Miller and Suzuki[5]. There are numerous cases reported of blood group systems which distinguish between individual species of the same genus[11].

We thank Drs. W. H. Stone and M. R. Irwin for the extensive test on the specificity of this reagent carried out at the Department of Genetics, University of Wisconsin. We also thank Drs. W. J. Miller and C. Stormont, School of Veterinary Medicine, University of California, Davis, for their analysis of an aliquot of this bison-specific reagent.

This project was supported in part by the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation and in part by a research grant *E* 1643 to M. R. Irwin and W. H. Stone from the Department of Health, Education and Welfare of the National Institutes of Health, Public Health Service.

Mutagenic Effectiveness of Ethyl Methanesulphonate and Methyl Methanesulphonate in Barley

THE monofunctional alkylating agent ethyl methanesulphonate (EMS) has been shown to be capable of producing mutations in more than one-half of the spikes of treated barley plants[1,2]. Smaller mutation frequencies (7·8 per cent, 16 per cent) have been reported for populations treated with methyl methanesulphonate (MMS). We wished to compare, under similar conditions, the mutagenic efficiency of EMS ($CH_3SO_3C_2H_5$) with that of MMS ($CH_3SO_3CH_3$). Since MMS is rather highly toxic to plants we were forced to use, in this comparative study, low concentrations of the chemicals and short exposure periods.

Dry seeds of barley (*Hordeum vulgare* L.) variety Montcalm were treated with freshly prepared non-buffered aqueous solutions of EMS, *p*H 3·8, and MMS, *p*H 3·7, at 20° C. After the treatment with the chemical the seeds were washed with tap water, surface dried and sown immediately in well-watered greenhouse beds. Chlorophyll mutations appearing in the M_2 (offspring of the treated plants) were classified according to the method of Gustafsson[3].

Table 1. SURVIVAL IN M_1 AND CHLOROPHYLL MUTATIONS IN M_2 AFTER TREATMENTS WITH EMS AND MMS

Treatment	No. of seeds	No. of plants maturing	No. of M_1 spikes	No. of chlorophyll mutations	Mut. per 100 M_1 spikes	Mut. per 1,000 M_2 seedlings
EMS 0·2% by vol., 2 h, 20°C.	300	161	321	12	3·7	7·5
MMS 0·2% by vol., 2 h, 20°C.	300	102	212	69	32·5	57·0

With the similar concentrations and treatment times MMS was more efficient than EMS in inducing mutations (Table 1). The mutation-rate reported here with MMS is about twice as high as the maximum reported previously. Differences in the treatment methods are probably responsible for this difference in effects. A considerably larger dose of EMS than was used here is required to induce mutations at a rate similar to that obtained with MMS in this experiment.

This investigation was supported by a grant from the National Research Council of Canada.

MISCELLANEOUS

Holey Films for Electron Microscopy

VARIOUS methods have been described[1] for the production of holey films required either for specimen support or astigmatism-correction purposes. Some of these methods are rather involved, and all can apparently produce pseudo-holes which are often difficult to detect and therefore very misleading.

A simple method in which films are formed from an emulsion of glycerol in 0·25 per cent 'Formvar' solution has been found reliably to produce holes ranging from about 0·05 to 25μ diameter. This size-range adequately covers all known electron microscopy requirements from astigmatism correction to the support of thin sections. The films are cast on microscope slides and after being allowed to dry for 10 min are exposed to a jet of steam for 1 min. They are then handled and mounted on grids in the usual

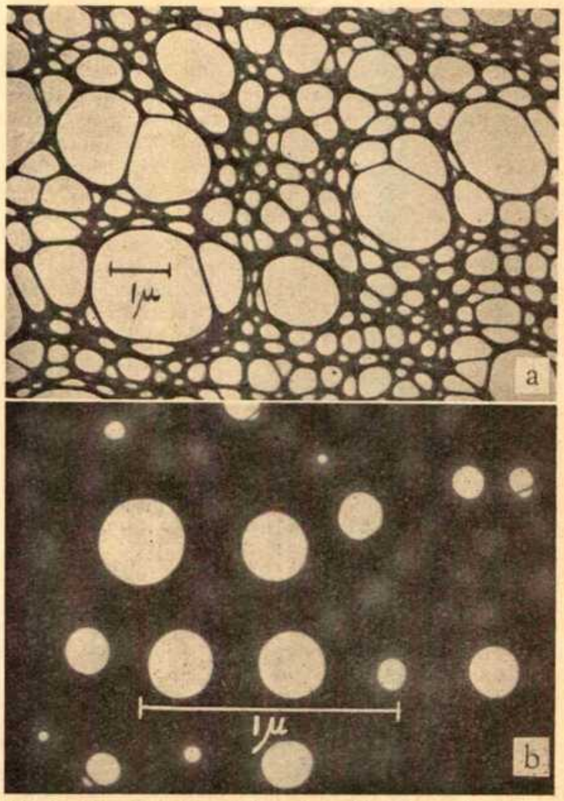

Fig. 1. Holey films formed from glycerol in 'Formvar' solution. *a*, 32 parts 'Formvar', 1 part glycerol; *b*, 120 parts 'Formvar', 1 part glycerol

Table 1

'Formvar' solution	Glycerol	Maximum hole diameter (μ)
8 parts	1 part	25
16 ,,	1 ,,	14
32 ,,	1 ,,	7
120 ,,	1 ,,	4

manner for films cast on glass and finally coated with carbon. Steaming of the cast film before it is dry will result in the formation of a multilayer meshwork which will contain many pseudo-holes.

The glycerol content controls the number of holes and also their size (Table 1), and therefore permits films to be made best suited to the particular requirement. Films made by this method are stable in the electron beam and sufficiently robust to permit such operations as the staining and washing of biological specimens.

Storage of Standardized Radioactive Solutions

A recent communication, Hamilton[1], directed attention to changes in concentration of standardized solutions stored in polythene bottles caused by transpiration. The conclusion was drawn that 'Pyrex' or quartz containers were necessary for the storage of such solutions to prevent loss of water.

Radioactive solutions were originally stored here in glass vials, but these have been replaced by polythene ampoules of 6 ml. or 40 ml. capacity[2]. Less adsorption of inorganic material from solution occurs in polythene and the ampoules, being unbreakable, are safer to handle. If the neck of the ampoule is drawn into a fine capillary, solutions may be easily drawn into or expelled from the container. The ampoule is perfectly sealed by melting gently the tip of the capillary and closing it by pressing with a pair of tweezers. Permanent labelling of polythene is easily accomplished with a hot wire.

The results of a series of international intercomparisons on radioactive counting techniques indicated that specific activity of solutions was increasing with time. This increase was attributed to transpiration from the polythene ampoules in which the solutions were transported. To test this theory several ampoules containing various quantities of water or dilute nitric acid were sealed and stored open to the atmosphere, but shielded from draughts. Monthly weighings over a period of one year showed that a fairly regular loss in weight occurred in the ampoules (Fig. 1). As one would expect, the loss varied with the wall thickness and surface area of the ampoules, but was independent of the volume of solution. This means that the concentration of the solution increases faster in ampoules containing smaller amounts of solution. Rates of change of up to 8 per cent per annum have been observed.

Rather than lose the advantages of polythene by reverting to glass vials the transpiration was reduced to acceptable levels by storing the ampoules in an enclosed space over water. A desiccator in which the desiccant is replaced by water makes an ideal store. Results already obtained (dashed lines in Fig. 1) show that no appreciable loss of weight occurs. As it might be argued that constancy of weight does not necessarily imply constancy of concentration, a direct experiment is also being carried out on cobalt-60 solutions.

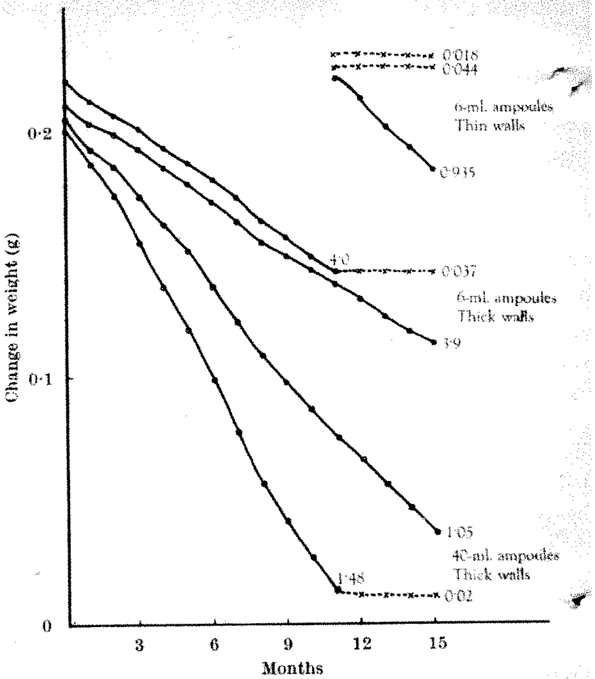

Fig. 1. Change in weight of polythene ampoules during storage. Total percentage change is given at the end of each storage period. ○, stored open to atmosphere; ×, stored over water

[1] Hamilton, E., *Nature*, **193**, 200 (1962).

[2] Herrington, J., and Vallis, D. G., *Chem. and Indust.*, 808 (1957).

The volume of standard solutions used in isotopic geological age investigations range from 100 to 1,000 ml., the latter being the most common. Keith's conclusions seem admirable for small volumes of solution. In my previous work similar experiments were carried out, but were discontinued for the following reasons:

(*a*) Preliminary experiments using radioactive traces indicated that over long periods of time the polythene walls of the bottles acted as a semi-permeable membrane. As the standards were stored in acid solution the use of an enclosed volume of water-vapour to reduce transpiration seemed inadvisable.

(*b*) The use of water in an enclosed space may require temperature control to prevent condensation of water vapour on the polythene and its adsorption into the outer walls of the polythene bottles, thus forming conditions suitable for osmotic transfer.

If the migration of acid out through the polythene walls is impossible then it is possible to flame spray the polythene with an impervious layer of zinc metal (private communication from Imperial Chemical Industries, Ltd.), or some other material. In this laboratory quartz bottles with ground stoppers are now used and variations of standard concentrates are being observed.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 5

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. D. E. Broadbent. "Theories of Short-Term Memory"

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. C. de Jager (University of Utrecht). "The Emission of Gas by the Sun".*

Institution of Mechanical Engineers, Steam Plant Group (at Nevill Hall, Westgate Road, Newcastle upon Tyne), at 6 p.m.—Meeting on "Some Design Problems arising in the Development of Very Large High Speed Turbines".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—Mr. H. Gibb· "Rituals of Rice" (Colour films with commentary).

Royal Institute of Chemistry, London Section (joint meeting with the Woolwich Polytechnic Chemical Society, at the Woolwich Polytechnic, Thomas Street, London, S.E 18), at 7.30 p.m.—Prof. R. N. Haszeldine· "Double Bonds that are Different".

Tuesday, November 6

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C 1), at 1.15 p.m.—Mr H. W Thorp: "Magnesia from Sea-Water—a New British Industry".*

University of London (at the Institute of Education, Malet Street, London, W.C.1), at 5.15 p.m —Dr. F. A. Vick. "Science and Its Standards".*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Dorothy Hodgkin, F.R.S.· "The X-ray Analysis of Large Molecules". (Seventh of eighteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C 1), at 5.30 p.m.—Prof L. Dudley Stamp: "Some Aspects of Medical Geography. 1· Climate and Disease".* (First of four Heath Clark Lectures.)

Institution of Electrical Engineers and the Royal Aeronautical Society London Joint Group (at Savoy Place, London, W.C.2), at 6 p.m.—Lecture on "Electrical and Electronic Problems in Service Aircraft".

Plastics Institute, London Section (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. R. N. Lewis· "Progress in Epoxide Resins".

Wednesday, November 7

Colour Group (Great Britain) (at the Royal College of Art, Kensington Gore, S.W.7), at 3 p.m.—Visit to the Stained Glass Department; 3.50 p.m.—(in the New Physics Department, Imperial College, S.W.7) —Meeting on "Stained Glass, Its Early Glory, Decline and Revival".

Royal Geographical Society (at 1 Kensington Gore, London, S W.7), at 5 p.m.—Mr. David Oates: "New Discoveries at Nimrud".

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p m.—Dr G. Milner "Some Aspects of Present-Day Town-Gas Supply".*

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. C. Bruinzeel (Amsterdam). "Electric Discharges during Simulated Aircraft Fuelling".

Institution of Electrical Engineers, Electronics Division (at Savoy Place, London, W.C.2), at 5 30 p.m.—Mr. G. Millington· "V H.F. Diffraction Problems introduced by the Rough Earth".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5.30 p.m.—Mr E. Knighting: "Numerical Forecasting" (Evening Discourse)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C 1), at 5.30 p.m.—Prof. L. Dudley Stamp: "Some Aspects of Medical Geography. 2: Climate and Health".* (Second of four Heath Clark Lectures.)

British Institution of Radio Engineers, Education Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C 1), at 6 p.m.—Meeting on "The Teaching of Communications in a Modern Context".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Prof. R. G. Bolten. "The Mechanics of Instrumentation".

Society for Analytical Chemistry (at the Wellcome Building, Euston Road, London, N.W.1), at 6 p.m.—Meeting on "Fluoride, Teeth and the Analyst".

Society of Chemical Industry, London Section and Heavy Organic Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. B. G. Ayling and Mr. J. O. Hughes· "Pipelines for Chemicals" (two papers).

Society of Chemical Industry, Plastics and Polymer Group (joint meeting with the Newcastle Section of the S.C.I., and the N.E. Section of the Plastics Institute, at King's College, Newcastle upon Tyne), at 6.30 p.m.—Prof. C. E. H. Bawn, F.R.S.· "New Developments in Vinyl Polymerization".

Thursday, November 8

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 10 a m.—Symposium on "Some Textile Processing Mechanisms".

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Dr. W. A. H Rushton, F.R.S.· "Visual Adaptation" (Ferrier Lecture).

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. Sydney Smith: "W. S. MacLeay, Charles Darwin, and Cirripedes"; Dr. F. B. Hora "Observations and Experiments on Toadstools in a Natural Habitat".

Mineralogical Society (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—General Meeting.

Institute of Refrigeration (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 5.30 p.m. Mr. W. B. Gosney, Miss M. V. Griffith and Mr. K. C Hales. A Review of the Washington Meetings of the International Institute of Refrigeration.

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5 30 p.m.—Mr I. L. Davies: "Optical Masers".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. A. C. Stevenson "Radiation-Induced Genetic Changes".* (Eighth of eighteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Oil and Colour Chemists' Association, London Section (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. E. J. W. Vogelzang (Delft). "Some Industrial Uses of New Non-drying Alkyd Resins".

Radar and Electronics Association (at the Royal Society of Arts, John Adam Street, Adelphi, London, W C.2), at 7 p.m.—Mr. W. J. Bray: "Satellite Communication Systems".

Royal Institute of Chemistry, London Section (at Croydon Technical College, Fairfield, Croydon, Surrey), at 7.30 p.m.—Dr. E C. Barton-Wright· "Judge, Jury and Expert Chemical Witness".

Friday, November 9

North East Coast Institution of Engineers and Shipbuilders (at Bolbec Hall, Newcastle upon Tyne)—Mr. N. Carter: "Calculations for the Sub-division of Passenger Ships".

Clay Minerals Group of the Mineralogical Society (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 11.25 a.m.—Autumn Meeting. 4.30 p.m —Annual General Meeting.

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Prof. J S Mitchell· "Some Problems in the Study of Radiosensitizers and Radioactive Drugs".*

Bone and Tooth Society (at the Institute of Orthopaedics, 234 Great Portland Street, London, W.1), at 4.30 p.m.– Symposium on "Citrate Metabolism"

Arthur Stanley Eddington Memorial Trust (at the Arts' School Lecture Theatre, Bene't Street, Cambridge), at 5 p.m —Prof. W. C. Kneale· "On Having a Mind".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. Audrey I. Richards: "The Pragmatic Value of Magic in Primitive Societies".

Saturday, November 10

Biochemical Society (at the Glaxo Laboratories, Greenford, Middlesex), at 10.55 a.m.—Scientific Papers.

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. John F. Potter "Journey to the Centre of the Earth".*

Monday, November 12

University of London (at Friends' House, Euston Road, London, N.W.1), at 5.30 p.m —Sir Vivian Fuchs. "The Human Element in Exploration" (Rickman Godlee Lecture).*

Plastics Institute (at the Royal Institution, Albemarle Street, London, W.1), at 6.30 p.m.—Dr. J. C. Swallow. Second Swinburne Award Address.

Society for Visiting Scientists (at the English-Speaking Union, Dartmouth House, 37 Charles Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Matching Men and Machines". Chairman· Dr. W. F. Floyd; Speakers: Dr D. J. K. Stuart, Dr. H. P. Ruffell and Mr. D. E. Broadbent.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p m —Dr. I. G. Gass· "Return to Tristan da Cunha".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or *before the dates mentioned*:

Lecturer or Assistant Lecturer (with qualifications in pure mathematics) in the Department of Mathematics—The Registrar, The University, Manchester 13 (November 10).

Assistant Lecturer (with an honours degree in archaeology, or its equivalent, and a good general knowledge of European and British prehistory, with some emphasis on the periods before the Neolithic) in the Department of Archæology—The Secretary, The University, Edinburgh (November 12).

Lecturer in the Chemistry of High Polymers in the Department of Textile Industries—The Registrar, The University, Leeds 2 (November 14).

Lecturer (Grade II) in Philosophy—The Registrar, The University, Bristol 8 (November 15)

Lecturer or Senior Lecturer in Livestock Husbandry at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 15)

Lecturer (*with special qualifications in experimental psychology*) in Psychology—The Secretary, The Queen's University, Belfast, Northern Ireland (November 15).

Lecturer or Assistant Lecturer in Philosophy—The Registrar, The University, Nottingham (November 16).

Assistant Lecturer in Dairying; and a Demonstrator in Dairying—The Registrar, University College of Wales, Aberystwyth (November 17).

Assistant Lecturer in Physiology—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (November 17).

Chair of Physics—The Registrar, University of York, The King's Manor, York (November 17).

Lecturer in Organic Chemistry—The Secretary of University Court, The University, Glasgow (November 17).

Temporary Lecturer (with qualifications and experience in the *general field of physical or inorganic chemistry*) in Chemistry, for one calendar year from January 1, 1963—The Registrar, University College, Singleton Park, Swansea (November 17).

Professor of Chemistry in the Faculty of Science, University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 18).

Lecturer (preferably interested in inorganic or physical chemistry) in Chemistry—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (November 20).

Lecturer and an Assistant Lecturer in the general field of *Applied Mathematics and Statistics—The Registrar*, The Manchester College of Science and Technology, Sackville Street, Manchester 1 (November 24).

Lecturer and/or Assistant Lecturer in the Department of Pure Mathematics—The Registrar, University College of North Wales, Bangor, North Wales (November 24).

Lecturer or Assistant Lecturer in the Department of Applied Mathematics—The Registrar, University of North Wales, *Bangor, North* Wales (November 24).

Librarian (graduate)—The Vice-Chancellor, University of Essex, c/o Divisional Education Office, Park Road, Colchester, Essex (November 24)

Tutorial Research Student in Mathematics (Pure or Applied)—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (November 26).

Chair of Forestry—The Secretary, The University, Aberdeen (*November* 30)

Lecturer (preferably with a special interest in economic geography) in Geography at the University of Melbourne—The Secretary, Association of Universities of the *British Commonwealth (Branch* Office), Marlborough House, Pall Mall, London, S W.1 (Australia and London, November 30).

Lecturer in Sociology at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, November 30).

Lecturer or Assistant Lecturer (with a good honours degree *in geology* and research and teaching experience in geochemistry and petrology) in the Department of Geology—The Registrar, The University, Keele, Staffs (November 30).

Assistant Lecturer in Biochemistry in the *Department of* Physiological Chemistry—The Registrar (Room 22, O.R.B), The University, Reading (December 1).

Lecturer (preferably with research experience in drug metabolism and the application of radio-isotopes in biological chemistry) in Pharmaceutical Chemistry at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W 1 (Australia and London, December 7)

Senior Demonstrator in Botany (Plant Physiology) at the University of Melbourne, Australia—The Secretary, Association of *Universities of the British Commonwealth (Branch* Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 30).

Head (with considerable experience in any suitable field of research work, preferably in applied plant physiology or in plant pathology) of the Department of Hop Research—The Secretary, Wye College (University of London), Near Ashford, Kent (December 31).

Lecturer in Botany (Genetics or Cytogenetics) at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 31).

PROBLEMS OF COMMUNICATING SCIENTIFIC IDEAS

ONE of the most fundamental discussions at the meeting of the British Association for the Advancement of Science in Manchester was that arranged by Section X on September 4 on problems of communication. It could be said that the subject was a dominant one in the proceedings of the Section. Prof. Bruce Pattison's presidential address on "English as an International Language" discussed a particular means of communication, and afterwards the special linguistic problems of foreign students in the United Kingdom were described to the Section by Mr. G. Perren of the British Council's staff. The general theme of Section L, "The Unity of Knowledge", also touches closely on problems of communication, and apart from Mr. P. Wilson's excellent presidential address on the unity of knowledge as a new dynamic for the schools, that Section heard a meritorious address from Dr. S. Toulmin on science and the British intellectual tradition, while Prof. D. Daiches was concerned with university education and the unity of knowledge, and Dr. C. S. R. Kitson-Clark on the use of history.

All these addresses bear on some aspect or other of the communication of knowledge or of ideas, and the whole meeting was remarkable for a painstaking effort to assist joint discussion between Sections and the cross-fertilization of ideas. The discussion on problems of communication went fairly to the root of the problem, particularly in the paper by Mr. B. C. Brookes, which dealt with the communication between scientists, and in that of Mr. J. Maddox, which discussed communication between scientists and the educated layman. Those by Prof. P. Sargant Florence, which discussed basic English for the social sciences, and by Dr. Elsie C. Graham, which considered basic English as an international language and its value for science, dealt with a more limited or specific aspect, and even though Dr. Graham recognized the range and wealth of meaning in ordinary English words, her paper scarcely met Prof. Bruce Pattison's fundamental objection to the artificial languages that they have no roots.

To the extent to which basic English denies itself that wealth of association and range of meaning, and to which Prof. Pattison referred, it is open to that general objection to an artificial language and cannot claim the advantages which English already holds as a language of science and learning—not simply as a channel for European and American experience, particularly in science and technology, but also for communication inside many of the new developing countries. Prof. Pattison's survey, in fact, points rather to the high importance of teaching English in these countries, to the value of spoken English and the provision of better trained teachers, especially with better command of spoken English. Rather than the exploitation of a partly artificial language, he urges the use and deliberate use of the opportunities which English already affords, and that we should be concerned to keep clear those old channels of communication and to open new ones from them.

Mr. Brookes's stimulating paper follows naturally from this point of view. He began by stressing the fact that the scientific method is essentially social and utterly dependent on the co-operation of scientists. The history of science is still written so largely in terms of the contributions of individuals that he suggested what was needed was a Trevelyan to restore the balance by displaying the importance of its internal social aspects. Mr. Brookes himself brings out emphatically some of those neglected human aspects of the whole scientific system, its dependence on the whole social corpus of scientists who operate the system and through them on the scientific societies and academies. Only with their founding could a scientific community of thought and attitude and a coherent approach to scientific problems become possible.

The importance of scientific societies is not always appreciated, though Sir Cyril Hinshelwood has directed attention to their functions on several occasions, and their place in the technological society of to-day merits close and critical assessment, particularly in the light of the limits of communicability, to which also Mr. Brookes wisely directs attention. It is not entirely on the ability of the scientist or technologist to express himself clearly that effective communication depends. The limit of communicability is also set by the inability of those addressed to discard or change the mode and structure of thought which they have established for themselves. Here the scientific or technical society may be an adverse or a favourable factor, and it has to be remembered that it is an essential part of the critical method that defence of old theories should be as tough as the criticism which overthrows them. The issue is decided by the uncommitted young generation of scientists and because of this the structure of the scientific society or institution merits some consideration in respect of age groups.

While Mr. Brookes accepts that it is largely true that a new scientific truth triumphs through the senescence of its opponents and the growing up of a new generation familiar with that truth, he looks critically and constructively at factors which impede freedom of scientific discussion and criticism, and his review is far more realistic than many contributions to this field. He recognizes, for example, that the overwhelming spate of scientific papers that are now published has both made inevitable the appearance of specialists in the handling of information who act as intermediates between the scientist and his literature, and fostered a disinclination on the part of the scientist to depend on published sources. More important, he examines the implications of both developments and his comments are penetrating and constructive.

For example, he points out that the 'information' scientist or specialist may easily become an obstacle to the primary transaction in communication. Moreover, encouraging the writing or presentation of scientific papers in a form more suitable for mechanical abstracting and indexing is bad in principle if it reduces the scientist's direct responsibility to keep himself informed. Here, as elsewhere, spoon-feeding is bad and could be disastrous. Again, he lays a welcome stress on the importance of personal contacts, and it is not merely that modern conditions have facilitated personal contacts overseas and encourage the scientist to resort to informed channels even if they mean by-passing formal channels of communication. Personal contacts, to-day as always, represent a factor of which more account should be taken before deciding whether or not the establishment of costly and elaborate mechanical systems is justified. They could sometimes represent a more decisive factor than the application of the law of scatter in relation to indexing or abstracting of scientific papers would suggest or allow.

That is a matter which concerns the scientist and the information officer or librarian alike, but the second factor on which Mr. Brookes makes some pertinent comments is of the scientists' own making. This is the practice of early or even premature publication, and, in view of what has previously been said in these columns, it seems unnecessary to add more than that Mr. Brookes expresses the hope that scientists will eventually recognize the soundness of Gauss's publishing motto: *Pauca sed matura*. Further, he firmly deprecates alike the pressure to publish which develops from the dependence of promotion at universities and like institutions on published papers and from the tendency to duplication of publishing. More serious, however, is the way the pressure set up by the demand on publishing space, especially in the leading periodicals, discourages or hinders the publication of unorthodox views. Mr. Brookes remarks succinctly that the progress of science demands that heretics be heard. Much more could be said, but the scientific societies should be well aware of a problem that is by no means easy to resolve and which bears vitally on the existence of science itself.

Of secrecy, whether imposed by real or imaginary demands of security or of industry, Mr. Brookes points out that it is always expensive and detrimental to science, and suggests that the shedding of scientific secrecy by industry might be a most rewarding policy in its effect on the quality of its scientific staff. He is, however, just as much disturbed at the indirect effects of the commercial exploitation of the development of scientific information, and the misgivings he expresses about the consequences of some of the centralization and mechanization in this field deserve attention. The risk of vested interests developing which are concerned with the means and not with the scientist or the science to be served is not to be ignored.

These problems undoubtedly merit more careful examination from the point of view of the scientist, not the information officer or the librarian, than they have received, and Mr. Brookes's suggestions for assisting the scientist, and especially the young scientist, to play a part in the system of communication on which science depends could contribute materially to such an examination. At present, as he rightly observes, the young scientist does not appear to be trained to that end at all, and while Mr. Brookes neither accepts at its face value much of the present-day criticism of the quality of scientific writing or lecturing, nor advocates seriously distracting the young scientist from laboratory work or theoretical studies, he believes that the young scientist could be greatly helped by the removal of uncertainty of purpose and provision of an appropriate model or standard for his written work. The scientific author is not normally a professional writer and needs assistance in planning the framework and in getting started; but if he is to be helped he must be treated as Rutherford treated him—as a responsible person, with something worthwhile to communicate and something that is essentially communicable.

Those responsibilities as a communicator are part of the scientist's task as a creative or critical worker, and to help the young scientist to become a better communicator is to help him become a more effective creative scientist. This, at least for the young scientist, is the right approach to the problem of communication: it is an element in his intellectual development. There are other aspects of communication even between scientists, but this may well be the most important, and if it is wisely handled could do much to relieve difficulties elsewhere.

They could also stimulate attention by scientists to the communication of science to the public and assist to overcome that indifference or neglect which Mr. J. Maddox noted in his following address. This indifference was quite inconsistent with the fact that science was an integral part of the intellectual life of civilization, and the communication of scientific ideas should be fostered for the same reason as was the cultivation or appreciation of great paintings, music or literature. It enlarged men's minds, and without proper appreciation of the intellectual significance of science in society even the administration of public affairs suffered. This was equally true of industrial activity, and scientists could not escape their responsibility for reducing the inevitable time-lag in the adoption of new ideas.

All this is, of course, implied in the debate instigated by Sir Charles Snow's thesis of the old idea of the two cultures, but on the positive side of improving communications Mr. Maddox had little new to contribute. He saw ample room for improvement in the part played by the schools and by the Press, but the weight of his criticism fell on the scientists. The British Association was an example of what could be done, but there were definite limits to its activities, and Mr. Maddox suggested that one of the outstanding needs was some organization which would permit the free expression of scientific opinion.

That suggestion calls for some examination, for although scientists might well do more to assist the formation of informed opinion it is open for discussion how far 'scientific opinion' can exist except in the sense of considered opinion on specific scientific or professional opinion on specific issues. Such opinion could largely be formulated by existing professional institutions if they recognized their responsibility and used their opportunities, particularly in association with, for example, the Parliamentary and Scientific Committee. Meanwhile, Mr. Brookes, in any event, has indicated some opportunities for constructive work by the professional institutions, and the British Association could well make sure that this general problem of communication is adequately discussed at future meetings as well as kept under continuous review as an aspect of the Association's function in serving the community.

HUMAN ENDOCRINOLOGY

Hormones in Human Plasma

Nature and Transport. Edited by Dr. Harry N. Antoniades. Pp. xvii + 667. (Boston, Mass.: Little, Brown and Company, Inc.; London: J. and A. Churchill, Ltd., 1960.) 25 dollars; 180*s*.

THIS is a most useful book. There has long been emphasis on hormonal excretion products, too long in the view of many, simply because they are more accessible. It is good to see the increasing importance attached in the past few years to hormones in the circulating blood. Previously there had been available the book of the Ciba Foundation Symposium on *Hormones in Blood*, but this dealt in a less-comprehensive way with mammals generally. In the book edited by Dr. Antoniades, we have a good account by thirty-three authors of the whole subject of hormones in human plasma. This book is fully comprehensive in its treatment of hormones and the history of their discovery, and even the zoological limitation to man is only nominal. It is the first of its kind, and as Dr. Thorn says in his preface, it may well be the last, because the growth of information in this field will make it impracticable in future to compress the subject in full detail into a single volume.

The book is divided into five parts: methods of blood collection and plasma fractionation; hormones of pancreatic origin; hormones of pituitary origin; steroid hormones; and hormones produced by thyroid gland, the adrenal medulla and the placenta. This subdivision is not quite logical in that there is a potential overlap between steroid and placental hormones; discussion under the latter heading, however, is restricted to gonadotrophins. An attractive feature of the book is the integration of new knowledge with the pioneer observations. In particular, it is pleasant to see recognition given to the work of R. T. Frank, who as early as the 1930's recognized that the place to look for functionally effective œstrogens was in the circulating blood, not in the urine, but whose work, owing to technical imperfection, was largely ignored at the time. Many books published at the present time seek only to scoop off a thin layer of the cream of current knowledge without acknowledgment that it has evolved from the work of many years. The book edited by Dr. Antoniades is a welcomed exception.

In a book containing so much good material it is perhaps invidious to pick out particular parts for mention, but I myself was naturally attracted by the chapters dealing with steroid sex hormones in human plasma. That on androgens in the testis, the ovary, the adrenal cortex or as metabolic products of the corticosteroids puts the subject in proper perspective in a satisfactory way. Much the same applies to W. H. Pearlman's chapter on progesterone, which is a very complete review of the whole subject of progestagenic substances in blood and deals not only with the sources of the substances but also with their occurrence in lower mammals and even in birds, frogs and reptiles. A further chapter on steroids deals with their binding by plasma proteins. Two other chapters deal respectively with gonadotrophins. That on hypophysial gonadotrophins reflects by its brevity the relative lack of information in this field. That on extra-hypophysial substances, although it deals with pregnant mare's serum gonadotrophin, in addition to human chorionic gonadotrophin, is also somewhat sketchy. As to the rest of the book, it need scarcely be said that the chapters on insulin and related substances, on adrenocorticotrophic hormone and on thyroid hormone are very substantial. This is a reference book which should be accessible to every endocrinologist.

A. S. PARKES

EVOLUTION OF MAN

Mankind Evolving

The Evolution of the Human Species. By Prof. Theodosius Dobzhansky. Pp. xiii + 381. (New Haven, Conn. and London: Yale University Press, 1962.) 7.50 dollars; 55*s*.

NO branch of science is more difficult to write about without bias than is the application of genetics to human history and evolution. The difficulties arise, not so much because of the possible conflict between science and theology, but because most statements about human genetics have far-reaching political implications. On one hand, reformers who have wished to believe that the application of some specified social policy would cure all human ills have also found it necessary either to deny that any of the existing differences between human beings are genetic, or to assert the Lamarckian view that appropriate environmental changes will, without the need for the cruelties of natural selection, produce desirable genetic changes. On the other hand, those, from Plato onwards, who have felt that the Golden Age is in the past, and that the preservation of the *status quo* is the best that can be hoped for, have usually found it necessary to justify the existing differences between the 'haves' and the 'have-nots'—whether they be individuals, classes or races—by arguing that all important differences between human beings are hereditary.

Faced with these twin dangers, a few geneticists have incautiously attempted to explain the whole of human history, politics and sociology in genetic terms. A commoner, if more cowardly, attitude has been to admit the relevance of genetics in such cases as blood groups or certain diseases, but tacitly to ignore its possible relevance to differences of personality or mental capacity, or to differences between classes or races. Relatively few have been able to steer a successful course between the Scylla of hereditarianism and the Charybdis of environmentalism. We should therefore be particularly grateful to Prof. Dobzhansky for writing *Mankind Evolving*. He has the breadth of knowledge and the wisdom to give a balanced picture of the importance of genetics in human affairs, and he writes so beautifully that his book will be read with pleasure both by professional geneticists and by those with no biological training.

The first half of the book deals with genetics and the theory of evolution, with the environmentalist thesis and hereditarian antithesis, and with the problems of nature and nurture and of natural selection in man. Later chapters deal with the fossil history of man, the origin of human mental faculties, with class, caste and race, and with eugenics. These are important subjects, and some of them have been discussed with passion for three thousand years. During the past hundred years they have gradually ceased to be matters on which a man can permit his views to be dictated by his religious and political prejudices, and are becoming matters on which opinion must be influenced by ascertained facts and accepted theories. This is a desirable change, and Prof. Dobzhansky's book will do much to accelerate it.

J. MAYNARD SMITH

MEANING OF MEASUREMENT IN THE SCIENCES

Quantification

A History of the Meaning of Measurement in the Natural and Social Sciences. Edited by Harry Woolf. Pp. 224. (Indianapolis and New York: The Bobbs-Merrill Company, Inc., 1961.) N.p.

THESE nine essays are accounts of papers read at a conference held under the auspices of the U.S. Social Science Research Council. Physics, chemistry, psychology, sociology, medicine and economics are among the fields covered, so it is no surprise that there are differences in approach—one almost has the impression of reading essays in different languages. In spite of this, there is a unanimous determination to put measurement in its place. Measurement for its own sake is useless without a theory to give it direction, and all the writers insist that qualitative work must precede quantification in any science. T. S. Kuhn, rejecting the over-simplified text-book picture of a physicist measuring and then finding a theory to fit his measurements, goes so far as to write (p. 43): "Knowing what results they should expect from chemical analyses, chemists were able to devise techniques that got them".

The fields of psychology, economics and sociology differ from the others in the need to use mathematical statistics and probability as an instrument of measurement. This has made the quantification of these subjects more difficult, leading to controversies of various kinds. The book contains plenty of examples of prolonged conflict between schools of thought, both in the social sciences, as "political arithmetic" versus "university statistics", and in the natural sciences, as the wave and corpuscular theory of light. It is, of course, impossible to give a history of measurement in any field without giving a good deal of background history of the field itself.

Among individual essays, I was most interested by T. S. Kuhn with his provocative view of the rolé of measurement and "crisis states" in the development of physics, and P. F. Lazarfeld, with his rich human story of the personalities who developed measurement in sociology. The repetition of key names, such as Descartes, Leibniz, Lavoisier, Laplace, shows how thinkers of the past applied their talents to many fields. Nowadays, intense specialization sets up barriers between different disciplines, and a book like this, written by experts in different lines, may help to break these barriers down

SPACE TECHNOLOGY

Proceedings of the 6th Symposium on Ballistic Missile and Aerospace Technology

Held in Los Angeles, August, 1961. Edited by C. T. Morrow, L. D. Ely and M. R. Smith. Vol. 1: Design and Reliability, and Invited Addresses. Pp. x+403. 64*s*. Vol. 2: Ballistic Missile and Space Electronics. Pp. x+453. 72*s*. Vol. 3: Propulsion, Space Science and Space Exploration. Pp. x+445. 72*s*. Vol. 4: Re-entry. Pp. x+240. 40*s*. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.)

THESE four volumes contain about half the papers presented—namely, those which escaped military classification—at the symposium on "Ballistic Missile and Aerospace Technology" held at Los Angeles in August 1961. The first volume includes 14 papers on missile design, structure and reliability. The second volume has 18 contributions under four headings: ballistic missile and space guidance, navigation and control; computers and digital techniques; information processing; communications. Volume 3, also with 18 papers, is devoted to rocket propulsion, space science and the exploration of the Moon and planets. The nine papers in Volume 4 deal with the design of space vehicles for re-entry into the Earth's atmosphere. The contributors are all from the United States, most of them belonging to industrial organizations. The papers are generally of a high standard and impressively thorough, being especially valuable for their wealth of detail and illustration. The volumes, though apparently printed photographically from typescripts not always uniform in layout, are nevertheless not unpleasing in appearance. Non-American readers would, however, be well advised to skip the "Addresses" occupying the first 14 pages of Volume 1, which are embarrassingly nationalistic.

In a short review only a few of the individual contributions can be mentioned, to illustrate their scope. There are two notable papers on the shielding of manned space-vehicles from high-energy particles in space: R. H. Levy describes shielding by magnetic means, with superconducting coils, and concludes that the weights required may be comparable with conventional methods; while A. J. Beck, E. Divita and S. L. Russak give a long and detailed account of the shielding of spacecraft of particular designs during a lunar journey. Volume 3 contains an interesting paper by V. Ilsen on rocket exit-nozzles of unconventional shape, designed for increased efficiency. R. Hermann reports on investigations into the problems of evaporative film-cooling at hypersonic speeds. R. H. Battin and J. S. Miller discuss the guidance requirements for a novel low-thrust approach trajectory to the Moon, spiralling out from the Earth and in towards the Moon, while J. W. Salisbury reviews the geological problems in establishing a base after arriving at the Moon. Together the volumes constitute a most useful and wide-ranging survey of space technology.

THE RUTHERFORD JUBILEE AND NUCLEAR PHYSICS

Proceedings of the Rutherford Conference

Edited by J. B. Birks. Pp. 856. (London: Heywood and Co., Ltd., 1961.) 189*s*.

The scientific proceedings of the Rutherford Jubilee International Conference on Nuclear Physics which was held in the University of Manchester during September 4–8, 1961, to commemorate the discoveries of Rutherford at Manchester, and in particular, the fiftieth anniversary of the Rutherford scattering law and the discovery of the atomic nucleus, are recorded in the present volume. The addresses delivered at the special commemorative session by four of Rutherford's former colleagues are to be published separately in a special volume which will contain also other biographical, historical and bibliographical articles and a selection of the important papers published from Manchester during 1907–19.

The contents consist of the brief welcoming address by the vice-chancellor of the University of Manchester (Prof. W. Mansfield Cooper) and the reply by the president of the Conference (Sir Ernest Marsden); contributed papers; invited papers; discussion; open session; and conference summary by D. R. Inglis. All the manuscripts, whether issued as preprints in time for the conference or obtained by tape-recording during the conference, have been corrected by their respective authors. Abstracts of the 180 contributed papers are included, together with a list of delegates and an index of authors.

There were seven sessions in addition to the commemorative session (Session 4) and the open session. In the first session, on high-energy investigations of nuclei, there were invited papers by H. Pierre Noyes on nuclear forces; H. McManus on the interaction of fast nucleons with nuclei and R. H. Dalitz on hypernuclei and hyperon-nucleon interaction. In the second session, on collective motion in nuclei, B. H. Flowers spoke on pairing correlations in nuclei; B. L. Cohen on experimental evidence for collective oscillations and G. E. Brown on the theory of collective oscillations. The third session, on the nuclear ground state, included papers by D. H. Wilkinson and P. E. Hodgson on the nuclear surface and J. S. Bell on the many-body problem. Session 5 dealt with direct interactions with three invited papers; session 6 consisted of two invited papers, by S. Devons on limitations and needs in instrumentation for nuclear physics and by W. A. Fowler on "Rutherford and Nuclear Cosmochronology" respectively; and session 7 was concerned with weak interactions, with invited papers by R. J. Blin-Stoyle; S. A. Moszkowski; C. Rubbia on muon capture in nuclei; and V. L. Telegdi on the spin dependence of the interaction responsible for muon capture. In the open session (Session 8) there were four invited speakers, including R. E. Peierls, who took as his subject "Velocity Dependent Nuclear Forces", and Bohr, who discussed selected topics concerning nuclear spectra.

The volume is excellently produced and will remain both of scientific and historical interest for a very long time. The discussions are valuable, but because they are given verbatim they sometimes reflect the heat of the moment and quite often descend to ridiculous comments like "Oh, no ! no !". It is a pity that some editorial deletions or alterations were not made before publication. The price is high, but not too high for the material the volume contains.

S. Weintroub

SALT RELATIONS OF PLANTS

Mineral Salts Absorption in Plants

By Dr. J. F. Sutcliffe. (International Series of Monographs on Pure and Applied Biology. Division: Plant Physiology, Vol. 1.) Pp. x+194. (London and New York: Pergamon Press, 1962.) 35*s*. net.

This is a straightforward account of the principles involved in the absorption of mineral constituents of plants. After a brief review of the methods and plant materials now generally used in investigations on salt absorption, the problems presented by the subject are dealt with in seven chapters. Under the heading "Mechanisms of Ion Transport" the various processes which might be concerned in the movement of ions into and in the plant are briefly considered; they are diffusion, mass flow, ion exchange, Donnan equilibria, adsorption, chemical combination and active transport. How various external and internal factors can affect salt absorption forms the subject of the next chapter, while the relation of salt absorption to metabolism rightly claims a chapter to itself.

Much of a chapter on the location of absorption mechanisms is naturally devoted to a discussion of the concept of free space, but brief consideration is also given to the salt relations of cell walls, cytoplasm, mitochondria and chloroplasts. The plasmatic membranes are indeed described but these important components of the cell might well have received a more detailed treatment. In a chapter entitled "Salt Relations of Vascular Plants" there are considered the zones of ion absorption in roots, salt absorption and translocation, transport across the root cortex, upward transport of salts, distribution of salts in the shoot, foliar absorption and excretion of salts. These altogether constitute a vast subject on which much work has been done and much written in the past thirty or forty years, and in a book of the size of the one under notice the brief outline which is given is all that can be expected. Much the same can be said of the subject-matter of the next chapter dealing with the soil as a source of mineral salts. The final chapter, apart from an epilogue, deals with salt tolerance, particularly of halophytes. The term diffusion pressure deficit, that is, suction pressure, is here introduced without definition. While many readers will no doubt be acquainted with the term this should probably not be assumed.

The book is clearly and pleasantly written and should be found useful to students who want a general account of the aspects of plant nutrition with which the book sets out to deal.

W. Stiles

NEW ZEALAND OBSERVATIONS OF THE HIGH-ALTITUDE EXPLOSION OF JULY 9 AT JOHNSTON ISLAND

GEOMAGNETIC and atmospheric effects of the explosion of July 9 observed in New Zealand and the Pacific were discussed at an informal conference held at the University of Canterbury, Christchurch, on August 16. This article presents a summary of the main observations, which are expected to be published by individual authors in a special issue of *The New Zealand Journal of Geology and Geophysics*. The titles of organizations supplying information are quoted in brackets throughout this summary. Outstanding features of the explosion were the intensity of the effects, which caused 'off scale' readings on many instruments, and evidence for the precipitation of particles over an area extending about 25° farther south than the magnetic conjugate point.

The time of detonation (hereafter referred to as *H*) was determined from the reception at Lower Hutt of a strong click type sferic, occurring at 0900 h 09·0238 sec ± 0·0005 sec U.T.; and the height of the fireball was deduced, from a newspaper photograph, as between 355 and 395 km (Geophysics Division, Department of Scientific and Industrial Research).

Auroral displays were observed from locations between Tarawa (1° N.) and Campbell Island (53° S.) (New Zealand Meteorological Service). At *H*, a white or greenish-white flash was observed in two areas, one between Fiji and Samoa, and the other, just east of the South Island of New Zealand, approximately between magnetic latitudes 45° and 50° S. At Apia, the flash was seen in the direction of the conjugate point, which lies to the south-south-west. A bright glowing area suddenly appeared, extending high in the north-west sky, with distinct ray structure through it. Colours were mainly light yellow, tinged with violet, and with a suggestion of green at the edges. At Tarawa, the observing point closest to the explosion, the flash was of greenish tinge. Rays were seen to emerge from the upper portions of the flash, and to take zig-zag paths which eventually became straighter as they extended southwards. Observations of the flash off the east coast of New Zealand were hindered by cloud; but its occurrence is established. White glows appeared in many areas. A red glow appeared over wider areas within a few seconds of *H* and dominated the white glows after about 1 min. Also within a few seconds, a blue-white ray was seen from Apia to rise above the horizon, at the azimuth of Johnston Island, and extend along the magnetic field direction upwards and southwards. Numerous reports exist of white glow and rays, and of red glow, and those available so far are summarized in Figs. 1 and 2 respectively (Dominion Physical Laboratory Auroral Station; New Zealand Meteorological Service). Comparison of these figures show that while quiet white and red displays coincide in many instances, especially near the conjugate point, the white rays were located independently of the red glow. At about *H* + 4 min, the red glow was at maximum intensity; there is little doubt that it covered the region from 0° to 50° geomagnetic latitude, with longitude boundaries within ±5° approximately of the magnetic meridian through the fireball. The absence of reports of white ray structure in the area between New Zealand and the conjugate point is noticeable. While this cannot be dissociated completely from an absence of observers in the same area, observations of radio propagation and of magnetic disturbances, discussed here, support the concept that the white ray structure occurred in the two regions shown in Fig. 1, and not significantly between them.

The sustained white ray observed from Apia in the direction of Johnston Island resembled a searchlight. One theodolite measurement of it gave an apparent angular width near the horizon of about 0·2°, from which it is deduced that the main luminosity was confined within 10 km diameter at a height of 700 km near Johnston Island. No measurements of the luminous intensity were made. At high elevations, other rays appeared successively to separate from this in upward and westward directions during the 12

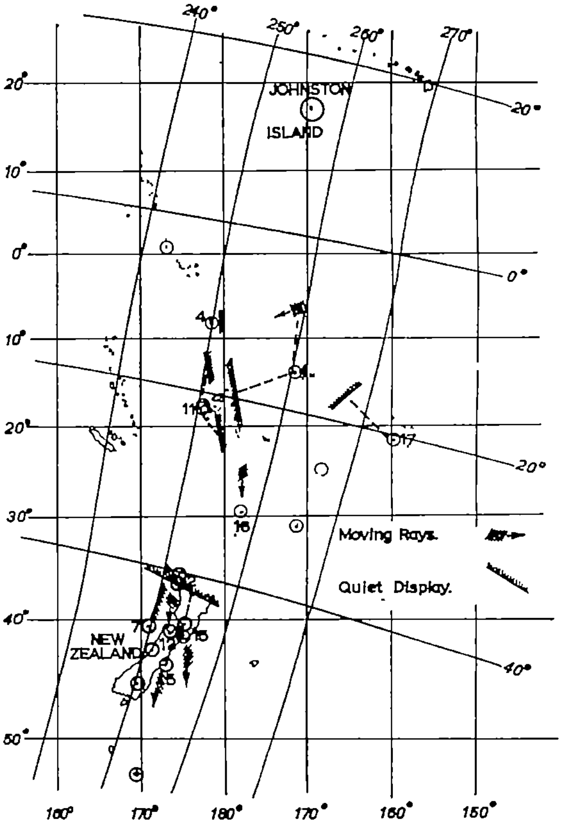

Fig. 1. The location of white auroral glows and rays due to the Johnston Island explosion. (Key to observing positions: 1, Apia; 2, Auckland; 3, Campbell Island; 4, Funafuti (Ellice Is.); 5, Christchurch; 6, Hokitika; 7, ship, 41° S. 171° E. 8, Lauder, Central Otago; 9, Lauthala Bay, Fiji; 10, Hauraki Gulf; 11, Nandi, Fiji; 12, Nelson; 13, Ohakea; 14, ship, 24° S. 167° W.; 15, Paraparaumu; 16, Raoul Is.; 17, Rarotonga; 18, ship, 31° S 172° W.; 19, Tarawa; 20, Wellington) (see also Fig. 2)

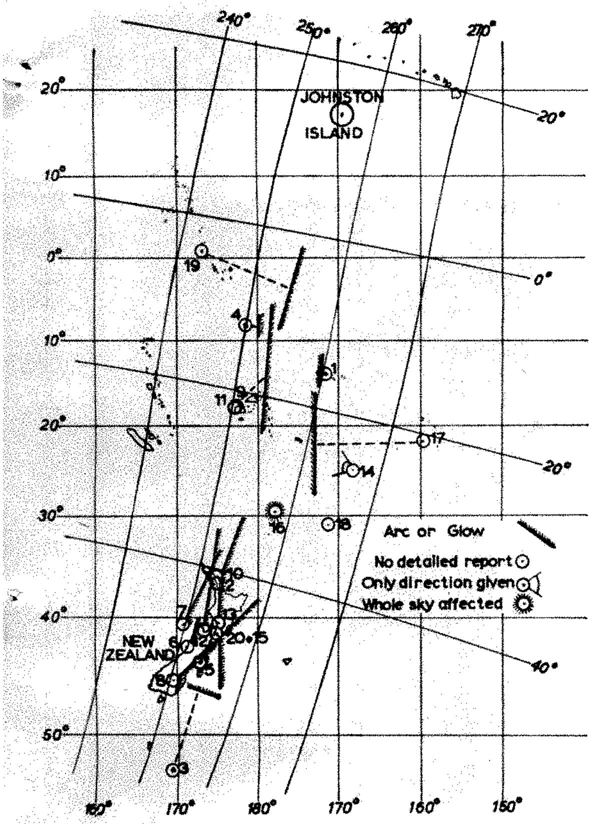

Fig. 2. As for Fig. 1, but showing location of red auroral glow

min of its existence (New Zealand Meteorological Service). The white ray structure clearly marked out the geomagnetic field directions. Luminosity was low at large elevations, giving the appearance of a gap in the rays near their zenith. The height of the rays was provisionally estimated as 700 km over Apia. The appearance of ray structure near the conjugate point observed at an azimuth of 331° and elevation of 54° from Apia is shown in Fig. 3 (University of Canterbury, Physics Department). Reports of the form of the display continue to be received from Pacific Islands. A colour sketch from Funafuti Island (New Zealand Meteorological Service) shows that, as seen from the west, the red glow extended in a north–south direction and filled the sky from horizon to an upper boundary obviously determined by the geomagnetic field direction. (The red area took the form of an archery bow, with string held horizontal, and colour between the bow and string.) South of the zenith of this glow, white rays appeared, starting at higher elevations than the red glow and approaching the horizon much more steeply. These rays are probably part of the structure shown in Fig. 3. The Funafuti Island observations clearly show differences in structure of the red glow and white rays, and establish a geomagnetic control of the upper limit of the red glow. The auroral displays at all locations faded between 0915 and 0920 U.T.

Spectrophotometry of the displays was carried out near Christchurch (University of Canterbury), and at Lauder, Central Otago (Dominion Physical Laboratory, Auroral Station). Near Christchurch, measurements were made of the variations of intensities of the *OI* emissions, λλ5577 and 6300 Å, and the N_2 + emission, λ4278 Å, during the display. At λλ5577 Å and 4278 Å, peak intensities occurred at $H + 2\frac{1}{2}$ min. The maximum intensity of λ5577 Å in the vertical direction was $2{\cdot}1 \times 10^4$ rayleighs, about 160 times the average intensity for the preceding month (University of Canterbury). At Lauder, an interrupted measurement suggested that the same radiation was increased only 20 times; and also that the rate of decay was faster than near Christchurch. Near Christchurch, the intensity of λ6300 Å showed a different time variation. Peak intensity was not reached until $H + 4$ min; and the maximum value was $1{\cdot}8 \times 10^5$ rayleighs, about 2,400 times the average intensity for the preceding month. This red glow corresponded to a Class III aurora. At Apia, a spectrogram taken in the first 11 sec showed that the display then corresponded essentially to a red type *B* aurora, with only a little hydrogen emission. The strong *OI*λ5577 Å line, and the much weaker *OI*λ6300 Å lines, indicated a height of the order of 100 km as the region of maximum intensity (University of Canterbury).

Magnetic effects of the aurora were observed at Lower Hutt (Geophysics Division, Department of Scientific and Industrial Research), at Amberley (near Christchurch) and at Apia (Magnetic Survey, Department of Scientific and Industrial Research). The scalar magnitude of the disturbance in total force at Lower Hutt was 300γ. At Amberley, the maximum disturbance in horizontal component was 220γ; and at Apia, the maximum disturbance was 55γ. Fig. 4 shows a tracing of the magnetic records from Amberley. The initial impulse was estimated as occurring at 0900 h 12 secs ± 1·5 secs U.T. From these records, the total force F is found to decrease steadily until $\Delta F = -45\gamma$ at $H + 45$ sec; then to increase, with ΔF reaching $+120\gamma$ at $H + 80$ sec, remaining near that value until $H + 105$ sec, followed by a rapid decay until $H + 150$ sec. A slow recovery continued for approximately 1 h. At Apia, the disturbance took a much simpler form. The large changes at the New Zealand stations, as compared with that near the conjugate point, are noteworthy.

Earth-potential gradients were measured near Christchurch (Magnetic Survey, Department of Scientific and Industrial Research), near Invercargill (University of Auckland, Physics Department; New Zealand Post Office), and at Lauder (Dominion Physical Laboratory, Auroral Station). Disturbances were noted within 0·2–0·5 sec after H. Off-scale deflexions occurred, but at Invercargill, the maximum range was (south) positive, 450 mV/km, negative 120 mV/km. At Lauder, fluctuations of quasi-period 3 sec and amplitude 7 mV/km occurred, but the main 'period' was in the region 40–100 sec. Comparison of the records from these latter two sites, 190 km apart, shows less occurrence at Invercargill of fast variations than at Lauder. The effect is believed not to be instrumental, and is ascribed to the existence of spatial irregularities in the exciting regions which affected Lauder but not Invercargill. If so, these regions were probably not more distant northwards from Lauder than a few hundred kilometres—a conclusion in general agreement with visual observations of the southerly limit of the auroral display.

A number of radio-wave experiments provided information on electron densities at various locations. These will be considered in order of increasing altitude. Recordings of transmissions from *NPM*, Hawaii (19·8 kc/s), showed a reduction in signal strength of 20 db. by $H + 0{\cdot}1$ sec, with recovery, starting at $H + 0{\cdot}3$ sec, to within 3 db. of earlier value at

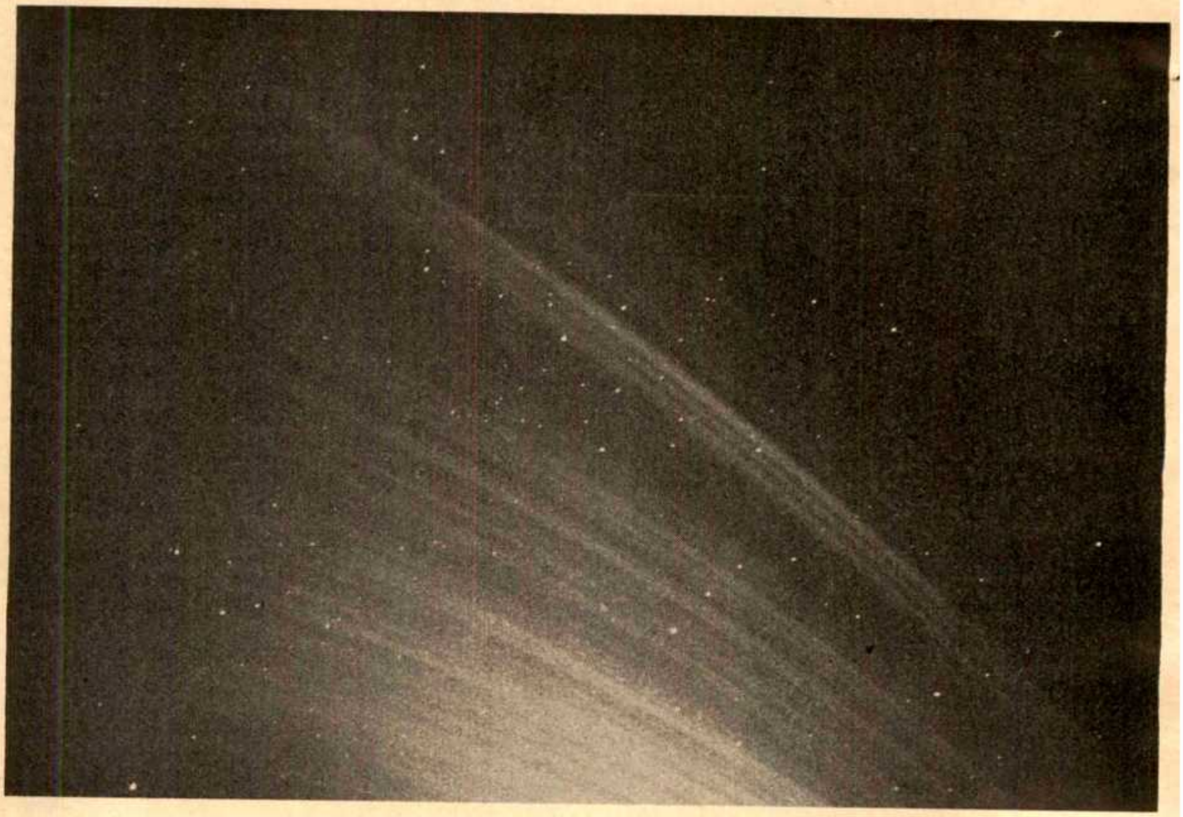

Fig. 3. Photograph of ray structure in aurora due to explosion, showing white rays from north merging into upper part of fading red glow. (Exposure from $H+10$ min 39 sec to $H + 11$ min 00 sec, with centre of photograph at 331·3° azimuth, 53·8° elevation, and field of view 40° × 28°, at Apia)

$H + 0{\cdot}6$ sec. This demonstration of momentary production of ionization, occurring a short time after H, and having a rapid recovery, suggests that the effects were located in a region relatively close to Johnston Island and deep in the atmosphere (Dominion Physical Laboratory). Comparisons of the time-scales of the variation of electron densities in the lower ionosphere, as a function of distance from the explosion, are possible through observations of cosmic noise absorption at 42 Mc/s, made with similar instruments located at Apia and at Lauder, New Zealand. At Apia, more than 10 db. reduction was noted for a few seconds after H, decreasing to zero in about 1 min. Assuming that the ionization was due to electrons of 300 KeV average energy, an electron density of approximately $10^4/\text{cm}^3$ occurred in a region centred around 70 km altitude (University of Canterbury). The rate of decay of the absorption appeared to be that of the ionizing agency, rather than determined by atmospheric processes. At Lauder, similar cosmic noise observations showed a slower rise to a maximum of 0·8 db. at $H + 2$ min, with rapid recovery starting at $H + 4$ min. The ionization involved was estimated to be located around 60 km, at a density of $4 \times 10^3/\text{cm}^3$. This could be produced by a proton flux of $10^3/\text{cm}^2$ sec and energy 15 MeV, or electrons of 1 MeV (Dominion Physical Laboratory, Auroral Station).

Information on low-height ionization away from the magnetic meridian was provided by observations of very low frequency transmissions from *GBR*, Rugby. At Lower Hutt, these are received predominantly by the shorter great circle path which passes within 3,000 km of Johnston Island, to the west. Immediately after H, a phase-change of 720° occurred, recovering in 3 h. This is interpreted, on the assumption of TM_{01} wave-guide mode propagation, as a decrease in effective guide boundary height from 85 to 68 km due to the explosion. A similar result was deduced from observations of station *NBA*, for which the phase-change was 630° (Dominion Physical Laboratory). To the east, at Rarotonga, ionosonde records showed moderate D-region

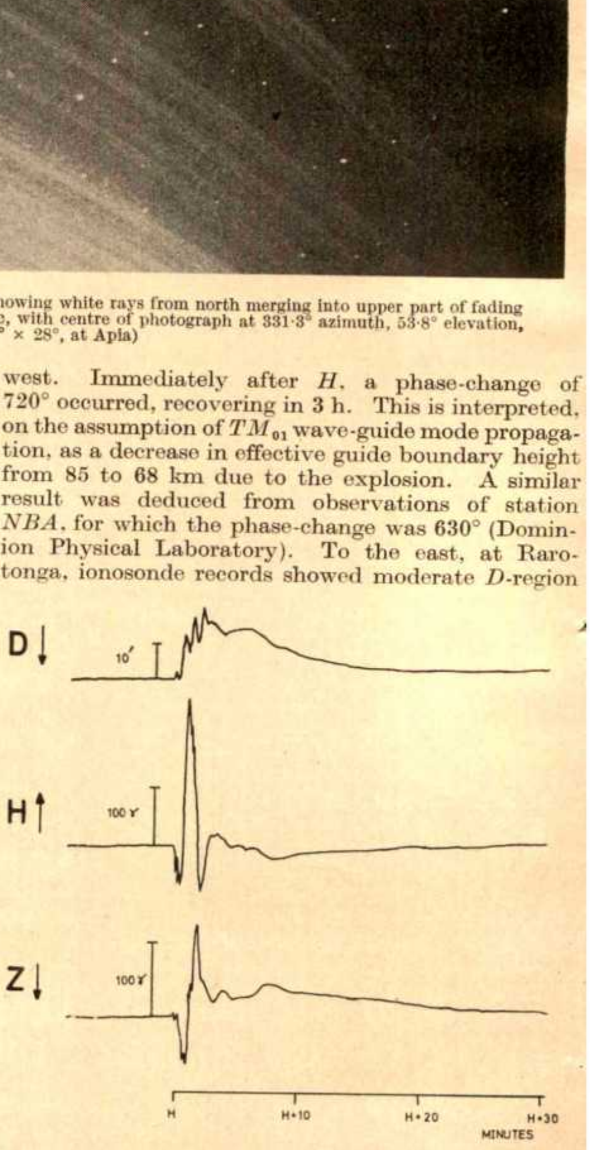

Fig. 4. Tracing of magnetic records from Amberley, New Zealand, showing disturbance due to explosion

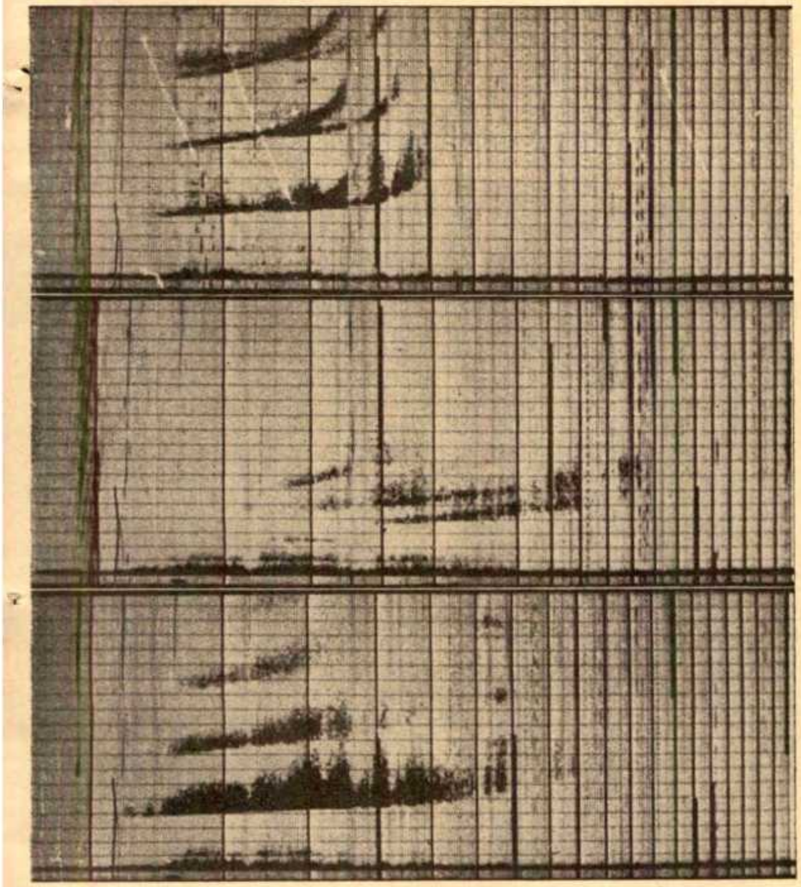

Fig. 5. Records from sweep frequency ionosonde at Christchurch showing effect of explosion. Top, at $H - 2$ sec; middle, at $H + 2$ min; bottom, at $H + 1$ h. Height markers are at 50 km intervals, and first frequency marker is at 1 Mc/s

absorption having essentially the same time variations as those noted at Apia. In the southerly direction, slight absorption was noticed at Christchurch and at Campbell Island, and there were negligible effects at Scott Base (Geophysical Observatory, Department of Scientific and Industrial Research).

The behaviour of electron densities at E-region heights was not measured directly, but upper limits could be set from inspection of ionosonde records. No strong sporadic or other E-region reflexions appeared at Christchurch or Campbell Island; and hence the corresponding electron densities probably did not rise above 5×10^4/cm^3. At Rarotonga, the appearance of the F-region trace suggested stratification, or a thick layer in E-region below. Information is available from a very high frequency pulsed forward scattered transmission at 52·5 Mc/s, for which the mid-point of the path is near Christchurch, as to variations in signal strength resulting from lower ionosphere electron density changes (Dominion Physical Laboratory). The transmission path, of length 910 km, extends from Invercargill to a receiver in the North Island, and makes an angle of 15° approximately with the magnetic meridian. A smooth increase in scatter strength started about $H + 2$ sec rising by 15 db. in 25 sec. Slight increases in greatest and least delays of the pulsed signals were recorded over the same period. At $H + 40$ sec, a rapid increase in strength by a further 20 db. was recorded. After a further interval of constant strength, a further rapid increase of strength at $H + 70$ sec caused 'off-scale' indications. Decay commenced about $H + 100$ sec and continued with an initial time constant of 13 min for a period of more than 2 h. The lowest height involved in the scattering was estimated from delay times to be between 80 and 85 km, and the greatest to be about 120 km. Signals with greatest delays showed 'filamentary' structure.

A second effect at E-region heights was detected by an auroral radar, operating at 55 Mc/s and located near Invercargill. The multi-lobed antenna radiation pattern was directed so as to intersect at right angles the magnetic field lines at E-region heights. This occurred over a distance of nearly 800 km, in a direction 175° true from the transmitter, over an area which lies across the magnetic meridian from Johnston Island. At $H + 40$ sec ± 6 sec, strong echoes appeared between ranges of 280–1,240 km. Using the known polar diagram of the array, it was deduced that the ionization responsible was field aligned, and located in a horizontal sheet, less than 6 km thick, at an average height of 103 km ± 1 km, some 8 km lower than the average height of thin layers giving rise to auroral echoes. The echoes showed an apparent motion to the south, with equivalent velocities, for horizontal motion at 103 km, lying between 25 km/sec and 1 km/sec. These values are greater than the velocity of sound in E-region. The echoes persisted for 17 min (Dominion Physical Laboratory, Auroral Station).

The main ionospheric effects in F-region were detected by the three ionosondes at Rarotonga Christchurch and Campbell Island, with greatest effects appearing on the Christchurch instrument (Geophysical Observatory). Fig. 5 shows a series of records from this location starting at $H - 2$ sec, $H + 2$ min and $H + 1$ h. The record at $H + 2$ min shows the maximum electron density noted in F-region after the explosion. At $H + 1$ min, an oblique echo appeared, due apparently to a high-density electron cloud. The density of the cloud increased up to $H + 2$ min and then decreased by $H + 6$ min. At $H + 7$ min, no reflexions were detectable from F-region, which was assumed to be too diffuse to give an echo. The region started reforming after $H + 8$ min. For $H + 3\frac{1}{2}$ h, 'spread-F' condition, much in excess of normal, persisted, as shown in the record for $H + 1$ h. Similar effects occurred at Campbell Island. The maximum density of the cloud was about ten times normal, and its approximate semi-thickness, assuming a parabolic layer, was estimated at 225 km. The probable total extent of the cloud is $5 \cdot 4 \times 10^{13}$ el/cm^2; and the minimum possible content $3 \cdot 6 \times 10^{13}$ el/cm^2.

At Rarotonga, the F-region effect took the form of an atmospheric wave which started about $H + 30$

min, reached a maximum about $H + 70$ min, and passed by $H + 120$ min. The disturbed condition of F-region precluded observations of the wave at Christchurch. The mean velocities of the onset, maximum and recovery of the wave were 147, 63 and 37 km/min respectively. This latter velocity, when corrected for electron recombination effects, is about the velocity of sound (40 km/min) in the region.

Effects on radio wave reception as a consequence of the ionization changes described here were widespread, and noticeable at frequencies from a few kc/s to 50 Mc/s. The click-type sferic used for determining the instant of detonation was followed by a clear multiple path whistler, of characteristics such that it can reasonably be attributed to the explosion (Dominion Physical Laboratory).

As expected, the interruption to communications circuits was greatest for those nearest the conjugate point. At Apia, complete and abrupt fade-out, commencing at H, of frequencies between 500 kc/s and 2·2 Mc/s, lasted until $H + 20$ min, for circuits to Fiji. Aeradio communications from Fiji were disrupted for periods of 5–25 min. Reports from ships indicate a complete interruption to transmissions between 4 and 9 Mc/s in the area 167°–176° W. and 24°–32° S. for 27 min (New Zealand Post Office).

In New Zealand, a complete fade-out occurred at Invercargill for frequencies about 2 Mc/s. A comparison of absorption of frequencies near 500 kc/s showed that paths over the South Island were affected more than those over the North Island, for north–south directions. High absorption affected all reception at Invercargill until $H + 80$ min. Trans-Tasman circuits suffered up to 60 db. absorption until $H + 5$ min. The recovery period extended throughout the night. Transmission from the Pacific coast of North America and from Hawaii to New Zealand, at frequencies near 10 Mc/s, faded out completely for 3 min, followed by 15–20 min of weak signals with rapid fading (New Zealand Post Office; New Zealand Broadcasting Corporation). Continued observations of broadcasting stations showed that high absorption persisted through the night of July 9, and that it was also present on July 10 and 11 around the New Zealand area.

The conference on August 16 was held essentially for comparison of observations, and a number of discrepancies was noted. The summary of observations permitted recognition of the three main visual effects, corresponding to initial flash, presumably due to decay electrons from fusion neutrons; the white ray structure due to material escaping from the explosion along the easy direction of the magnetic field, and the red glow, constrained within the magnetic field, and apparently due to excitation of atomic oxygen by low-energy electrons. The existence of much larger effects near New Zealand than near the conjugate point and the unexpected southward extension of the region affected were well established. Individual speakers were able to deduce hydromagnetic wave propagation as best explaining delay times of about 40 sec for E-region effects, and the atmospheric wave at higher altitudes was compared with those from previous explosions. Detailed accounts of these deductions will be presented by the workers concerned.

The conference acknowledged the indebtedness of various groups to the Royal New Zealand Air Force for transportation to locations in the Pacific.

CATASTROPHIC STORM EFFECTS ON THE BRITISH HONDURAS REEFS AND CAYS

By D. R. STODDART
Department of Geography, University of Cambridge

INTEREST in the effects of catastrophic storms on reefs and reef islands has been stimulated by investigations at Jaluit Atoll, Marshall Islands, following typhoon *Ophelia*[1,2], and at Ulithi Atoll, Caroline Islands, following another storm of the same name. Hurricane *Hattie*, which passed across the British Honduras reefs on October 30–31, 1961, presented an unusual opportunity to add to these Pacific investigations, since, during two expeditions in 1959–60[3] and 1961[4] I had completed field mapping of most of the sand cays of this coast, photographed all the cays from the air, and also observed living reefs, both on the three outer atolls (Turneffe, Lighthouse and Glover's Reefs) and the 150-mile long barrier reef. Accordingly, the hurricane-damaged areas were re-surveyed during February–June 1962. This article presents some of the main conclusions from the re-survey; the detailed reports on individual cays will be presented elsewhere.

Hurricane *Hattie*[5] was first identified as a tropical storm near San Andres Island, Nicaraguan coast, on October 27, 1961; it moved steadily northwards and intensified until the early hours of October 30, when it turned westwards in the neighbourhood of Grand Cayman Island and made for British Honduras. Heavy swells began to break on the outer reefs of British Honduras during October 29–30, and the first high winds reached Lighthouse Reef about 1600 h (Belize time) on October 30. The storm centre crossed Sandbore Cay, at the north end of Lighthouse Reef, at about midnight, October 30–31, when the minimum pressure recorded was 27·4 in. At this time the cay was covered to a depth of 7–8 ft. by a surge associated with the storm. The M.V. *Tactician*, 45 miles to the south-west in the barrier reef lagoon, also recorded 27·4 in. as the eye passed over at 0500 h, October 31. A minimum pressure of 28·5 in. was recorded at Belize, 20 miles north-west of the storm track, at 0600 h. The storm surge reached Belize at about this time, and by 0800 h sea-level at Belize had risen 10–15 ft. above normal, subsiding by 1030 h. No wind-speed records are available at Stanley Field, Belize, after 0500 h, when the anemometer ceased recording after gusts up to 115 m.p.h., but sustained speeds of 150 m.p.h. within 15 miles of the storm centre, with gusts up to 200 m.p.h., are considered likely. Hurricane *Hattie* was thus one of the most severe Atlantic hurricanes of 1961, and th

most severe in the British Honduras area since Hurricane *Janet* in 1955. Intense wind and wind-driven wave conditions combined with the high storm surge to the immedate north of the storm track to inflict severe damage to reefs and reef islands over a limited segment of the British Honduras coast.

Effect on Reefs. Damage to living coral reefs was variable and in places catastrophic. The windward reefs of Lighthouse Reef, immediately south of the storm track, suffered little damage, and the groove-buttress system remained intact. Damage to the windward reef of Turneffe was greatest near the north end, where fresh reef debris now forms a submerged shingle carpet on the reef crest, but the groove-buttress system is still largely intact. On the barrier reef, however, between English Cay and Rendezvous Cay, over a zone extending for 5 miles north of the storm centre, 80 per cent of the reef corals have disappeared. Patch-reefs which previously were coated with surface-breaking brown and orange *Acropora* now rise, greenish white, devoid of corals, to near sea-level. Along the reef-front all trace of the groove-buttress system has disappeared, and cannot be traced until one reaches Cay Glory, 10 miles south of the storm centre, where reef remnants indicate a pre-existing lineation. Reef species most affected were *Acropora cervicornis*, not seen living along the whole of the central barrier reef north of Curlew Cay; *Acropora palmata; Porites porites;* and numerous more fragile species, including *Porites furcata*, *Cladocora arbuscula*, *Manicina aerolata*, *Siderastrea radians*, *Eusmilia fastigiata*, *Favia fragum*, *Isophyllastrea rigida*, *Mycetophyllia lamarckana*, and even *Agaricia agaricites*. Consistently, the only species to survive in any quantity was *Montastrea annularis*, in massive hemispherical colonies. Other corals of similar habit, such as *Diploria labyrinthiformis*, *D. strigosa*, *D. clivosa*, *Siderastrea siderea*, *Solenastrea bournoni* and *Porites astreoides*, also survived in lesser numbers. The survival of the more massive, slower-growing species and destruction of fragile rapidly growing ones has also been observed at Low Isles, Great Barrier Reef of Australia, by Stephenson and others following the minor 1950 cyclone[6]. Many corals have been inverted or rolled across the reef-flat, but remain alive. Most of the reef constituents were washed into deeper water round the reef and are no longer visible, though in many places submerged areas of *A. cervicornis* debris indicates disintegration of this species *in situ*. Very little material larger than shingle size has been thrown above high-water-level, except on the east side of Turneffe, where mangrove hinders transportation into deeper water across the reef flat. South of Cay Glory, damage to the reef decreases rapidly; and no change was seen at Glover's Reef or along the southern barrier reef.

Effects on Reef Islands. The degree of damage to any particular cay depends: (*a*) on its location relative to the storm track; (*b*) on the type of cay, whether sand or mangrove; (*c*) on the size of the island; (*d*) on the nature of its vegetation and the extent of human interference. Four zones of cay damage are distinguished in Fig. 1, and will be discussed in turn.

Damage is greatest in a zone extending 15–20 miles north and south of the storm centre, especially on small cays where the natural vegetation has been replaced by coconuts with little undergrowth. In such cases, the cay has either disappeared or suffered severe marginal erosion; surface sand has been stripped to a depth of 1–3 ft., exposing coconut roots; fresh gravel has in some cases been patchily deposited on the cay surface; scour holes and channels have been cut on the cay surface and on the lee shore; and vegetation has been wholly or partly removed. Very large cays in comparable situations suffer only limited marginal erosion; surface erosion and deposition is restricted to a relatively narrow peripheral zone; and while coconut and other trees are thrown down in large numbers, much of the original ground vegetation survives. It is very noticeable that where cays retain much original vegetation, such as thickets of *Cordia sebestena* and *Bursera simaruba*, the effects are different: thus, along the south shores of Half Moon Cay, Lighthouse Reef, the section cleared for coconuts, formerly 7–10 ft. in height, suffered 3–5-ft. vertical erosion, whereas along the section covered with *Cordia* bush, much sediment was heaped against the vegetation barrier, with resultant increases in height of 3–5 ft. Similarly, scour channels were only cut across cay surfaces where the original dense vegetation had been cleared for coconuts or houses, as at St. George's Cay, Mauger Cay and Sandbore Cay.

Cays 20–40 miles from the storm track suffered less severe damage; they were unaffected by the storm surge and were subject to less extreme wave conditions. Physiographic changes were limited to minor shore retreat, exposing fresh beach-rock (South Water Cay, Carrie Bow Cay) or cay sandstone (Cay Chapel); the disappearance or modification of small spits; minor near-shore sand-stripping and root-exposure; and deposition of narrow carpets of sand and shingle inland from this erosion zone. Dominant storm effects were vegetational: on cays planted to coconuts 50–80 per cent of the trees were knocked down, often leaving small hollows filled with ground-water. Damage to other trees was generally restricted to defoliation and snapping off of branches, though in exposed areas large specimens of *Coccoloba uvifera* were seen overturned. Damage was greatest where natural vegetation had suffered most human interference, especially where this allowed unrestricted passage to waves across narrow portions of cays, as at Cay Caulker. Here, scour holes, channels and sand-stripping were well developed. Again, the larger the island the less was the damage sustained inland.

A third zone includes the cays between Placencia and Gladden Spit, barrier reef lagoon, where the main hurricane winds blew from the south across water 15–25 fathoms deep. In most of these cays the vegetational effects were insignificant, but all had sand or shingle deposited on their south and east shores. These deposits take the form of narrow carpets 1–5 ft. thick overlying the old cay surface, broad shingle flats adjoining the old shoreline, and offshore shingle ridges. Some of the offshore deposits are already being destroyed by wave action, the finer materials being flushed out leaving a coarse lag gravel. This zone is not duplicated to the north of the hurricane track, and its existence seems to depend on local conditions.

Finally, the cays of Glover's Reef and of the southern barrier reef and lagoon suffered no vegetational and little or no physiographic change, apart from insignificant shoreline readjustments which may or may not result from the hurricane itself. The Glover's Reef cays lie only 40 miles south of the storm track; while at Punta Gorda sustained gale force winds, perhaps reaching hurricane force, were insufficient to defoliate mangrove or lead to physiographic changes to the cays off Punta Ycacos. This zone is not represented in British Honduras to the north of the storm track, partly because of the absence of cays in that area, partly because of the greater wind velocities and storm surge, and hence greater extent of damage in the northern sector of the storm.

Beach-rock. Old relict beach-rock was remarkably successful in resisting damage, even where cays were completely destroyed, as at Cay Glory. Intertidal beach-rock within 20 miles of the storm centre was swept bare of larger algæ by wave action. Shore re-adjustments on many cays led to the exposure of new beach-rock, including low 'promenades' (Deadman's Cays) with pitted upper surfaces[7], similar to features previously interpreted as due to elevation of reef-rock. Much of this new beach-rock is poorly cemented; but in some cases areas where incipient cementation was previously noted now exhibit one or two lines of hard well-indurated beach-rock. Exposure of fresh areas of lithified sands above present sea-level at Harry Jones, Grand Bogue Point and Big Cay Bokel, Turneffe, and Cay Chapel, barrier reef, indicate that the rock is a cay sandstone rather than an elevated intertidal beach-rock.

Vegetation change. The most conspicuous vegetation changes were: (*a*) defoliation of mangrove within 40 miles of the storm centre; (*b*) the widespread destruction of coconut palms. Mangrove defoliation gradually decreased away from the storm centre, until at 20 miles distance on the south side, mangrove in the centre of large cays escaped defoliation. In early 1962, six months after the storm, some of the *Rhizophora* was again beginning to bear leaves, chiefly on the side of the cays in the lee of hurricane winds and waves, but it is not yet clear how much will ultimately recover. Large-scale fall of coconuts (in excess of 50 per cent) was found within 20–40 miles north and south of the storm track, and gives an indication of direction of extreme hurricane winds. Tree-fall direction at any point is generally constant within 30°–40°. Trees were uprooted, snapped off a few feet above the ground, or lost their crowns. Other trees which suffered heavy damage include *Cordia sebestena*, *Coccoloba uvifera*, *Bursera simaruba* and *Terminalia catappa*. All except *Cordia* tended to remain upright, losing leaves or branches; *Cordia* was generally uprooted and the debris piled by waves against obstructions. In the shallow northern barrier reef lagoon, uprooted trees, generally palms, have been carried several hundred yards from the nearest land, deposited on the lagoon floor, and are now visible above sea-level. *Rhizophora* showed great tenacity: not only are the details of mangrove areas almost unchanged by the storm, as shown by air photographs, but also in one case, Big Calabash East Cay II, the island was completely washed away, leaving only a ring of dead *Rhizophora* still in place. Greatest proportionate damage was caused to those species most abundant in exposed situations. *Tournefortia gnaphalodes* and *Suriana maritima*, formerly widespread near-shore plants, are not now to be found in the central zone of cay damage. On devastated cays and areas of freshly deposited sand, the chief colonists during the 4–7 months since the hurricane were, during the re-survey, *Portulaca oleracea*, species of *Euphorbia*, *Sesuvium portulacastrum* and *Ipomoea pes-caprae*.

Human settlement. The cays were previously habited by lighthouse keepers, coconut workers and hermen. The lighthouses at Sandbore Cay (Lightuse Reef) and Cay Bokel (Turneffe) were destroyed the storm, and that at Mauger Cay (Turneffe) was t out of action. Only the Half Moon Cay and nglish Cay lights remained in operation. Of the ur cays previously inhabited at Lighthouse Reef, ree have been abandoned; of the six settlements at urneffe, all are abandoned; and several cays on e barrier reef are no longer inhabited. The main urce of livelihood, apart from the lighthouses—the coconut industry—suffered very heavy damage, and all the loading installations at Calabash Cays were destroyed. It will be at least seven years before coconuts planted now begin to bear; but it is unlikely that private or public capital will be available for coconut investment following the succession of recent hurricanes. The larger islands near the storm centre, which were inundated by the storm surge, suffered contamination of their fresh-water lenses. Ground-water on these cays is now brackish and almost undrinkable. Since previous inhabitants, however, relied almost exclusively on rain-water vats for water supply, this is of less immediate practical importance than might be expected.

Birds. Two bird colonies in the devastated area were not markedly affected by the storm. The Half Moon Cay red-footed boobies, *Sula sula sula*, were not diminished in numbers, in spite of great damage to their nesting area, but the nesting period was delayed. Normally the young hatch in January–February, but in 1962 hatching began in mid-April and continued into May. *Fregata magnificens* was nesting in considerable numbers on Man of War Cay, barrier reef lagoon, in April.

Prospect. Investigations at Jaluit[8] indicate that, over a period of years, cays tend to revert to the position obtaining before the hurricane struck, shown, for example, by landward migration and erosion of shingle ridges, and by vegetation recovery. This is already beginning on some British Honduras ays. On the other hand, as at Jaluit, certain prosses are irreversible: the stripping of fine surface aterial and exposure of roots, erosion of scour holes nd scour channels in cay surfaces, deposition of shingle and sand carpets above high-tide-level, all are likely to be permanent. The large-scale destruction of living reef along the central barrier reef has both provided much new debris for cay accumulation and permitted larger waves access to cay shores. As a result sandbores have appeared in areas where none was previously seen, and many cay beaches are steeper. This, too, is likely to be a short-term effect, for studies in Australia indicate a period of 10–20 years for reef recovery following hurricane damage[6]. Future vegetation changes are difficult to assess. With the decline of economic interest in coconut plantations, and hence of the incentive to clear, many areas may tend to revert to bush, consequently decreasing the danger of catastrophic damage during subsequent hurricanes. Recovery will be most delayed in areas where the cay was completely destroyed, and has re-appeared or is likely to reappear, as a shifting unvegetated sandbore. A second re-survey in 3–4 years, as at Jaluit, could be instructive in assessing the long-term effects of hurricanes on reefs, reef islands and their human utilization. At present the most important practical conclusion, within the general zonation of damage, is the severity of change where human interference with island vegetation has been most intense.

I thank the Royal Society for supporting the re-survey expedition, and Miss E. L. Pruitt, Geography Branch, Office of Naval Research, Washington, for transatlantic transportation. Previous expeditions were supported by the Cambridge Expedition to British Honduras 1959–60, the Office of Naval Research, and the Coastal Studies Institute, Louisiana State University. I also thank Prof. J. A. Steers, Dr. F. R. Fosberg and Dr. Adrian Richards for help with the present investigation.

CANCER RESEARCH IN CHILE

By Dr. R. S. d. ZALDÍVAR*

Department of Biology, University of Chile, Santiago

CANCER research, along many different lines, is being successfully pursued in Santiago. These vestigations are concerned with experimental, nical and epidemiological problems.

Profs. G. Gasic and O. Badínez, Dr. F. Loebel and rs. Tatiana Baydak (Departments of Oncology and mbryology, University of Chile School of Medicine) ve for several years been studying the process of etastasis. At first, these investigations dealt with e capacity of cortisone in increased metastatic read in mice bearing mammary adenocarcinoma[1]. urther work dealt with the invasiveness of transanted neoplasms in mouse brain. It has been shown t in four different combinations of host and breast mour there is a close relationship between the ability of neoplasm for metastatic spread and its potency for invading the Virchow–Robin perivascular spaces when transplanted into the brain. However, sarcoma 180 and leukæmia *H* apparently show a different behaviour[1,2]. Recently, investigation has been focused on intercellular cementing substances and metastasis. The ground-substance of eight transplantable sarcomas of mice was examined by means of the Hale reaction. Hale-positive material is considered to be a non-sulphated acid mucopolysaccharide. A large amount of Hale-positive material was present in the ground-substance of non-metastasizing sarcomas. On the contrary, in tumours with moderate or high metastatic capacity the Hale reaction of the ground-substance was negative. Examination of the intercellular cement in five

---

* Address: Casilla 5539, Santiago, Chile.

carcinomas with the same histochemical reaction confirmed this relationship[4]. Then the Golgi zone was examined using the Mowry variant of the Hale reaction. Several ascitic and solid tumours as well as normal tissues were examined; in almost all tissues, cells showed a positive-reacting Golgi zone[5]. Experiments to examine the chemical nature and biological meaning of this reacting Golgi material are in progress.

Dr. R. Iglesias (Institute of Experimental Medicine, National Health Service) has continued, through transplantation, his investigations of the biological behaviour of some spontaneous neoplasms in *A* × *C* rats and the influence of steroid hormones on such tumours. He found in the right ear of an animal a melanoma which did not show metastasis. Two groups of animals received inoculations, subcutaneously and intramuscularly. After 288–558 days, the neoplasm grew in four of the animals injected subcutaneously, and in only one of the rats with intramuscular inoculation. This tumour is being transplanted, and the probable influence of the gonads and of steroid hormones on tumour growth investigated[6]. Precocious metastasis of a transplantable sarcoma has been reported[7]. Lately it was found that the responsiveness to androgen of the Iglesias functional ovarian tumour, which was previously reported[8,9], has been changed. One tumour (*A*) maintains its original responsiveness, growing faster in intact males than in castrates and testosterone propionate stimulates its growth. But the other (*B*) is now growing faster in castrated males than in intact males and than in castrated males receiving the androgen[10]. Investigations dealing with the activity of large and sub-physiological doses of testosterone propionate on growth of two ovarian neoplasms were performed. The author concludes that masculinizing and sub-physiological doses of this hormone stimulate the growth of both tumours[11].

Dr. R. S. d. Zaldívar (Department of Biology, University of Chile) has been engaged in research with guinea pigs on gastric lesions induced by 3-methylcholanthrene and on the pathological effects of heated fat in the gastric mucosa. After intraperitoneal administration of 3-methylcholanthrene crystals, depositing the hydrocarbon on the gastric serosa of 66 animals, 9 pre-cancerous lesions (5 diverticula and 4 infiltrating epithelial lesions) and a true adenocarcinoma were induced (15·1 per cent). Also the liver developed proliferative changes as cholangiofibrosis, bile-duct hyperplasia, and cholangio-cellular tumour[12]. When the same carcinogen was implanted into the wall of the gastric antrum, 14 out of 41 animals (34·1 per cent) showed stomach lesions. Twelve diverticula (two of them associated with infiltrating lesion) and 2 infiltrating epithelial lesions appeared. In advanced stages of its development, the diverticulum may undergo malignant changes. On the other hand, the infiltrating lesion exhibits an evident neoplastic behaviour[13]. In further studies on this problem, an intramural injection of this carcinogen in the gastric antrum was given, using polyethylene glycol-400 as solvent. Pre-cancerous gastric lesions appeared in 14 out of 25 treated animals (56·0 per cent). With regard to the histogenesis of the infiltrating lesions, it originates from the deep mucosa, and one case showing perforation of muscularis mucosæ in three areas would indicate that this tumour develops from multicentric neoplastic foci[14]. However, as a detailed histogenetic study is pertinent, an experiment is now in progress. The problem of heated fats as possible carcinogens for the glandu epithelium of the stomach has also been investigate The carcinogenic activity of heated fat given ora —the physiological way—on the gastric gland mucosa of mice has not yet been demonstrated However, when a single dose (0·05 c.c.) of fat heate 361°–365° C for 30 min is injected into the wall the gastric antrum of guinea pigs, perforation muscularis mucosæ by pyloric glands appears[17]. other series the animals receiving heated fat (0·10 c. and using the same technique, all the six anim show gastric changes as epithelial hyperplasia of t mucosa, perforation of muscularis mucosæ and diverticula[18]. In both series[17,18] guinea pigs injecte with non-heated fat did not show epithelial change These observations would suggest that heated fat may play a part in the ætiology of human gastri adenocarcinoma.

At present, one experiment to study the hist pathological changes of bronchial and pulmonar epithelium in the rabbit after a single intra venous injection of 3-methylcholanthrene is in progress.

Drs. G. Contreras, Adela Ohlbaum and J. Toh (Bacteriological Institute, National Health Service and Institute of Physics and Mathematics, Universit of Chile) have been working on some aspects of th virus-cell relationship. Research has been focuse on biochemical changes related to poliovirus multipl cation in HeLa cells. First the kinetics of incorpor tion of phosphorus-32 into phosphoproteins a ribonucleic acid and the inhibitory activity of chloram phenicol were described[19]. Then the kinetics of on complete growth-cycle of poliovirus in suspende HeLa cells was investigated, the relation of it wit certain biochemical changes, and the effects chloramphenicol on the multiplication of the virus Experiments are now in progress on the kinetics the antibiotic inhibition in the HeLa cells–poliovir system.

Prof. Graciela Leyton, Dr. E. Raventos and other (Bacteriological Institute, National Health Servic and Fundación A. López Pérez), using different chen ical and immunological techniques, have been exami ing urinary proteoses in patients bearing malignan neoplasms[21].

Prof. L. Vargas and Drs. J. Rodríguez, A. Lucchir and J. Arraztoa (Departments of Physiopatholog Pathological Anatomy and Surgery, Catholic Univer sity School of Medicine) have been working on clinic chemotherapy of tumours. Thirty-six post-men pausal women were treated with hexœstrol during th terminal stages of metastatic mammary cancer. Th treatment was given after androgen therapy. I 22 patients (61 per cent) a good reaction was observe In these 22 patients the average survival-time w 27 months after the first subcutaneous implantati of hexœstrol pellets. After about the fourth to six day post-implantation, 50 per cent of the 22 wom showed a rapid decrease in size of lymphatic met stasis. The rapid regression of these metasta induced by the drug produced the so-called 'metast lysis syndrome', characterized by nausea, vomitin fever and chills. The syndrome is considered to be good reaction to hexœstrol treatment[22]. A study the effects of thiotepa on advanced breast cancer w performed. The patients received this compou after neither androgens nor œstrogens showed a therapeutic effect. A transitory regression of me stasis was noted, and the average survival time 10 months[23].

Finally, other investigations in 20 patients showing advanced cancer was done. Adrenocorticotrophic hormone, dexamethasone and 'Nitromin' were associated together as treatment. In 7 cases the complete course of the disease became known and the corresponding necropsies were performed. Each of these patients exhibited a different type of neoplasm. The therapy was well tolerated, and regression of the primary tumours or their metastases were not observed. The average survival-time was only eight weeks. Five out of the 7 patients suddenly died. The histological study of the viscera showed a diffuse tumoral infiltration, not detectable macroscopically. The spleen, which is generally not invaded in patients dying from cancer, was infiltrated in 100 per cent of the cases[14].

Prof. J. Moroder (Department of Preventive Medicine, University of Chile School of Medicine) has been working on the epidemiology of cancer. Preliminary studies on cancer mortality and morbidity in our country were reported[25,26]. Further investigation deals with statistical data of the years 1959 and 1960 [27]. These investigations have confirmed former observations on the very high incidence of stomach carcinoma. Furthermore, on January 1, 1959, the National Cancer Registry began its work.

OBITUARIES

Sir Leonard Rogers, K.C.S.I., C.I.E., F.R.S.

Major-General Sir Leonard Rogers died in Truro, Cornwall, on September 16, 1962, at the age of ninety-four.

He was a Cornishman, born near Plymouth, and he returned to Cornwall after the death of his wife in 1951. His father was a captain in the Royal Navy, who brought up his large family in a deeply religious atmosphere. Rogers was educated at Tavistock Grammar School, Plymouth College, and St. Mary's Hospital, London, and in his schooldays he was a notable mathematician, taking several prizes. As an undergraduate he did some clinical research, published a paper, and won a scholarship in pathology. He qualified in 1891, and gained the F.R.C.S. in the following year, and at the same time passed the London M.B., B.S., with honours.

After a short period during which he demonstrated bacteriology at St. Mary's, and perhaps influenced by the fact that two of his brothers had entered the Indian services, Rogers passed the competitive examination for the Indian Medical Service. In this he hoped to find the opportunities for research which attracted him, and began his long series of investigations even in the early days when he was assigned to military duties, experimenting on the clotting of blood and inquiring into problems of malaria. As a result of this malaria work he was appointed to investigate kala azar, which was then epidemic in Assam, and which was thought to be a form of malaria. He did not succeed in differentiating the two diseases—this was done a few years later by Leishman and Donovan—but he did recognize that it was an infection associated with certain villages, and devised a method of control by removal of the people from those villages, which was very largely effective.

In 1900, Rogers (who had by then achieved the M.D. of London, and M.R.C.P.) was appointed professor of pathology in the University of Calcutta, and there he worked on amœbiasis, showing that liver abscess was due to *Entamoeba histolytica*, and proving that repeated aspiration was a much more desirable treatment than open operation. Knowing that ipecacuanha had some reputation in dysentery, but recognizing its undesirable toxic effects, he began to think about its component principles, and learned that one of them, emetine, had been found lethal to non-pathogenic water amoebae. He obtained some, tried it in amoebiasis, and thus started an effective treatment which, with its modifications, remains standard at the present time. Similarly, hearing that antimony salts had been used for African trypanosomiasis, he argued that they might be valuable in kala azar—another protozoal infection—and again he started a line of treatment which has remained standard.

These successes were achieved in clinical medicine, though he was essentially, and remained, a pathologist, and the same is true of much of his work on cholera and leprosy. In cholera he knew that infusion of normal saline gave only moderate results, and he argued that a stronger solution of salt might help to retain fluid in the body and prevent that excessive loss of fluid which is the characteristic of the disease. He therefore doubled the salt, and the treatment worked well—and once more it has remained standard practice. Towards the end of his life it became a matter of intense satisfaction to him that the Government of India accepted the advice he had long since given, that vaccination against cholera should be made compulsory for all pilgrims attending the great religious festivals, during which cholera had formerly so often been epidemic. Under British rule such a measure would probably have been unacceptable to the people.

In leprosy he started from the knowledge that chaulmoogra oil had some reputation for beneficial action, but was difficult to administer, and he isolated from it sodium gynocardate, which could be given more easily, and proved to be relatively effective. This remained the main basis of treatment until the sulphones were introduced.

Rogers undertook research on several other problems—snake venom, trypanosomiasis of horses, and other subjects—and devoted his inexhaustible energy to raising funds for a School of Tropical Medicine in Calcutta, which was opened in 1916; it remains an active institution and a permanent memorial to him.

He returned from India in 1920, was appointed medical adviser to the Secretary of State for India and physician to the Tropical Diseases Hospital; but the main interest of his later life was the British Empire Leprosy Relief Association, to which he gave large sums of his own well-earned money and time. He was president of the Royal Society of Tropical Medicine and Hygiene during 1933–35.

Rogers received many honours, as the list of his distinctions shows, and his work was well acknowledged in his lifetime, but he remained frugal in his habits, simple and even austere in his private life. He loved walking and cycling, not probably for the opportunities these gave of appreciating the beauty of Nature so much as for the release of energy they involved. Apart from his family he had few interests outside his work, but this work enraptured him, as he admitted in his autobiography, *Happy Toil*. He remained a religious man, but he also retained a critical, caustic mind, enthusiastic and resilient. His knowledge was exact, and he was at home with figures, which he could produce from memory on any public platform. He had immense innate authority, and at the same time a sense of fun, and he did not act the part of a great public figure—he was always himself, a single-minded scientist with the egocentricity which is part of genius. He was a very great man.

He married, in 1914, Una Elsie North, by whom he had three sons, who survive him, and he was ideally happy with her.

CHARLES WILCOCKS

Dr. B. P. Eddy

DR. B. P. EDDY died in Cambridge on August 11 at the age of thirty-seven, tragically cutting short a promising career in microbiology and leaving his many friends and colleagues with a deep sense of loss. Brian Pollard Eddy was born in Newcastle upon Tyne and received his education there; first at the Royal Grammar School (1936–43) and then, by virtue of an open scholarship, at King's College, Newcastle. After graduating with first-class honours in botany he was awarded the Pemberton postgraduate studentship. During its tenure for two years he did research on the formation of anthocyanins under Prof. Meirion Thomas.

In 1948 he was invited to fill a vacancy which existed for a bacteriologist at the Low Temperature Research Station, Cambridge, and he joined the staff in November of that year. While attending courses in bacteriology he completed his work on anthocyanins and was awarded the degree of Ph.D. of the University of Durham in 1949.

His work on problems relating to food began with a study of the bacterial reduction of dehydroascorbic acid. He showed that, in the bacterial cell, this depended on a rather specific activating enzyme and a particular type of cytochrome complement. He then turned to the problem of using micro-organisms for the production of new food materials. An attempt was made to produce dried 'mushroom' powder by the deep tank culture of various Basiodiomycetes Though acceptable powders were made, the desirable 'mushroom' flavour was absent. The mass cultivation of algae was also studied. *Dunaliella*, rather than *Chlorella*, was selected because it does not develop a prominent (and indigestible) cell wall and it was established that yields and growth rates were comparable with those of *Chlorella*.

Eddy's interest in the bacterial production of nitrite led him to investigate problems of meat curing. It was with this background that he edited the proceedings of the second International Symposium on Food Microbiology on the subject of "The Microbiology of Fish and Meat Curing Brines" (H.M.S.O., London, 1958). His recent activities in this sphere related to problems arising from the introduction of the new process of vacuum packing sliced bacon.

In the past few years, Eddy was especially interested in the physiology of Gram-negative bacteria. His recent revision of the genus *Aeromonas*, on which he was actively engaged at the time of his death, was probably his best known work. He published more than thirty papers, many jointly with colleagues in the Low Temperature Research Station, who will miss his co-operation. They will also miss his untiring efforts on the committee of the local branch of the Institution of Professional Civil Servants. His principal hobbies were music, of which he was passionately fond, and photography.

He was not strong physically and was for this reason exempt from War service. Temperamentally he was highly strung. However, he was throughout his university and research careers a likeable and sincere colleague, and it is as such that he is remembered.

E. C. BATE-SMITH

Mr. C. C. Calder

CHARLES CUMMING CALDER, who died in Aberdeen in April 1962, was one of a long and distinguished line of Scots who held high botanical office in India, and three of his immediate predecessors, Sir George King, Sir David Prain (later director of the Royal Botanic Gardens, Kew) and Colonel A. T. Gage were, like himself, graduates of the University of Aberdeen. Calder was born at Dunphail in Morayshire in December 1884, and was educated at Robert Gordons College, Aberdeen, and later at the University, where he took the degree of B.Sc. both in pure science and in agriculture. After graduation he went for a period of study to Berlin and on his return to Aberdeen he was for a time assistant to Prof. J. W. H. Trail, who was a close friend of King, to whom he had recommended young Prain for appointment to the Indian service. Trail no doubt influenced Calder in accepting the post of curator of the Herbarium at Sibpur in March, 1912, where he remained, apart from a short period on active service in 1918, until his appointment in January, 1923, as superintendent of the Royal Botanic Gardens, Calcutta, conjointly with the directorship of the Indian Botanical Survey. Another cognate office which he held, and to which he devoted most of his time, was that of quinologist, with responsibility for the care and distribution of the important quinine stocks for the Government of India. In his official duties he was much more concerned with administration than with scientific research, so that his publication record is rather meagre. He wrote short papers on *Oxalis* and *Vernonia*, a brief account of the vegetation of India, and, with Dr. K. P. Biswas, a handbook of the aquatic plants of India and Burma.

Calder retired in 1937, an event probably hastened by his own and his wife's poor health. He returned to Aberdeen where, during the Second World War, he concerned himself with agricultural affairs which mainly involved the direction of labour to farms. For some years before his death he was not well, and he is survived by his widow, a son and a daughter. His elder brother, who predeceased him, was Sir William Moir Calder, an eminent classical scholar, who was professor of Greek in the University of Edinburgh.

GEORGE TAYLOR

NEWS and VIEWS

Nobel Prizes:

Chemistry: Dr. M. F. Perutz, F.R.S., and Dr. J. C. Kendrew, F.R.S.

THIS year's Nobel Prize for Chemistry has been awarded jointly to Dr. M. F. Perutz, chairman of the Medical Research Council Laboratory for Molecular Biology, Cambridge, and Dr. J. C. Kendrew, deputy director of the Laboratory and head of the Structure Studies Division. This most welcome announcement follows quickly on that concerning the award of the Nobel Prize for Medicine to another member of the staff of the same Laboratory, Dr. F. H. C. Crick (jointly with Dr. M. H. F. Wilkins and Prof. W. Watson; see *Nature* of October 27, 1962, p. 319). Dr. Perutz was elected a Fellow of the Royal Society in 1954, and Dr. Kendrew in 1960. The award was made for their work on the structures of globular proteins. Both are also readers in the Davy Faraday Laboratory of the Royal Institution, London.

Physics: Prof. L. D. Landau, For.Mem.R.S.

THE Nobel Prize for Physics has been awarded to Prof. L. D. Landau, of the Institute for Physical Problems, Moscow. The award was made for his "pioneering theories for condensed matter, especially liquid helium". Prof. Landau was elected a Foreign Member of the Royal Society in 1960.

The Gairdner Foundation Awards

THE Gairdner Foundation Award of Merit has been given to Dr. F. H. C. Crick, Medical Research Council Laboratory for Molecular Biology, Cambridge, for his contributions to the solution of the genetic code. This is the first time that the Award, which is accompanied by a prize of 25,000 dollars, has been won since 1959. Four additional awards, with prizes of 5,000 dollars, have also been made to: Dr. A. H. Coons, Harvard Medical School, Boston, for his work on methods of tagging proteins with fluorescent dyes; Dr. C. Crafoord, Karolinska Institute, Stockholm, for his contributions to heart surgery and the heart–lung machine; Dr. H. G. Kunkel, Rockefeller Institute, New York City, for his contributions to the understanding of the formation and behaviour of protein molecules that are found in blood and body tissues; Dr. S. J. Sarnoff, National Institutes of Health, Bethesda, for his contributions to cardiac physiology. Established in 1957 by J. A. Gairdner, of Gairdner and Co., Ltd., Toronto, the Foundation has now conferred its awards and cash prizes totalling 150,000 dollars on 23 scientists.

Director of the Forest Products Research Laboratory: Mr. J. Bryan

MR. JOHN BRYAN has been appointed director of the Forest Products Research Laboratory of the Department of Scientific and Industrial Research. Mr. Bryan, at present deputy director of the Laboratory, succeeds Dr. A. C. Copisarow (see *Nature*, **186**, 934; 1962), who has been chief technical officer on the staff of the National Economic Development Council on a part-time basis since March, and is now to be released on full-time secondment. Mr. Bryan, who is fifty-nine, has been on the staff of the Forest Products Research Laboratory since 1926 and has been assistant director for eight years. Born and educated in Sheffield, he read civil engineering at the University of Sheffield, and worked in the field of structural steel design for three years before joining the Laboratory. After forming and leading the section working on wood preservation and later leading the section of timber mechanics, Mr. Bryan took charge of all engineering studies at the Laboratory in 1945. For some years he has worked in close co-operation with the Forestry Commission, and is chairman of a joint Department of Scientific and Industrial Research–Forestry Commission Committee on research into home-grown timbers.

Forest Products Division of the F.A.O.: Dr. N. A. Osara

DR. NILS ARTHUR OSARA, formerly director-general of the Finnish State Forestry Board, has been appointed deputy-director of the Forestry and Forest Products Division of the Food and Agriculture Organization. Dr. Osara replaces Sir Henry Beresford-Peirse, who has returned to the United Kingdom as director-general of the Forestry Commission of Great Britain. Dr. Osara was born in Ikaalinen, Finland, and attended the University of Helsinki, receiving his degree of Doctor of Forestry in 1936. During the period 1924–36, he was also employed by both the University of Helsinki and the Forest Research Institute. A war-time member of the Finnish Government, Dr. Osara was appointed Minister of Supplies and Forestry during 1943–44. From 1938 until 1948 he was professor of forest economics at the Forest Research Institute. He then became director of the Central Forestry Association, 'Tapio', from 1948 until 1952, before going on to head the Finnish State Forestry Board. From 1937 until 1952 he was also associate lecturer on forest policy at the University of Helsinki.

Physical Properties at the U.S. National Bureau of Standards : Dr. J. B. Wachtman, jun.

DR. JOHN B. WACHTMAN, JUN., has been appointed chief of the Physical Properties Section of the National Bureau of Standards, U.S. Department of Commerce. This section, which studies the physical properties of inorganic, non-metallic crystals, with particular reference to the effects of structural defects and chemical impurities, is a part of the Inorganic Solids Division. Dr. A. D. Franklin, chief of the Division, has served as acting chief of the section since it was established in March 1961. Dr. Wachtman joined the Engineering Ceramics Section of the National Bureau of Standards in 1951, and received a Meritorious Service Award from the Department of Commerce in 1960 for his research work in that area. Born in Conway, South Carolina, in 1928, he received his B.S. and M.S. in physics from the Carnegie Institute of Technology in 1948 and 1949 respectively. Dr. Wachtman was a research and teaching assistant at the Carnegie Institute of Technology from 1949 until 1951. He received his Ph.D. in physics from the University of Maryland in 1961. Dr. Wachtman is a member of the American Physical Society, the American Ceramic Society, the Society of Rheology, the Washington Academy of Sciences, Sigma Xi, and the Washington Philosophical Society.

The Christmas Lectures at the Royal Institution, London

THE Christmas Lectures for children were started at the Royal Institution, London, in 1826 and have been given every year since then. These lectures have always been well known for their vivid demonstrations and experiments. The scene of the 1961 Christmas Lectures, being given by Sir Lawrence Bragg, Fullerian professor of chemistry and director of the Davy Faraday Laboratory in the Institution, has been painted by Terence Cuneo. The picture reveals Sir Lawrence demonstrating electrostatic effects before a young audience in the world-famous and beautiful lecture theatre at the Institution. The painting was commissioned by the Royal Institution and unveiled by the president, Lord Brabazon of Tara, after one of the equally famous Friday Evening Discourses on October 12, 1962. This is the first painting of a Christmas Lecture since the well-known picture was painted of Faraday himself giving a lecture in 1856. In it (Fig. 1) Mr. W. A. Coates is seen assisting Sir Lawrence with the demonstration. Lord Brabazon of Tara is sitting in the president's chair. Also in the audience are Lady Bragg (second row, second seat), and Prof. R. King, professor of metal physics in the Institution, and Mr. K. D. C. Vernon, librarian of the Institution (left of front row, right). The head porter, Mr. T. Ryan, is standing at the door.

The National Universities Commission, Nigeria

A NATIONAL Universities Commission has been set up in Nigeria. Its inaugural meeting was held on October 11 in Lagos. Its membership is as follows: Mallam Muhammadu Tukur, Emir of Yauri (*chairman*); Mallam Abdu Gusau; Alhaji Abdurrahman Okene; Dr. S. E. Imoke, Minister of Education, Eastern Region; Mr. J. O. Udoji; Dr. F. Ogunro; Mr. G. A. Konolafe; Mr. S. O. Wey, Permanent Secretary, Prime Minister's Department; Mr. A. Ikoku; Mr. E. E. Esua; Mr. E. A. Osindero. The Commission has a full-time secretary of senior status, Mr. Okoi Arikpo; he is a graduate of the University of London (University College) and a barrister. He

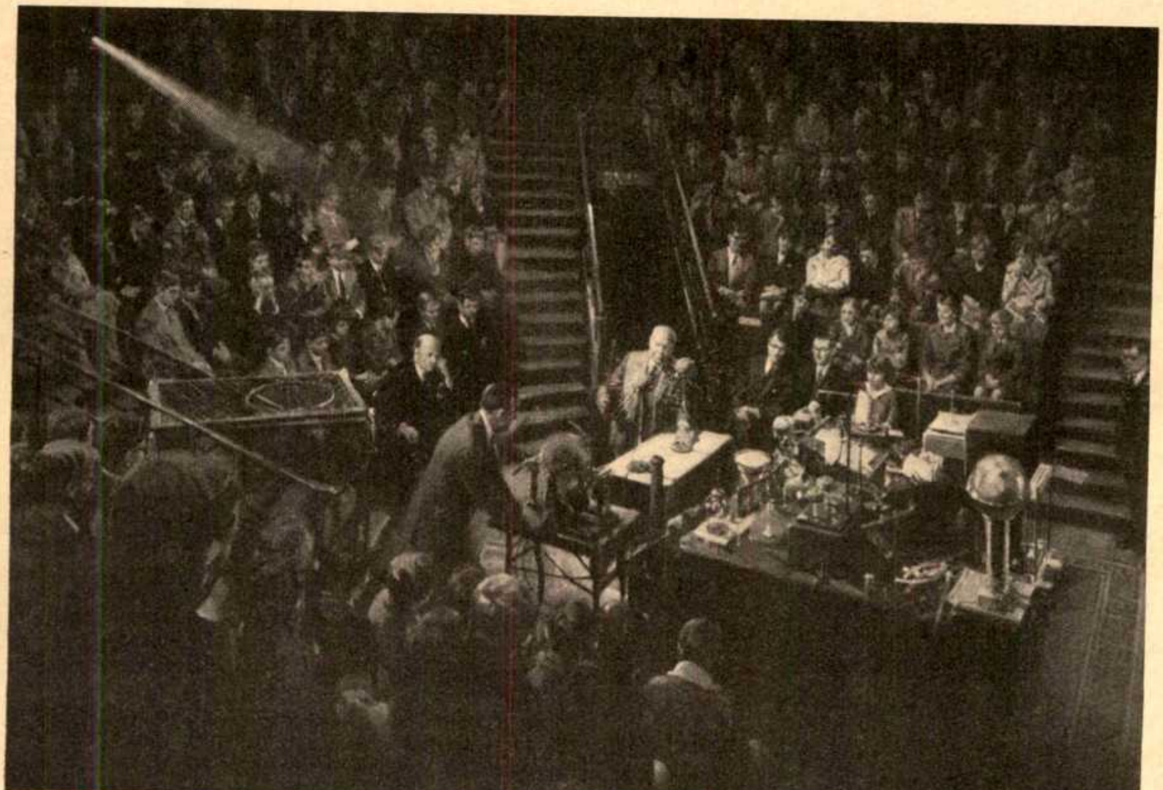

Fig. 1. Photograph of the painting. (*By courtesy of the Royal Institution and The Times*)

was formerly a member of the Council of Ministers, and a lecturer in anthropology in University College, Ibadan. He delivered the second series of Lugard Lectures in 1957, which were published as a pamphlet, *Who are the Nigerians?* The Commission is directly under the Federal Prime Minister and was appointed by him. The Prime Minister has invited Sir Eric Ashby, Master of Clare College, Cambridge, to act as honorary adviser to the Commission. The Commission has wide terms of reference, which include advising the Federal Government on the financial needs of university education in Nigeria, assisting in planning the balanced and co-ordinated development of the universities, receiving annually a block grant from the Federal Government and allocating it to the universities with such conditions attached as the Commission may think advisable, and making such other recommendations to the Federal Government or to universities relating to higher education as the Commission may consider to be in the national interest.

The National Bureau of Standards Stratton Awards

Dr. James R. Wait, Dr. Peter L. Bender and Raymond L. Driscoll are the first recipients of the newly established Samuel Wesley Stratton Award. These awards are given in recognition of outstanding contributions by scientists at the National Bureau of Standards, Washington. Each award consists of a bronze plaque and 1,500 dollars, and is named after the first director of the National Bureau of Standards. In 1901, Dr. Stratton organized the Bureau as a unique scientific institution and, during a 21-year tenure of office, firmly established its position in the scientific and industrial community. Dr. Stratton left the Bureau in 1922 to become the ninth president of the Massachusetts Institute of Technology. Dr. James R. Wait was cited for "his contributions to a better understanding of the mechanisms of electromagnetic radiation and radio wave propagation". Dr. Peter L. Bender and Raymond L. Driscoll were honoured for "their contributions to precision electromagnetic measurement and, particularly, the determination of the gyromagnetic ratio of the proton". Their work has provided a better standard for magnetic fields and made possible more accurate values for many other fundamental constants of physics.

The National Institutes of Health London Office

The National Institutes of Health, United States Public Health Service, has opened an office in London (24–31 Grosvenor Square, W.1) in connexion with its grant and fellowship programmes in the United Kingdom, as part of the Institutes' Office of International Research. Prof. Willoughby Lathem is the scientific representative in the London office. He is on leave of absence from the University of Pittsburgh, where he is associate professor of medicine, and will represent the National Institutes of Health in negotiations and consultations with British and international scientific organizations, collect information on the character and extent of medical and biological research, advise grantees and assist the Institutes' advisory groups by providing information concerning research projects proposed by British institutions for support from the Institutes.

The Optical Society of America: Awards

At the forty-seventh annual meeting of the Optical Society of America, held at Rochester during October 3–5, the Frederic Ives Medal for 1962 was conferred on Dr. Max Herzberger, senior research associate in charge of optical research in the Physics Division of Eastman Kodak. Dr. Herzberger was cited for "his outstanding contributions to optics and image formation". Born in Germany, he worked with the Leitz, Wetzlar and Zeiss Companies, and joined the Eastman Kodak Co., Rochester, in 1935. Also at the meeting Prof. Alfred Kastler, professor of physics at the University of Paris, received the first award of the C. E. K. Mees Medal, an award recently established by the Optical Society for recognition of a scientist, regardless of nationality, who has made outstanding contributions to the science of optics. Prof. Kastler is well known for his contributions to research in spectroscopy, especially spectra of the night sky and the sodium line at twilight, in atomic excitation by electron impact, and, more recently, in optical pumping.

Elections

At the Rochester meeting Prof. Richard C. Lord, professor of chemistry and director of the Spectroscopy Laboratory at the Massachusetts Institute of Technology, was named president-elect of the Optical Society of America. Prof. Lord is also president of the Commission on Molecular Spectroscopy of the International Union of Pure and Applied Chemistry. He is well known for his work on far-infra-red spectroscopy, the spectra of deuterium compounds, and the calculation of the thermodynamic properties of gases and crystals from spectroscopic data. In addition to Prof. Lord, the following were announced as directors of the society: Dr. John A. Sanderson, superintendent of the Optics Division, U.S. Naval Research Laboratory; Dr. W. Lewis Hyde, director of development, J. W. Fecker Division, American Optical Co.; and Dr. George Wald, professor of biology and an authority on physiological optics at Harvard University. The new officers will assume their duties after January 1, 1963. Dr. Lord will serve as president-elect until January 1, 1964, when he begins his term as president. Dr. Stanley S. Ballard, chairman of the Department of Physics at the University of Florida in Gainesville, will assume office as president on January 1, 1963. Dr. David L. MacAdam, of the Eastman Kodak Co., is now president.

The River Lee Basin

The Lee drains a small area (548 square miles) but is important because of its proximity to north London with its growing population and the increasing need of water for domestic consumption and for the disposal of sewage. Furthermore, the Lee Valley contains a large area of glasshouses requiring watering, and irrigation is of great value for increasing the yield of crops and potatoes for the London market which tends to augment the abstraction of river water in dry spells during the summer. In an area of about 23 in. of rainfall per annum and a large loss by evaporation, the Surface Water Survey is requested to assess the demand and to install more gauges to estimate the potential supply. Gauging stations measure the flow of the Mimram at Panshanger Park, of the Rib at Wadesmill, of the Ash at Mardock and Easneye as well as of the Lee at Fieldes Weir and of Pymmes Brook at Edmonton. The mean annual run-off from the whole drainage area is reported as 5·4 in. per annum, and only about half this is expected to be usable because suitable sites for reservoirs are few and because of the small rainfall and the excessive loss by evapotranspiration. The abstraction of ground water from the chalk has risen steadily during the past five years, and a recent report dealing with the River Lee Basin makes suggestions for re-charging this underground reservoir, the level of which is falling alarmingly (*River Lee Basin.* Hydrological Survey. Hydrometric Area No. 38. London: H.M.S.O., 1962. 9*s.* 6*d.*). Some importation of water from outside the hydrometric area, it is hinted, will be needed.

Food Preservation Quarterly

THE canning of water for emergency use is discussed by D. J. Casimir in a recent issue of *Food Preservation Quarterly* (22, No. 2; June 1962). Of the six different treatments which were compared, it was found that the simplest (involving boiling without additions, hot filling and no subsequent retorting) gave a satisfactory product after storage for three years at 100° F. Among other articles in this issue are the following: accelerated freeze-drying, by J. D. Mellor; a discussion of the mechanism and control of freezer burn, by G. Kaess and J. F. Weidemann; some chemical aspects of food processing, by C. O. Chichester; the use of bulk bins for fruit storage, by E. G. Hall (and Mellor); and the internal corrosion performance of electro-tinplate cans, by E. G. Davis. The journal is published by the Commonwealth Scientific and Industrial Research Organization, Melbourne, Australia.

The National Central Library, London

THE forty-sixth annual report of the National Central Library for the year ended March 31, 1962, records some progress in planning the new building in Store Street and it is hoped that actual building can commence by January 1963 (Pp. 26. London: The National Central Library, 1962). Inter-lending again increased, issues from or through the Library being 87,011 compared with 90,612 in 13 months of 1960–61. Of these, 16,667 were from or through university libraries, 9,953 special outlier libraries, 2,159 Government departments, 3,380 industrial and research organizations and 36,617 public libraries. Loans to libraries overseas totalled 3,699 lent and 2,550 borrowed, while 633 photo-copies were supplied and 786 obtained from abroad. Outlier libraries now number 352. Of 7,546 volumes added to the stock, 4,080 were purchased, including 851 British Government publications which are now all being purchased. Stress is laid on the part played by university libraries in meeting the needs of other libraries. The present book fund of the Library is about £9,000, which has to cover books for adult classes as well as binding, but when adequate funds are forthcoming the Trustees consider the Library could function as an effective national lending library. This would be mainly in the humanities, and would not duplicate the large number of books and periodicals already available for loan from other libraries. Besides additional funds for purchase of books and periodicals, additional housing space will also be required.

Ramsay Memorial Fellowships for Advanced Students of Chemistry

APPLICATIONS for two Ramsay Memorial fellowships for advanced students of chemistry will be considered in February 1963. One of the fellowships will be limited to candidates educated in Glasgow, but they can apply to be considered for either fellowship. The value of each fellowship will be £750 per annum, to which may be added a grant for expenses of research not exceeding £150 per annum, and will normally be tenable for two years. Further information can be obtained from the Joint Honorary Secretaries, Ramsay Memorial Fellowships Trust, University College, Gower Street, London, W.C.1. Completed application forms must be received not later than December 31.

Stimulated Emission of Radiation

A SHORT course of four lectures on masers is to be held at Battersea College of Technology during November and December, commencing November 22. The title of the course is to be "Stimulated Emission of Radiation". The lecturers will include Drs. G. D. Sims (University College, London), J. C. Walling (Mullards), O. S. Heavens (Royal Holloway College) and Mr. M. S. Lipsett (Imperial College of Science and Technology); the course is under the direction of Mr. G. R. Parlett. The topics to be included are radio and optical frequency masers, their developments and applications. The first lecture will be in the form of an introduction. Further information and application forms can be obtained from the Secretary (Spectroscopy Courses), Battersea College of Technology, London, S.W.11.

Announcements

MR. R. L. MICHAELSON, controller of administration at Elliot Automation, Ltd., has been elected president of the British Computer Society. Last year, Mr. Michaelson was chairman of the Executive Committee of the Society.

A MEETING on "The Viscosity and Visco-Elasticity of Inorganic and Organic Glasses", arranged jointly by the Society of Glass Technology and the British Society of Rheology, will be held in the University of Sheffield during January 8–10. Further information can be obtained from Mr. D. Hawksworth, Society of Glass Technology, Thornton, 20 Hallam Gate Road, Sheffield, 10.

A SHORT course of lectures on "Problems of Radioactivity at Water and Sewage Works", arranged by the Manchester College of Science and Technology, will be held in the College during January 10–11. The programme will include lectures on: radioactivity; radiation effects; radiation measurement; radiochemical analysis; radioactive waste disposal by discharge to sewers; problems at waterworks; environmental discharge of radioactive waste; and films will also be shown. The fee for the course will be £7. Further information and forms of application can be obtained from the Registrar, Manchester College of Science and Technology, Manchester 1.

A MEETING of the Illuminating Engineering Society will be held on December 11 at the Federation of British Industries, 21 Tothill Street, London, S.W.1. The programme will include the following papers: "Colour Perception and Colour Rendering", by Mr. R. W. Brocklebank and Mr. M. H. Wilson (Goethean Science Foundation); "Colour Rendering Tolerances and the Colour Rendering Properties of Light Sources", by Dr. B. H. Crawford (National Physical Laboratory); "Practical Problems of Specifying and Measuring Colour Rendering Properties", by Mr. G. T. Winch. Further information can be obtained from the Secretary, the Illuminating Engineering Society, 32 Victoria Street, London, S.W.1.

SOVIET VIEWS ON VITAMIN B_{12}

By Prof. J. BIELY

Department of Poultry Science, University of British Columbia, Vancouver, Canada

IN the summer of 1961 I attended the fifth International Congress of Biochemistry held in Moscow, U.S.S.R. As a result I was able to establish friendly relations with a number of prominent Russian investigators in the field of vitaminology from whom I have since received a number of very interesting monographs. These cover research work of which I had no previous knowledge, although they contain a wealth of original information. They do not contain summaries in English, French or German, languages with which English-speaking people are familiar, which is most regrettable because most of the published papers deserve much wider recognition than they now receive, since they are available only in the Russian language.

As one means of overcoming the difficulty I suggest that some of the more significant papers be translated into English and published. This would make available to English-speaking people some knowledge of the vast research work being carried on in the U.S.S.R.

I recently received a monograph entitled *Vitamin Resources and their Uses* published by the Institute of Biochemistry which was named after Prof. A. N. Bach*. This is the fifth volume in a series. It contains 311 pages and deals with 28 different topics. The introduction is written by Dr. V. N. Bukin and Mme. L. Y. Areshkina. I think the best way of reviewing the contents of this monograph is by way of a translation (more or less free) of this introduction, which gives a general idea of the subject-matter covered. The majority of the papers are of a highly technical nature, and it is very gratifying indeed to see the number of references made to foreign publications, particularly those in English. There are, of course, many references to Russian authors.

"The high biological activity of vitamin B_{12} excited unusual interest, initiating an enormous flood of publications dedicated to the study of the various aspects of the problem.

"This type of work began in the U.S.S.R. in 1952 when in the Vitamin Laboratory of the Institute of Biochemistry, named after A. N. Bach, the first crystals of vitamin B_{12} were received and turned over to sixteen clinics for experimentation.

"In the course of these experiments, significant results were obtained in the clinic of the Central Institute of Hæmatology and Blood Transfusion, and other clinics treating hæmatopoietic disorders. At the same time it was established that, over and above participation in hæmatopoiesis, vitamin B_{12} also plays an important part in the functions of the liver and nervous system.

"Since then a series of biochemical, technological and clinical researches were twice discussed at symposia on vitamin B_{12} in 1958 and 1960. Simultaneously with clinical experiments with the crystalline preparation, tests were also made of less-refined preparations to be used with livestock, produced by the same laboratory and the All-United Vitamin Institute. The combined results of these tests are reported in two bulletins.

"The results of all this research were published in a journal *Vitamin B_{12} and its Clinical Uses*, (Medgiz, 1956), which also included tests in the field of biosynthesis and technology in the production of vitamin B_{12}.

"The contents of this monograph therefore express in various ways the different trends of the experiments. There is a definite reason for this kind of grouping of related works as the mutual familiarization of specialists of different branches of knowledge, working on one and the same subject, is a source of incentive to new methods and expressions of new areas of study and use of the vitamin. The articles in the monograph are grouped in the following basic divisions: biochemistry of vitamin B_{12}: its biosynthesis and technology of production; chemical, microbiological and biological methods of determination; the use of vitamin B_{12} in clinics; its use in livestock breeding. In each of these divisions new experimental results appear as well as conclusions and recommendations of a scientific or practical nature, and methods of testing are given in such detail that these could be reproduced in other laboratories.

"A large part of the monograph is set aside for the reporting of work on the biosynthesis of vitamin B_{12} and this is very gratifying. Over and above the scientific interest in this work, this has an independent practical meaning since on an adequate synthesis depends the health and potential productivity of livestock. Unfortunately, one cannot say the same of research dedicated to the study of the biochemical functions of vitamin B_{12}. These works are no less important, but they are few; it is essential to develop research in this direction.

"A whole series of papers in the monograph is dedicated to research in the uses of vitamin B_{12} for the clinical treatment of serious illnesses.

"In these articles there appears an exceedingly important and new proof, obtained in the course of experimentation on animals (S. V. Andreyev) and in the clinic (a series of authors), of the outstanding role of vitamin B_{12} in the treatment of severe traumas of nervous, muscular, vascular and bone tissues. This material could be the starting point for extremely important biochemical research of normal and traumatized tissue.

"Finally, there are two articles showing the vast effect of the use of vitamin B_{12} on livestock. One especially interesting fact determined in the course of this work is the interrelation and synergism of the growth-stimulating action of vitamin B_{12} and antibiotics. Quantitative interrelation in this connexion has not as yet been studied although it would appear to be most important from a practical stand-point and also in explaining the mechanics of the growth-stimulating action of antibiotics.

---

* *Vitamin Resources and Their Uses*—Vitamin B_{12}—its biosynthesis, functions and uses. Foreword by Dr. V. N. Bukin and Mme. L. Y. Areshkina. (Published by the Bach Institute of Biochemistry, Moscow, U.S.S.R.) 1.25 dollars.

"We hope that the publication of this monograph will assist in developing further theoretical research and a wider application of vitamin B_{12} in clinical work and on livestock with the view that all the valuable qualities of this vitamin may be most fully utilized for the protection of animal health and ensuing material benefits."

In view of the present interest in vitamin B_{12} I think it would be well worth while if some agency could undertake to provide an English translation of this monograph and also perhaps of the four which preceded it.

I thank Mrs. Pauline Renacre, 205 East 29th Ave., North Vancouver, for her assistance with the translation, and Mrs. A. McCullough, secretary in the Faculty of Agriculture, for help in editing the manuscript.

GLOBAL FALL-OUT IN AUSTRALIA DURING 1960–61

DURING the years 1960 and 1961, continuous monthly sampling of fall-out over Australia for gross radioactivity was maintained by the Atomic Weapons Tests Safety Committee at eight stations: Perth, Adelaide, Melbourne, Hobart, Sydney, Brisbane, Townsville and Darwin. The Committee's network of 24 stations taking daily samples was closed down in April 1960, when no active samples had been detected for more than a year. In the past, this monitoring programme, and, especially, the daily sampling, provided information on tropospheric and early stratospheric fall-out over Australia from nuclear weapon tests held overseas. Accordingly, when the Soviet Union resumed testing of high-yield weapons in the atmosphere in September 1961, the daily sampling was recommenced using the 24-station network to give representative measurements for the regions inhabited by the majority of the Australian population.

The observations of gross radioactivity in fall-out are complementary to data obtained by the Committee in its extensive and continuous survey of strontium-90 in the Australian environment. Results from this survey to the end of 1960 have already been published in detail. A report by Drs. J. R. Blake, L. J. Dwyer, J. R. Moroney, D. J. Stevens and Prof. E. W. Titterton* presents the results of total β-activity measurements on the monthly samples taken from January 1960 until December 1961, and on the daily samples taken from September 15 until December 31, 1961, following the resumption of weapon testing by the U.S.S.R.

During the two years for which results are presented, the U.S.S.R. tested about 50 weapons in the atmosphere from September to November 1961; France tested three weapons in the atmosphere over the Sahara Desert in February, April and December 1960; late in September 1961, the United States commenced a new programme of underground testing at the Nevada test site.

The major weapon tests by the U.S.S.R. were carried out in the vicinity of Novaya Zemlya in the Arctic; the United States Atomic Energy Commission has estimated the total explosive yield for the series to be about 120 megatons and the fission yield at about 25 megatons. This corresponds to an injection of radioactivity into the atmosphere of the northern hemisphere in the order of twice that which resulted from the weapon tests conducted by the U.S.S.R. in the Arctic in October 1958; those tests produced, during 1959, marked increases in radioactivity in the biosphere of the northern, but not of the southern, hemisphere. France tested only low-yield nuclear weapons of estimated total yield considerably less than 1 megaton. No global fall-out has arisen from the underground weapon tests being carried out by the United States.

Results show that the level of total β-activity in fall-out over Australia continued to decrease during the period 1960–61. The data give no indication of the arrival of debris from the French tests during this period or the major U.S.S.R. series of September–November 1961. Some fall-out over Australia of long-lived fission products from these Soviet tests may be expected in the spring of 1962.

NORWAY INSTITUTE OF ATOMIC ENERGY

AN illustrated survey of the work of the Institute for Atomenergi (IFA) at Kjeller and Halden, Norway, during 1961, together with details of the organization and an abstract of the accounts for the budget year 1961, are given in the recent report*. Mr. Gunnar Randers continued as managing director with Mr. O. R. Kåsa as assistant director and project manager of the Halden Project.

The main facility for physics research and isotope production is the 10-year-old 450-kW heavy-water reactor *Jeep* at Kjeller. The reactor, which is operated continuously, except for routine stops for isotope insertion and removal, and the semi-annual inspection of the fuel element canning, released 130·3 MWD of heat during 1961, bringing the total up to 680·5 MWD since the reactor commenced operation. At the summer inspection the aluminium canning of one fuel element showed several cracks. This was the first time that such damage had been detected. Various improvements in the reactor system and auxiliary equipment were made during the year. In order to compensate for the neutron loss due to the slightly thicker walls of the new reactor tank installed during 1960 and to improve neutron flux conditions, some fuel elements consisting of 1·7 per cent enriched uranium oxide are to be installed and the first of these, installed in November 1961, has already improved the flux and reactivity conditions.

---

* Institutt for Atomenergi, Kjeller. Survey of Activities, 1961. Pp. 24. (Kjeller: Institutt for Atomenergi, 1962.)

The report states that one of the most significant events of the year under review was the commissioning during June, and the official inauguration on November 29, of the zero energy reactor *Nora* and of the fuel processing pilot plant. The reactor was established as a joint IFA–IAEA undertaking and was designed and built by NOR–ATOM *A/S*. The research programme has been approved by the *Nora* Committee under its chairman, Dr. R. Ramanna of India. For this programme three fuel charges are available, the first a 3 per cent enriched fuel charge provided by the U.S. Atomic Energy Commission, the second a reference charge of 2·5 tons of natural uranium metal, and the third a charge of elements from the Halden second core. The research programme is concentrated on the physical aspects of spectral shift controlled reactor systems.

In the spring of 1961 the design of the *Jeep II* reactor was reviewed in order to simplify the design and bring down costs; to introduce a flux trap; and to consider the use of the principle of spectral shift for long-term reactivity control. The reactor will be built and started as a heavy-water reactor and will be housed in a thermally insulated steel containment shell 22·4 m high and 22 m in diameter to withstand a pressure of 0·15 kg/cm^2. The erection of the shell and control building was started in the summer of 1961. The reactor will be moderated and cooled by heavy water and fuelled by slightly enriched UO_2 canned in aluminium tubes. *Jeep II* is planned to go critical during 1965, and it is estimated that the thermal neutron flux at a power-level of 2 MW in the centre of the reactor will be about $1 \cdot 5 \times 10^{13}$ neutrons/cm^{2}sec.

The experimental programme at the Halden reactor continued with the first fuel charge up to May, when the reactor was shut down prior to the insertion of the second, enriched core. During the second phase of the programme the reactor will be operated at 20 MW instead of 6 MW at 155° C. The programme so far includes the determination of data on various reactor physics parameters, such as temperature and water-level coefficients, and the critical buckling as a function of moderator temperature has been calculated. Modifications, partly based on experience gained during the operation of the reactor, which will be introduced for operation at the higher power, include the installation of a new steam transformer to be operated in parallel with the original one, and a tertiary loop with a new steam generator for dissipation of the steam produced.

During 1961 two new wings of the Netherland–Norwegian Reactor School were taken into use, thus increasing the capacity of the school considerably by providing facilities for experimental work in reactor engineering, physics and radiochemistry. The nine weeks standard course in fundamentals of nuclear engineering was held twice, and during March a course on analogue computer techniques and their application to nuclear engineering and chemical processing problems was held for the staff at Kjeller and Halden.

The report concludes with details of the safety work and health physics; the technical information service including a list of Kjeller Reports and Halden Project Reports issued during the year; international co-operation; and the numbers and distribution of the staff at the Institute on December 31, 1961.

PUBLICATIONS OF THE NATIONAL PHYSICAL LABORATORY, TEDDINGTON

FOUR new booklets in the series *Notes on Applied Science* of the National Physical Laboratory, Teddington, have recently been published*. The first, No. 25 in the series, entitled *Hydrometers and Hydrometry*, deals with basic considerations of air buoyancy, surface tension and the spacing of the scale; the general use of hydrometers with examples; the verification and adjustment of hydrometers with particular reference to practice at the National Physical Laboratory; and types of hydrometer scale and the relationship between scales. It is emphasized that ordinary hydrometers of constant mass are convenient instruments for the measurement of the density and specific gravity of liquids, and that greater accuracy can be obtained by their use than is generally realized. Though *British Standard* 718: 1960 contains considerable information on hydrometers and hydrometry, several interesting points outside the scope of the *Standard* are dealt with in the booklet.

The information given in No. 27, *Inspection of Gauging Dimensions Involving Linear and Angular Measurements*, is intended to assist engineering inspectors in checking gauges, jigs and workpieces, involving combined measurements of length and angle. The use of the Universal Measuring Block manufactured by the Pitter Gauge and Tool Co. Ltd. is described, and full particulars of the measuring equipment associated with it are given together with the types of measurement which can be made with the equipment. A principal purpose of the booklet is to present a general procedure for the type of measurement in which the required dimension must be obtained by calculation from indirect measurements of the work. Examples of both the simpler direct measurement technique and of the indirect measurement procedure are given and fully explained. The derivation of the associated trigonometrical formulæ required in the calculations are set out in an appendix.

Measurements of frequency with an accuracy approaching one part in 10^{10} are now required not only for precision laboratory measurements but also for routine operations. The techniques which make such measurements possible are briefly discussed in No. 28 of the series, entitled *The Measurement of Frequency*, where an account is given also of the more usual types of frequency meter utilizing a resonant circuit. The standard of frequency at the National Physical Laboratory is a cæsium atomic resonator and this is used to calibrate the quartz clock working standards. These in turn monitor the carrier frequencies of a number of transmitting stations, with the call sign *MSF*, which are operated from the Laboratory from the British Post Office Station at Rugby. Details of these transmissions and of the more powerful carrier wave of the station *GBR*, which is controlled by the *MSF* standard, are given in the booklet. Separate sections deal with frequency synthesis and measurement and with cavity-resonator frequency meters and their testing and calibration. These meters are most useful in a wide field of applications where an accuracy of about one part in 10^4 is adequate.

* Department of Scientific and Industrial Research. National Physical Laboratory. *Notes on Applied Science*.

No. 25: *Hydrometers and Hydrometry*. By J. B. Rands and P. H. Bigg. Pp. iv+31+1 plate. 2*s*. 6*d*. net.

No. 27: *Inspection of Gauging Dimensions Involving Linear and Angular Measurements*. By Dr. J. C. Evans and C. O. Taylerson. Pp. v+42. 3*s*. 6*d*. net.

No. 28: *The Measurement of Frequency*. By Dr. L. Essen, E. G. Hope and K. Morris. Pp. v+17. 1*s*. 9*d*. net.

No. 29: *Physical Photometry*. By Dr. B. H. Crawford. Pp. iv+16. 1*s*. 9*d*. net.

(London: H.M.S.O., 1962.)

The fourth booklet, No. 29, *Physical Photometry* by Dr. B. H. Crawford, describes those procedures in photoelectric photometry which have their worth in precise measurement and which are in regular use at the National Physical Laboratory. Photometry is essentially the measurement of radiant energy by a selective receiver, the human eye, but individual eyes vary and it is assumed that there is a statistically satisfactory 'standard eye'. A value for the photopic (light-adapted) standard observer was accepted in 1933 by the International Committee on Weights and Measures and for the scotopic (dark-adapted) by the Commission International de l'Éclairage in 1951. These values are tabulated in the booklet. After a general examination of the photoreceptors in present-day use, the spectral correction of vacuum emission photocells and of radiation thermopiles and bolometers is discussed in some detail. Finally, there are two sections dealing with amplifiers and photometers.

S. Weintroub

PETROLEUM CHEMISTRY: U.S.S.R.

THE past decade has witnessed a spectacular commercial development of the petroleum industry in the manufacture and marketing of petroleum-derived organic and inorganic chemicals in Great Britain. Julian M. Leonard, in a recent presidential address to the Institute of Petroleum (*J. Inst. Pet.*, **48**, 271, 1962), quotes figures showing that the share of petroleum as raw material for the chemical industry has increased from about 9 per cent in 1949 to 47 per cent in 1959, at present running at more than 50 per cent and anticipated to reach 65 per cent when 1962 figures are available. In the United States the production of petrochemicals was a much earlier development than in the United Kingdom and it is estimated that to-day some 80 per cent of organic chemicals manufactured there are based on petroleum. It is doubtful whether the petroleum technologist, not directly concerned with modern refinery flow-sheets, is himself aware of the phenomenal expansion in this new field and of its technical and economic significance in the future of the world's chemical industry. Certainly the layman is even less informed on this subject, probably because it is not one that can be easily propagated in the popular Press.

The starting point of petrochemicals, as Leonard stated, is the complex of naturally and artificially produced petroleum gases from which are synthesized ethylene, propylene, butadiene, benzene, toluene, xylene, etc. Some of the more important products stemming from these foundations are synthetic rubber, synthetic fibres, detergents, thermoplastics, and agricultural insecticides and fertilizers, many of these replacing materials formerly derived from purely natural, mainly vegetable resources. The possibility of producing edible oils and fats from petroleum, although not yet matured on a large scale, is none the less practicable and in itself opens up another highly specialized prospect in the chemical industry.

In the academic and technical worlds concerned with petrochemicals there has naturally evolved an extensive literature during the course of development of this fascinating subject, especially in the United States and the United Kingdom. Western European countries have also contributed their share. In these spheres language is no bar to the past or present records of research, discovery or progress. But the same cannot be said of published work in the U.S.S.R., which despite its magnitude and value, must necessarily remain a 'closed book' to all but those chemists who can read the Russian publications *per se*. The increasing amount of research in the U.S.S.R. on the nature and configuration of petroleum hydrocarbons, composition of sulphur and nitrogen-bearing compounds, and on conversion processes used in the manufacture of petrochemicals, is of such a volume that it has led to the launching in the U.S.S.R. of a new periodical *Neftekhimiya—Petroleum Chemistry*, which aims at co-ordinating the work of "investigators on the chemistry of petroleum and on the petroleum chemicals industry". This is the quote from the foreword to the English version of *Petroleum Chemistry: U.S.S.R.*, a quarterly published by Pergamon Press for Pergamon Institute, Oxford, of which the first volume and number* has just appeared in the United Kingdom, under the editorship of D. L. Samuel with translator B. J. Hazzard. The former writes: "Such work is of great interest to all workers in similar or related fields and they will doubtless be well pleased with the opportunities of reading of the work of their Russian colleagues, made possible by the issue of an English edition. The papers of greatest interest to western research workers are translated in full and an abstract provided of those of lesser appeal".

The first volume of this English publication contains translations of twenty-five original papers by Russian scientists of considerable academic and technical importance in the modern realm of petroleum chemistry in general and petrochemicals in particular. Abstracts of other relevant papers in *Neftekhimiya*, running to a total of thirty-eight (of which the publishers are prepared to supply full English translations), conclude what, in future numbers, is obviously destined to become a most valuable medium of international exchange of knowledge of petroleum chemistry conceived in the fullest sense of its modern terms of reference.

THE ROWETT RESEARCH INSTITUTE

IN these days when research tends to be so highly specialized, it is obviously difficult for the director of a research institute to write a report which will be interesting and understandable throughout, even to readers reasonably conversant with the general trend of the institute's work. This is particularly so where the institute is a large one containing a number of departments each applying the techniques and using the jargon of a different science. The difficulty is not decreased when the approach to the practical objects of the institute is in large measure through basic research on the underlying scientific problems.

A report appealing to the non-specialist, and understandable throughout by a well-informed reader, would require to discuss each topic with some fullness and to include some account of previous work on the subject. This would mean, especially for a large institute, an annual report of considerable bulk and cost, and from year to year these would be largely repetitive as the work summarized one year would have to be repeated the next.

In an endeavour to solve this problem, recent annual reports of the Rowett Research Institute have each contained two main sections. Summaries have been given of all the papers published during the period under review. These summaries have been arranged under appropriate headings, and full references given to the original publications. This enables any specialist to discover new work which may interest him. The other main section has consisted of a couple of reviews, each by some member of the staff of the Institute, of a topic on which he is an acknowledged authority. Each review naturally deals at some length with work carried out at the Institute, but has not been limited to that work and has presented a critical survey of the whole subject in the light of present knowledge. Consequently, over the past few years, a number of valuable reviews has appeared within these annual reports.

The current annual report of the Rowett Research Institute, which covers the year 1960–61, again contains these two main sections*. The review articles this year are on "Calorimetry, 1952–1961" by J. D. Pullar, and on "Epithelial Form and Function in the Intestine" by B. F. Fell. These well-written articles will be very useful to anyone wishing to follow recent advances in these subjects.

In the past, one drawback to the form of report prepared by the Rowett Research Institute, based on summaries of published papers, has been that work appears in these reports only a considerable time after it has been carried out. In the present report an effort has been made to meet this difficulty by extending the summaries so as to give some account, not only of published papers, but also of others 'in the press' or in preparation. Though this perhaps does not completely solve the problem, it does succeed in bringing the report more up to date and of increasing its interest.

The research work described in this report extends from basic research, such as that on the use of hydrogen-bond-breaking extraction solvents and fractionation procedures for the characterization of non-protein forms of bound amino-acids in leaves and seeds and the determination of their metabolic significance, to the demonstration that it is possible to fatten beef cattle on a diet of 85 per cent bruised barley and 15 per cent of a protein-rich-mineral-vitamin supplement containing sodium bicarbonate and no roughage. As an example of work of great interest from both the theoretical and practical points of view, reference may be made to the elucidation of the relationship between deficiency of copper in lambs and 'swayback'. It had already been shown that deficiency in copper accompanied by ataxia could be produced in lambs by feeding molybdenum and sulphate supplements to their ewes. The affected lambs showed demyelination in the spinal cord motor tracts and other lesions of the central nervous system. It has now been found that cytochrome oxidase, which in all probability contains copper as an essential constituent, is deficient in the brains of lambs suffering from 'swayback'. This reduced activity of the enzyme is associated with copper-levels in brain tissue of less than three parts per million. Animals with abnormally low contents of copper in the liver may or may not suffer from 'swayback', but in the non-affected animals with abnormally low copper in the liver it was found that the brain level was invariably more than the critical three parts per million. It is suggested that cytochrome oxidase assay may provide a rapid method for confirming suspected cases of 'swayback'. This investigation into copper, cytochrome oxidase and 'swayback' is but one example of the many items which a reader browsing through this report will come across to stimulate his interest and curiosity.

FRAGMENTATION OF METEOR BODIES

By DR. B. LEVIN

O. Schmidt Institute of Physics of the Earth, U.S.S.R. Academy of Sciences, Moscow

ACCORDING to the conventional physical theory of non-fragmenting meteors, if to neglect deceleration, the form of the light curve $m = m(H)$ does not depend on the initial mass M_0 and velocity v_0 of the meteor body and on the zenith distance z of its radiant, but only on parameter μ, which characterizes the relation between the changes of the frontal cross-sectional area S and mass M in the course of the ablation of the meteor body:

$$S \sim M^{\mu} \qquad (1)$$

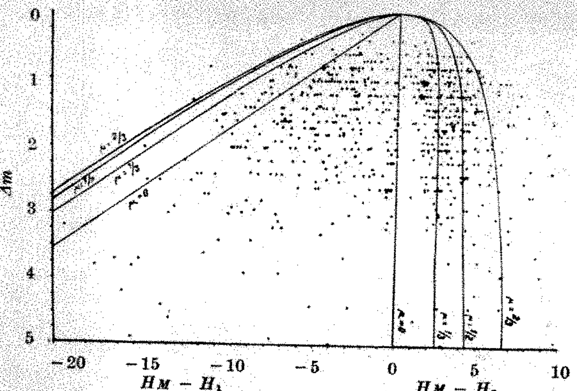

Fig. 1. Comparison of photometric data for photographic meteors with theoretical light curves for different values of parameter μ

Denoting I and m the luminous intensity and magnitude of a meteor on the height H at which the air density $\rho = \rho_0 e^{-H/H^*}$ and marking with the subscript 'M' the values of these quantities in the point of maximum light we have (ref. 1):

$$\frac{I}{I_M} = \frac{\mathrm{d}M/\mathrm{d}t}{(\mathrm{d}M/\mathrm{d}t)_M} = \mu^{-\mu/1-\mu} \frac{\rho}{\rho_M}\left[1 - (1-\mu)\frac{\rho}{\rho_M}\right]^{\mu/1-\mu} = e^{\Delta H/H^*}\left[\frac{1}{\mu} - \left(\frac{1}{\mu} - 1\right)e^{\Delta H/H^*}\right]^{\mu/1-\mu}$$

(where $\Delta H = H_M - H$). Or:

$$\Delta m = m - m_M = 1{\cdot}09\left\{\frac{\Delta H}{H^*} + \frac{\mu}{1-\mu}\ln\left[\frac{1}{\mu} - \left(\frac{1}{\mu} - 1\right)e^{\Delta H/H^*}\right]\right\} \qquad (2)$$

Other authors have considered only the case $\mu = 2/3$, which corresponds, in particular, to a spherical body which does not change its form during ablation. Really on the average it is $\mu < 2/3$. The corresponding light curves lie inside the curve for $\mu = 2/3$ (Fig. 1).

Hawkins and Southworth[2], in their analyses of 360 meteors photographed by Super-Schmidt cameras, showed that almost all points of appearance and disappearance of meteors lie within the theoretical curve for $\mu = 2/3$, that is, the observed length of meteor trails is shorter than the theoretical one. Ananthakrishnan[3] removed the systematic deviation for the points of disappearance calculating the theoretical curve, adopting an *ad hoc* hypothesis that the luminosity factor $\tau \sim \rho v$ (instead of the conventional $\tau \sim v$). But this systematical deviation can be removed on the basis of the conventional theory if we take a light curve for $\mu \approx 1/2$ (Fig. 1). The systematic deviations for the points of appearance remain because they are due to fragmentation of meteor bodies.

The conventional physical theory of meteors, when $\tau \sim v$, gives the following expression for maximum luminous intensity:

$$I_M \sim M_0 v_0^4 \cos z \qquad (3)$$

By means of this formula the absolute maximum photographic magnitudes m_M of meteors given by Hawkins and Southworth[2] were reduced to m_M^*, corresponding to $M_0 = 1$ g, $v_0 = 10$ km/sec, $\cos z = 1$ (the data on the masses of meteor bodies were kindly sent us by Hawkins and Southworth prior to publication. These masses were obtained by the photometric method and expressed in the Opik-Jacchia scale). For 358 meteors (for 2 meteors the masses are lacking):

$$\overline{m_M^*} = +\,0^m{\cdot}66.$$

The mean square deviation is great and amounts to $\pm\,0^m{\cdot}62$.

When the fragmentation decreases the path-length, L, of the meteor its light energy must be radiated on a shorter path. The increase of the mean light intensity is directly proportional to the decrease of the path-length. If to approximate the light curve by triangle

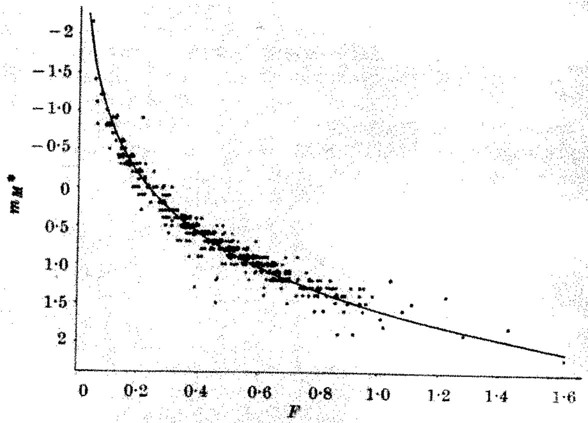

Fig. 2. Reduced maximal magnitudes of meteors versus fragmentation factor F

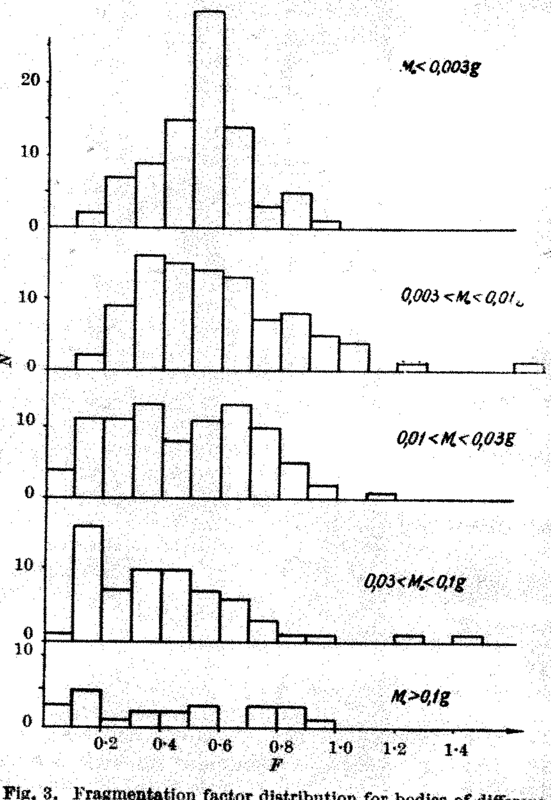

Fig. 3. Fragmentation factor distribution for bodies of different mass

with a height I_M and a base L the same becomes true also for a maximum intensity I_M.

Let us introduce a fragmentation parameter, F, which is defined for each meteor according to the equation:

$$F = \frac{L_{\text{obs}}}{L_{\text{theor}}} = \frac{(H_1 - H_2)_{\text{obs}}}{(H_1 - H_2)_{\text{theor}}} \qquad (4)$$

$(H_1 - H_2)_{\text{theor}}$ is obtained, for the Δm value observed for a given meteor, from the theoretical light curve for $\mu = 1/2$. Only few meteors have $F \approx 1$, but for more than 90 per cent the length of a trail is markedly shortened by fragmentation.

Fig. 2 gives a graph of the dependence of $m_M{}^*$ on F. All points lie in a narrow band along the curve which corresponds to the equation:

$$m_M{}^* = 1{\cdot}60 + 2{\cdot}5 \log F \qquad (5)$$

The mean square deviation from this curve is only $\pm 0^{\text{m}}16$ or about 4 times smaller than without allowance for fragmentation and even smaller than the error of measurements of m_M which is $\pm\ 0^{\text{m}}3$ according to Hawkins and Southworth. The excellent representation of the observations by equation (5) is somewhat unexpected because $(H_1 - H_2)_{\text{theor}}$ should be obtained not for the observed Δm but for its unknown theoretical value.

Equation (5) means that for the meteors produced by fragmenting meteor bodies equation (3) must be changed into:

$$I_m = \frac{M_0 v_0{}^4 \cos z}{F}$$

If to adopt the same correction $+\ 1^{\text{m}}8$ to transfer photographic magnitudes into visual, as for brighter meteors, it follows from equation (5) that a non-fragmenting meteor body which produces a meteor of zero visual magnitude during vertical motion with $v_0 = 40$ km/sec must have an initial mass $M_0 = 0{\cdot}09$ g and when a fragmentation is intense and $F = 0{\cdot}1$ a ten times smaller mass, $M_0 = 0{\cdot}009$ g, is sufficient. To a mean value $m_M{}^* = 0^{\text{m}}66$ corresponds $M_0 = 0{\cdot}04$ g which is close to $M_0 = 0{\cdot}055$ g obtained earlier[1] from the analysis of 117 meteors photographed by conventional cameras.

For meteor bodies of different masses their distribution according to F is found to be different (Fig. 3). For massive bodies a maximum lies in the region of $F \approx 0{\cdot}1 \div 0{\cdot}2$, and for small bodies it is in the region $F \approx 1/2$. The evidence that the big bodies produce more fragments than the small ones was found earlier for Jiacobinid meteors[1]. The dependence of fragmentation on the mass of meteor bodies influences the magnitude distribution of meteors. Even for shower meteors one cannot suppose that the magnitude distribution of meteors depends only on the mass distribution of meteor bodies. All previous determinations of the mass distribution based on this supposition must be revised. The results based on radio-echo observations also need revision.

MICROSCOPIC EXAMINATION OF HIGHLY RADIOACTIVE FALL-OUT PARTICLES

By T. MAMURO, A. FUJITA, T. MATSUNAMI and K. YOSHIKAWA

Radiation Centre of Osaka Prefecture, Shinkecho, Sakai,
Osaka, Japan

IT is well known that highly radioactive fall-out particles were found throughout Japan, resulting from the series of large-scale nuclear test explosions carried out by the U.S.S.R. during September and October 1961[1-5]. Towards the beginning of November 1961, when abnormally high concentrations of radioactivity in the atmosphere were observed at our Laboratory, we were able to find and collect many highly radioactive particles with the aid of a Geiger–Müller survey meter in various places, for example, on the roof, on the rain collector, on the surface of leaves, on polyethylene bottles or polyvinyl chloride sheets which were left outdoors. Since the rainfall on November 17, it became very difficult to find any of these particles where rain-water had washed away dusts; however, we were able to continue to find such particles on dust films formed inside buildings into which the wind blew freely. Especially were we able to collect many particles in the oil tank of a multipanel air-filter which is set by the air-feeding apparatus of a building in our Laboratory.

Highly radioactive particles were isolated from among non-radioactive dust particles after elaborate procedures. They were immersed into a very small drop of cedar oil and photomicrographs of them were taken. Figs. 1–21 are examples of these photographs. Fig. 22 is a photograph of the scale, one division of which is 10μ. Photographs designated by P were taken focusing at the perimeter of particles, showing the shape of the particle contour clearly, but the front side only vaguely. Photographs designated by F and M were taken in order to show the change in depth of the surface state of particles, focusing on the front side of particles and on the middle part between the front side and the perimeter, respectively.

We observed microscopically more than fifty highly radioactive particles. Most of them were quite, or nearly, spherical. There were, however, a few particles which deviated appreciably from the spherical (Figs. 11 and 14). The surface of some particles was irregular and creased. Several particles were coated with colourless amorphous materials like frosting (Figs. 8 and 9). These materials were assumed to be non-radioactive because they had the same appearance as that of non-radioactive air-borne dust particles.

Almost all the particles were yellowish or reddish brown; however, there were some colourless, golden or black particles. Isolation procedure was more difficult for colourless particles than for those which were coloured, because the recognition of a colourless particle under a microscope was more difficult.

It has been reported that division of radioactivity seems to happen during the handling of fall-out particles by a needle[2,6]. We experienced such a phenomenon twice. The larger radioactivity was separated and confirmed to be due to a spherical radioactive particle; the smaller radioactivity, on the other hand, was divided further into two or more smaller radioactivities which gave so low counting-rates that they could not be separated. The photographs as shown in Figs. 6–9 suggest that such division of radioactivity was caused by the separation of two or more closely adjacent radioactive particles by the impact of a needle. All the highly radioactive particles that we could isolate and observe microscopically seemed to be so hard that even the impact of a needle could not crack them into two or more particles.

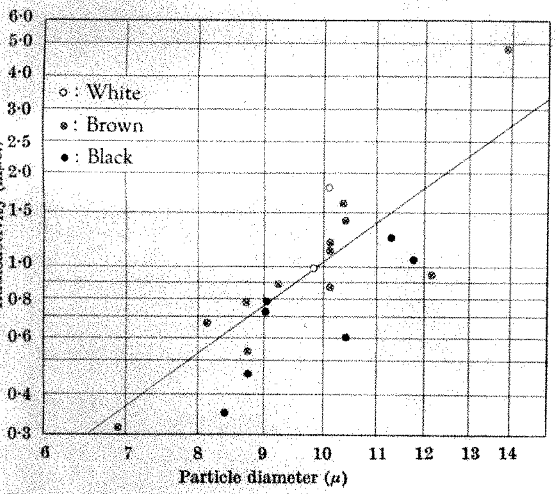

Fig. 23. Relation between diameter and β-activity of the particles

Table 1 presents a summary of the results of observation on twenty-one highly radioactive particles the photomicrographs of which are given in Figs. 1–21. Fig. 23 shows the relation between diameter and β-activity of the particles. A straight line of gradient 3 is drawn for comparison. Activity is roughly proportional to volume, as expected[7]. It seems that particles of light colour have larger specific activity than those of dense colour and that the conditions of formation differed from one to another.

PREFERENTIAL ADSORPTION OF NORMAL HYDROCARBONS ON CAST IRON

By A. J. GROSZEK

Petroleum Division, British Petroleum Co. Research Centre,
Sunbury-on-Thames

IN the course of work on the determination of heats of preferential adsorption of surface active compounds and hydrocarbons on metal surfaces, it was noticed that normal hydrocarbons gave exceptionally high heats of adsorption on an iron powder containing 1·1 per cent carbon. Further work revealed that even larger heats of adsorption are obtained for a cast iron containing 3·5 per cent carbon.

The work was carried out in a flow calorimeter described previously[1]. The procedure used was to inject different organic substances into a carrier liquid (n-heptane) flowing through a bed of cast iron powder. The injected substances come into contact

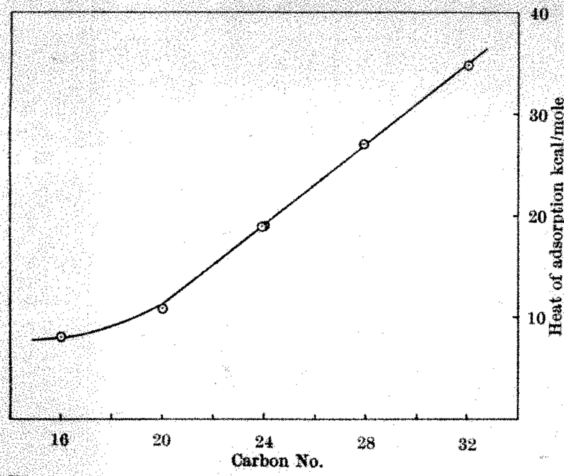

Fig. 1. Heat of adsorption of normal hydrocarbons from n-heptane on iron at 25° C

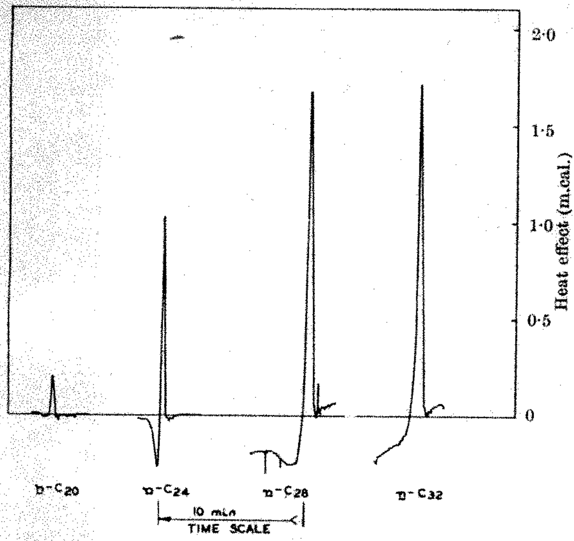

Fig. 2. Adsorption of normal hydrocarbons on iron. 0·05 mg quantities of the hydrocarbons injected into n-heptane carrier

with the powder and are adsorbed from the carrier liquid. Equilibrium conditions are not attained because the carrier desorbs the adsorbed solute after the solution has passed through the iron. The adsorption process is rapid (10–15 sec) and is accompanied by a positive heat effect. Desorption takes place more slowly (normally 1–15 min) with a corresponding negative heat effect. The heat effects are reproduced for calibration purposes by an electrical coil immersed in the iron powder with the carrier flowing through it. The flow-rate of the carrier was fixed at 0·4 ml./min.

Adsorption of normal hydrocarbons and mineral oil fractions on cast iron was also studied by replacing n-heptane as the carrier liquid by 1 per cent weight solution of the compounds dissolved in n-heptane. The solute is then adsorbed until an equilibrium is reached and the heat effect produced corresponds to the adsorption of the equilibrium amount of solute. The amounts of the solutes adsorbed were found by determining the decrease in their concentration when 0·5 ml. of the solutions were placed in contact with 2 g of the iron powder. The determinations were carried out by using the flow calorimeter as a detector for the solutions injected into the carrier liquid. The calorimeter was calibrated by injecting known amounts of the solute into the carrier. A similar procedure described previously[1] was used to estimate the proportion of solute adsorbed from solution when it was injected into the carrier liquid.

Results obtained for different normal hydrocarbons are given in Figs. 1 and 2. The results in Fig. 1 are for the adsorption on the iron powder with a carbon content of 1·1 per cent. In each experiment the iron was saturated with a 1 per cent solution of a normal hydrocarbon. It can be seen that the heat evolved during the adsorption procedures increases linearly with the carbon number of the hydrocarbons between C_{20} and C_{32}. The order of the heat effects is comparable with the heats of crystallization of the normal hydrocarbons. The experiments with branched hydrocarbons, such as squalane, gave very small heat effects (1–2 per cent of the effects produced by n-C_{24} to n-C_{32}). Therefore the iron powder adsorbed the normal hydrocarbons selectively. In Fig. 2, the peaks represent heat effects produced when 0·05 mg quantities of the normal hydrocarbons were injected (in the form of 1 per cent solutions in n-heptane) into the carrier. Only a part of the injected hydrocarbons was adsorbed. The heats of adsorption calculated from these peaks are therefore lower than the heats calculated from the results of the experiments in which the iron was saturated with the hydrocarbon solutions.

The heat evolved on adsorption of n-dotriacontane on iron containing 1·1 per cent carbon is represented in Fig. 3. Before the adsorption of n-dotriacontane on the iron had begun, 0·1 mg of n-hexadecanol was injected into the carrier as an internal standard. The heat evolved when the alcohol was adsorbed on the clean iron was 3·5 millicalories. After desorption of the alcohol the iron was saturated with a 1 per cent solution of n-dotriacontane. Injection of 0·1 mg of the alcohol into the solution produced a very small heat effect. Evidently the adsorbed hydrocarbon formed a layer on the iron surface, which prevented to a large extent the adsorption of the alcohol. Afterwards, the adsorbed dotriacontane was desorbed with n-heptane and a corresponding negative heat effect recorded. The desorption process was relatively very slow. After 50 min of passing n-heptane through the iron powder, 0·1 mg of the alcohol

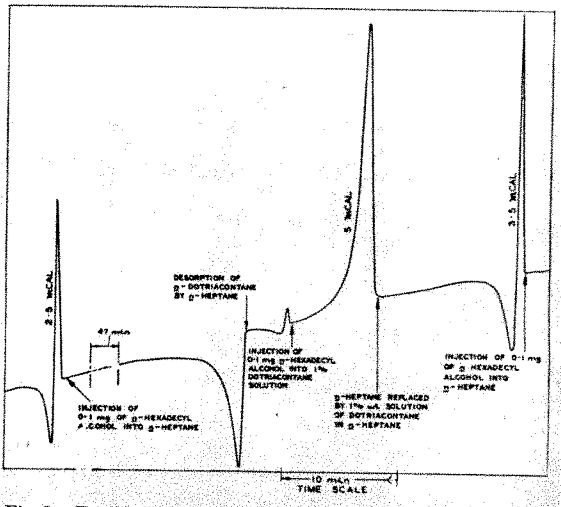

Fig. 3. Equilibrium adsorption and desorption of n-dotriacontane on iron

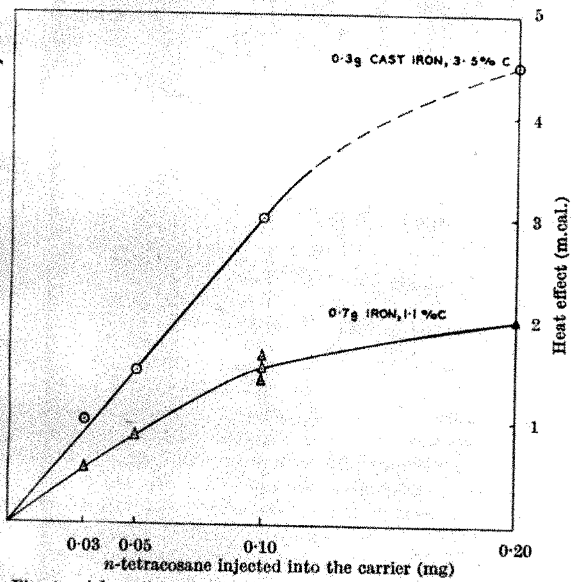

Fig. 4. Adsorption of tetracosane on iron powders with different carbon contents

was injected into the carrier and the heat evolved was only about 70 per cent of the heat produced when the alcohol was adsorbed on the clean iron. When the same adsorption-desorption cycle was carried out with *n*-tetracosane, the hydrocarbon became almost completely desorbed after about 5 min and then the injection of the alcohol gave the same heat effect as that produced before the adsorption run was begun.

Thus the rate of desorption of *n*-dotriacontane from the iron powder is considerably slower than that of *n*-tetracosane. The same conclusion can be reached by examining the peaks reproduced in Fig. 2, where the negative heat of desorption is much sharper for n-C_{24} than the heats for n-C_{28} and n-C_{32}. For *n*-eicosane the desorption is so fast that it overlaps to a considerable extent with the positive heat of adsorption and thus a very small peak is recorded. The same applies also to *n*-hexadecane.

In Fig. 4, the heat effects produced on injection of *n*-tetracosane into *n*-heptane and its subsequent adsorption on to iron with 1·1 per cent carbon content are compared with the heat effects produced by the adsorption on a cast iron with a carbon content of 3·5 per cent. Similar injections on an iron powder with a very low carbon content produced negligible heat effects. It appears therefore that the preferential adsorption of normal hydrocarbons on cast iron is connected with its carbon content. It is possible that the effects observed are chiefly adsorptions on carbon similar to those reported by Breshchenko[2] and by me[3].

I found recently that many fractions of lubricating oils are strongly adsorbed on cast iron, and that this is connected with the presence in the oils of molecules with long normal hydrocarbon chains. This observation has an obvious relevance to the mechanism of lubrication of cast iron by mineral oils.

I thank the Chairman and Directors of the British Petroleum Co. for permission to publish this article.

ROLE OF OXYGEN IN THE PRIMARY FORMATION OF H AND H_2O^- IN THE RADIATION CHEMISTRY OF WATER

By Dr. E. HAYON

Department of Physical Chemistry, University of Cambridge

A GENERAL phenomenon[1-9] of the radiation chemistry of air-free aqueous solutions of organic compounds is the dependence of the yields of hydrogen on solute concentration and *p*H. It is now fairly well established that $G(H_2)$ decreases with increase (above $\sim 10^{-2} - 10^{-1}$ M) in solute concentration and with decrease in the hydrogen ion concentration. An interpretation[2-5] has been provided to account for the effect of solute concentration and *p*H. More recently, attention has been focused on the observation that the yields of hydrogen in neutral air-free solutions of organic solutes are well above the 'molecular' yield of H_2, $GH_2 = 0{\cdot}45$ for γ-rays. The actual yield was found to be dependent on the particular solute used and could be as high as 2·5–3·0. H_2O^-, the alkaline form of hydrogen atom formed by the radiation[2,3,10], cannot dehydrogenate an organic solute (RH_2), but in the absence of electron-acceptors it dissociates slowly to give an H atom ($H_2O^- \rightarrow H + OH^-$), which can then dehydrogenate. In the presence of quantities of electron scavengers, which could be the solute itself[3], initial impurities in the water[8], products from the radiation[6], or added second electron-accepting solutes[6,8,9], $G(H_2)$ reaches a low limiting value of $1{\cdot}00 \pm 0{\cdot}05$.

Allan and Scholes[6] have suggested that the yield of H_2 above 'molecular' results from reducing radicals generated initially in the acid form, H atoms:

$$H_2O^* \rightarrow H + OH \qquad (1)$$

followed by $H + RH_2 \rightarrow H_2 + RH$. Hence $G(1) \sim 0{\cdot}55$ or ~ 20 per cent of the total yield of reducing species in neutral water. Recent[10] kinetic evidence shows that in the radiolysis of water molecular hydrogen is formed by two mechanisms. The main portion results from recombination of H_2O^- and about 22 per cent of the total H_2 via recombination of H atoms generated initially in the 'spurs' of the radiation.

The formation of H atoms directly from water and their presence in the bulk of the solution was recently questioned[3,11]. The reasoning was based on the results of the relatively simple and extensively studied radiolysis of oxygenated aqueous solutions of hydrogen peroxide. Barr and Allen[12] had indicated from their work that the basic and acid forms of H behave very differently in their competition between oxygen and hydrogen peroxide, and later Czapski and Allen[11] showed on the basis of such a competition that all the reducing species (100 ± 5 per cent) must be present in their basic form, H_2O^-.

The conclusions from the O_2–H_2O_2 and the organic systems are each quite valid and correct in themselves. It is suggested that the apparent difference is due to the presence of oxygen. Oxygen affects (see following) the precursor of the directly produced H atom such that H_2O^- is formed quantitatively instead of H. This suggestion is substantiated as follows:

(*a*) In the radiolysis of air-free neutral H_2O_2 solutions, on the basis of reactions (2)–(4), $G(-H_2O_2) = 4\cdot70$ and

$$H_2O^- + H_2O_2 \rightarrow OH + H_2O + OH^- \tag{2}$$

$$OH + H_2O_2 \rightarrow HO_2 + H_2O \tag{3}$$

$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2 \tag{4}$$

$$H + O_2 \rightarrow HO_2 \tag{5}$$

$G(O_2) = 2\cdot55$, taking $G_{\text{red}} = 2\cdot85$, $G\ \text{OH} = 2\cdot25$ and $GH_2O_2 = 0\cdot70$. However, if $G(1) = 0\cdot55$, and since $\frac{k(H+O_2)}{k(H+H_2O_2)} \simeq 3{,}000$[11], according to reactions (2)–(5), $G(-H_2O_2) = 3\cdot60$ and $G(O_2) = 2\cdot00$. Hochanadel[13] found the initial yield of $G(-H_2O_2) = 3\cdot7$ at 10^{-4} M and 4×10^{-3} M H_2O_2, in good agreement with assumption of direct formation of H atoms. This indicates, furthermore, that the apparent difference mentioned here is not a property of organic systems but applies to both organic and inorganic solutes irradiated in air-free solutions.

(*b*) Barr and Allen[12] interpreted their results in the irradiations of H_2–O_2–H_2O_2 solutions by a mechanism consisting of reactions (2) and (4)–(7).

$$OH + H_2 \rightarrow H + H_2O \tag{6}$$

$$H_2O^- + O_2 \rightarrow HO_2 + OH^- \tag{7}$$

This mechanism gave a satisfactory explanation to their results. They expected, however, the rate of consumption of oxygen to be constant and equal to $\frac{1}{2}(G_{\text{red}} + G_{\text{OH}}) = 2\cdot55$. Starting with known initial concentrations of O_2 they actually found that the initial yield of $G(-O_2)$ was very close to 2·55, but that the maximum dose required for complete consumption of oxygen and start of the chain-decomposition of H_2O_2 was greater than anticipated, making $G(-O_2)$ at maximum dose $\leqslant 2\cdot15$ (ref. 12) as compared with 2·55. This difference is here interpreted to mean that initially when the solutions have a relatively large $[O_2]$ reaction (1) does not take place, but that at doses near maximum, that is, when $[O_2]$ is very low, H atoms can be formed via reaction (1). It follows that in the latter case the extent of reaction (2) will be reduced, that of (5) and (4) increased, resulting in a continued increase in the formation of H_2O_2 and therefore an increase in the maximum dose required before H_2O_2 is rapidly decomposed by a chain reaction. This means that the ratio of initial O_2 concentration to the maximum dose, expressed in molecules per 100 eV, that is $G(-O_2)$ would be smaller by a G-value of up to 0·55 ($=G(1)$). A micromolar of O_2 seems sufficient for reaction (2), (5) or (7) to take place, but between 10–100 μM are necessary for reaction with the precursors of directly formed H atoms.

If H atom is produced from dissociation of an excited water molecule, H_2O^* could be formed either by direct excitation or as a result of ion neutralization[14]. The role of oxygen may be in intercepting the returning electron and preventing ion neutralization. But it is clear that this electron is not the same as the 'thermal' electron, H_2O^-, since high concentrations (up to 10^3–10^4 times $[O_2]$) of good scavengers for H_2O^-, for example, chloroacetic acid[3], cannot compete with O_2 in this electron capture process, though:

$$\frac{k(H_2O^- + O_2)}{k(H_2O^- + \text{ClAc})} = 3\cdot4 \text{ (refs. 3, 11)}$$

An alternative interpretation, which at present is considered much more likely, is the quenching by oxygen of excited water molecules leading to electron transfer:

$$H_2O^* + O_2 \rightarrow H_2O^+ + O_2^- \tag{8}$$

The electron once formed in water will reduce O_2 or migrate to other acceptors, on the basis of concentration and rate constants of competing solutes. Although oxygen is an efficient trap for the electron, having a reaction rate constant $\geqslant 10^9$ l./mole-sec (H_2O_2, H^+ are about equally efficient), the migration of the electron is still considered to occur. This is because the electron, with its great mobility and great selectivity to traps, will not 'stick' except in a fully competitive way.

Oxygen dissolved in water[15] or organic solvents[16] is known to cause an ultra-violet absorption spectra, in the case of water starting below 220 mμ. This has been interpreted by Mulliken *et al.*[16] to a charge-transfer interaction between oxygen and the solvent. It is also well known that oxygen quenches fluorescence[17] very efficiently, and Weiss[18] has explained such quenching in polar solutions by a similar mechanism. The life-times of the excited water molecules are probably[14,16,19] sufficiently long, thus providing ample probability for encountering oxygen molecules.

In conclusion, H and H_2O^- can both be formed directly in the radiolysis of oxygen-free water. In neutral solution $GH = 0\cdot55$ and $GH_2O^- = 2\cdot30$. In the presence of oxygen, all the reducing species formed ($G = 2\cdot85$) are present as electrons. The independent formation of the two possible reducing species in neutral water, one capable of dehydrogenating (the 'acid form') and the other of reacting with electron acceptors (the 'alkaline form') provides further evidence that the main reducing specie is the hydrated electron, H_2O^-.

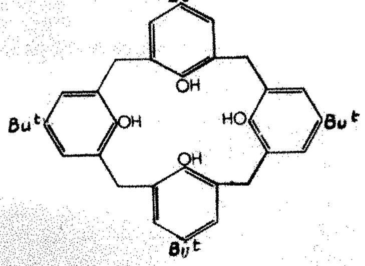
HYDROGEN BONDING IN PHENOLS

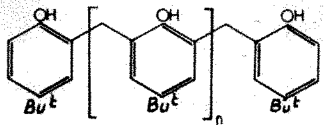
By T. CAIRNS and Dr. G. EGLINTON

Department of Chemistry, University of Glasgow

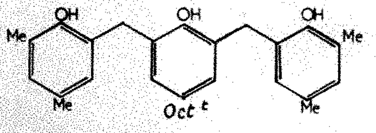
CONFORMATIONAL analysis of fairly rigid molecules such as those of the steroids and triterpenoids is well established, but comparatively little attention has been given to the stereochemistry of more flexible systems and of molecular aggregates in solution. As part of a general investigation[1] in this field we have examined the infra-red absorption spectra of a number of polyphenolic compounds (I, II, III and IV) of the novolak[2] type. Our results (Table 1, Fig. 1) show that in carbon tetrachloride solution these flexible molecules, in which the phenolic nuclei are linked by methylene bridges, assume well-defined, intramolecularly hydrogen-bonded conformations, both as monomers and, in certain cases, as intermolecularly bonded dimers. These conformations are represented in stylized form in Fig. 2 and a drawing of the Dreiding molecular model of a single example is reproduced in Fig. 3.



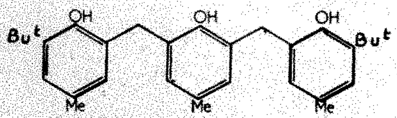
(I)



(II)
n = 0, 1, 2, 3, 4



(III)



(IV)

Oct^t = $-C(CH_3)_2CH_2C(CH_3)_3$

The experimental approach[3] distinguishes non-bonded from bonded hydroxyl groupings by comparing the lowered hydroxyl stretching absorption frequency of the latter with the non-bonded value of about 3,600 cm^{-1}. Further, hydroxyl absorption frequencies due to intermolecular hydrogen bonds differ from those pertaining to the intramolecular type in being dependent on concentration, and the number of non-bonded hydroxyl groupings may be inferred from the intensity of the 3,600 band relative to the intensity of the same band in simple phenols[4]. Certain stereochemical requirements have to be met by conformations for which reasonably strong (ν_{OH} ~ 3,300 cm^{-1}) hydrogen bonds involving phenolic hydroxyls are postulated: approximate coplanarity of the C—O—H bond with the benzene ring[4]; and O····O distance[5] of approximately 2·7 Å; and the hydrogen atom must lie somewhere near a line joining the two oxygens. (The exact positioning is not certain. The lone pairs on the receptor oxygen probably induce a pseudo-tetrahedral disposition with respect to the latter, though there is likely to be more trigonal character in phenolic bonding than that of alcohols owing to electron delocalization involving the aromatic nucleus.) The weaker, OH···· benzene ring, type of hydrogen bond is unlikely to compete, except in unusual steric situations.

The cyclic tetranuclear novolak (I) represents, perhaps, the simplest case of those listed in Table 1.

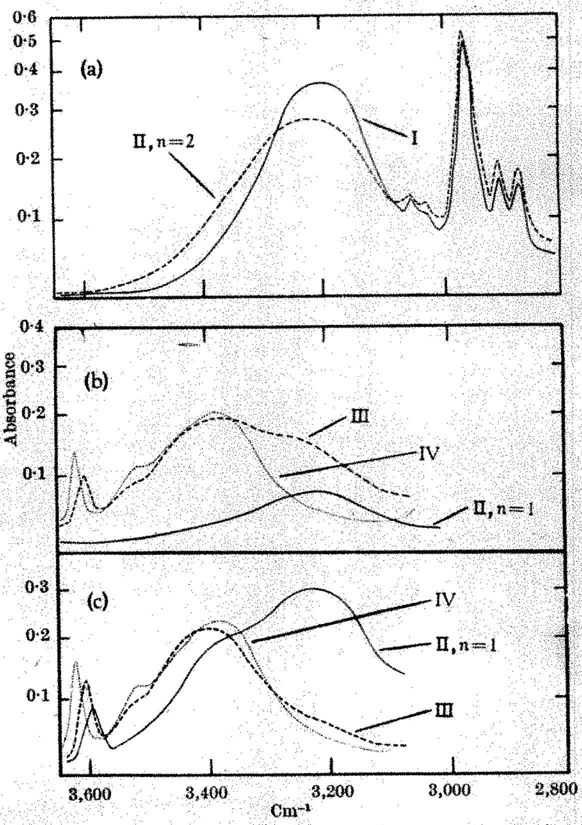


Fig. 1. Hydroxyl stretching absorptions, in carbon tetrachloride of the novolaks I, II (n=1 and 2), III and IV. Concentrations: (a) c. 0·3 mM, (b) c. 15 mM except for II, n=1 saturated solution, and (c) c. 0·5 mM. Cell paths: (a) 20 mm, (b) 0·5 mm, and (c) 20 mm

Values in parentheses are approximate; —, not measured; *sh*, shoulder, *br*, broad band. Intensities are given as apparent extinction coefficients, [ε^a], (l. mole^{-1} cm^{-1}) rounded to the nearest 5 units and measured from a solvent–solvent base-line superimposed on the record of the spectrum of the solution (determined with solvent in the reference beam). Recording conditions are set out fully in reference 1. Gifts: Prof. A. Zinke, compounds I and II, $n=0$, 1, 2, 3, and 4; Mr. A. R. Philpotts, Dr. H. C. Bailey, and Mr. P. A. Jenkins of the Distillers Co., Ltd., compound III; and the American Cyanamid Co. compound IV.

From an examination of the Dreiding model, it would appear that the most stable conformation should be that having a closed ring of hydrogen bonds, with each of the hydrogen atoms between two oxygen atoms as indicated diagrammatically (*C* in Fig. 2). The absorption data are in complete accord as the only hydroxyl absorption in dilute carbon tetrachloride solution is the broad, intense, symmetrical band near 3,200 cm^{-1} (Fig. 1*a*) which was concentration independent over the range examined (since a closely similar band was observed for the solid state, the crystal may well consist of an array of such basin-shaped molecules). Most interestingly, the acyclic tetra-, penta- and hexa-nuclear novolaks (II, $n = 2$, 3, and 4) absorb in a similar manner and it would seem, therefore, that in solution these substances exist as the 'cyclic' intramolecularly hydrogen-bonded monomers *D*, *F* and *G*, respectively. The similarity in absorption pattern of the cyclic (I) and the acyclic (II, $n = 2$) tetranuclear novolak is illustrated in Fig. 1*a*. The increased width and asymmetry of the band of the latter compound is probably a result of the increased mobility of the molecular backbone. Dimeric association at the low concentrations examined is conceivable but unlikely in view of the ease with which the models of the monomers can be induced to take up the conformations illustrated (Figs. 2 and 3).

Unlike the preceding compounds, the di- and tri-nuclear novolaks (II, $n = 0$ and 1) show concentration dependent absorptions implying the existence of self-association even at very low concentrations. This behaviour (Table 1 and Fig. 1*b*, *c*) is almost certainly due to monomer–dimer equilibria and arises from the inability of the di- and tri-nuclear monomers (*A* and *B*, respectively) to form closed rings of hydrogen bonds in the manner already discussed for the monomers of the tetra-, penta- and hexa-nuclear compounds (*D*, *F* and *G*, respectively). Examination of Dreiding models suggests that relatively unstrained closed rings of hydrogen bonds are possible for the di- and tri-nuclear dimers, the former species (*E*) being closely analogous to the tetranuclear compound (*D*), and the latter (*H*) to the hexanuclear compound (*G*). Although both *E* and *H* apparently persist to very low concentrations (about 1 mM), the trinuclear dimer (*H*) seems the more strongly associated on the grounds of both ν_{max} and the relative intensities of the monomer and dimer bands.

We have been able to examine the effect of ortho-substitution of the terminal rings of the trinuclear novolak. As anticipated, introduction of the methyl groupings (compound III, Fig. 1*b*, *c*) greatly reduced dimer formation, while no dimer at all could be detected in fairly concentrated solution of the di-*t*-butyl compound (IV). Models of the type *H* dimer of compound (III) show pronounced interaction between the ortho methyls and it is conceivable that other cyclic conformations (for example, *I* and *J*), where some of the benzene rings are orientated in opposing senses and the methyl groups are directed away from each other, may be more stable.

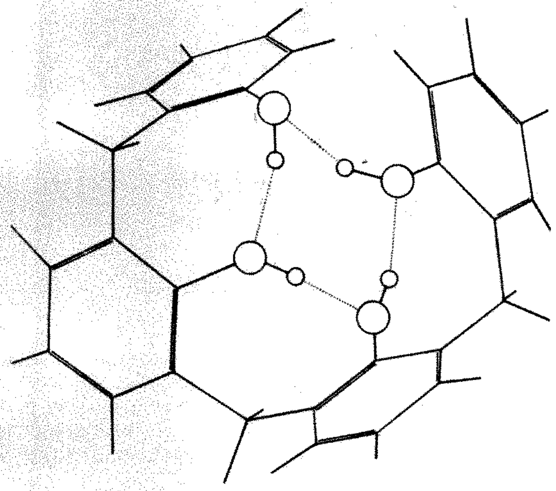

Fig. 3. Planar projection of the Dreiding molecular model of the postulated conformation (D) of the acyclic tetranuclear novolak II, $n=2$. The large and small circles indicate the oxygen and hydrogen atoms of the hydroxyl groups respectively. The dotted lines indicate hydrogen bonds. The para-t-butyl groups have been omitted

Coggeshall[6] and, later, Goddu[7] have examined the hydroxyl stretching region of a number of alkyl substituted dinuclear novolaks (*bis*-phenylol alkanes) related to (II, $n = 0$) but the concentration and frequency-ranges covered were narrow and these workers did not elucidate the monomer–dimer relationships established in the present work. However, it is clear from Coggeshall's data for an ortho-di-t-butyl substituted novolak that dimeric association is absent in quite concentrated (0·5 M) solutions in carbon tetrachloride (cf. II, $n = 0$). The *cis* and *trans* forms postulated by Coggeshall to explain the non-bonded and bonded hydroxyl absorptions are now unnecessary, but the peculiar effect reported[6,7] for the dinuclear novolaks substituted on the central aliphatic carbon requires elucidation.

The absorptions ascribed to the monomers (species B) of the three trinuclear novolaks merit some comment. First, the trend in the free hydroxyl frequencies: no *ortho* substituent 3,596, ortho methyl 3,606, and *ortho* t-butyl 3,622 cm^{-1}. The values for the corresponding *cis*-conformations (OH directed towards the alkyl grouping) of single *ortho*-alkyl substituted phenols[4,8,9] are 3,612, 3,621 and 3,647 cm^{-1}, respectively. (The *ortho* methyl value given is that for 2,6-dimethylphenol since only a single unresolved band at 3,613 cm^{-1} is observed for 2-methylphenol itself.) The lower values of the novolak monomers undoubtedly register the electronic effect[10] of the intramolecular hydrogen bond on the terminal hydroxyl. The same effect can be detected in the data given by Coggeshall[6] and Goddu[7]. Secondly, the broad bands assigned to the intramolecular bonded hydroxyls show some sign of sub-structure and, indeed, frequency differences might be expected between the two hydroxyl groups involved. Kuhn and Bowman[11] sought an indication of such behaviour in their somewhat parallel study of simple acylic triols.

It is interesting to compare the hydrogen bonding shifts, $\Delta\nu$, for the monomers of the series of novolaks (II, $n = 0$, 1, 2, 3, and 4) given in Table 2. The considerable increase in $\Delta\nu$ on going from II, $n = 1$ to II, $n = 2$ must certainly reflect the increased effectiveness resulting from the formation of the cyclic system (D) of hydrogen bonds. The simple addition of a fourth oxygen to the first three would otherwise be of little consequence. Numerous workers[3,4,8,11] have discussed the nature of the association equilibria present in solutions of alcohols and of phenols. Both cyclic (for example, K) and acyclic (for example, L) hydrogen-bonded species have been proposed. In the case of phenol itself the bands at 3,485 and 3,350 cm^{-1} (Table 1) are generally held to be due to dimers (L) and trimers, respectively, and on steric grounds it seems likely that the latter might well be cyclic (K). On the other hand, the hydroxyl region of a concentrated (2·5 M) solution of phenol in carbon tetrachloride closely resembles that of a very dilute solution (Fig. 1c) of a trinuclear novolak where the acyclic monomer predominates, and it is tempting to propose that the phenol trimer is also acylic. This argument is unsatisfactory, however, as the novolaks are more closely analogous to the *ortho* alkyl-substituted phenols for which different values for ν_{OH}[dimer] and ν_{OH}[trimer] are quoted[4,9]. In fact, the $\Delta\nu$ values for phenol are dimer (equivalent to species A, Table 2) 126 cm^{-1} and trimer 261 cm^{-1}. The relatively large increase from 126 to 261 cm^{-1} is a strong indication that the band centred at 3,350 cm^{-1} is mainly due to cyclic trimer. Acyclic trimer or higher polymers may well be present, but a cyclic tetramer could not be a major contributor.

Where $\Delta\nu = \nu_{OH}[\text{non-bonded}] - \nu_{OH}[\text{bonded}]$.
$= 3{,}611 - \nu_{OH}[\text{bonded}]$.

It would seem desirable to extend the foregoing approach to measurements in more polar solvents, so that closer analogies may be found for the more general problems of the conformations of polymer molecules in solution and of molecular specificity in biological systems.

We thank Mrs. F. Lawrie for the infra-red measurements, Prof. A. Zinke for his co-operation in supplying the series of para-t-butyl substituted novolaks, and Mr. A. R. Philpotts and his colleagues for samples and helpful suggestions. One of us (T. C.) thanks the Scottish Education Department for financial assistance.

SMALL-ANGLE DIFFRACTION OF POLYETHYLENE

By K. KOBAYASHI
Kyoto University
AND
M. KUROKAWA
Textile Research Laboratory, Fukui University, Japan

SEVERAL investigators have reported that small-angle diffraction is noted on the meridional direction at the drawn filaments of synthetic polymers. Applying the Bragg equation, long periods are calculated from the interference maxima, and these periods are interpreted as corresponding to the periodic alternations of crystalline and amorphous regions[1-4]. Regularity is limited to short range, so in general only first-order diffraction is noticed; but at the suitably prepared specimens two or three higher-order diffractions appear weakly[5]. It has also been shown that these long periods can be increased as the specimens are annealed at higher temperature[1-4]. Recently, we have found new forms of small-angle diffractions in Ziegler polyethylene, which are quite different from ordinary small angle diffractions.

Samples used were undrawn filaments of Ziegler polyethylene (commercial name, 'Hizex'), which were drawn about seven times at 20° C or in boiling water and then annealed at various temperatures. Pellets of Ziegler polyethylene (mol. wt. 66,000) were used, from which films were made by melt compression as usual, and these films were drawn and annealed in the same way.

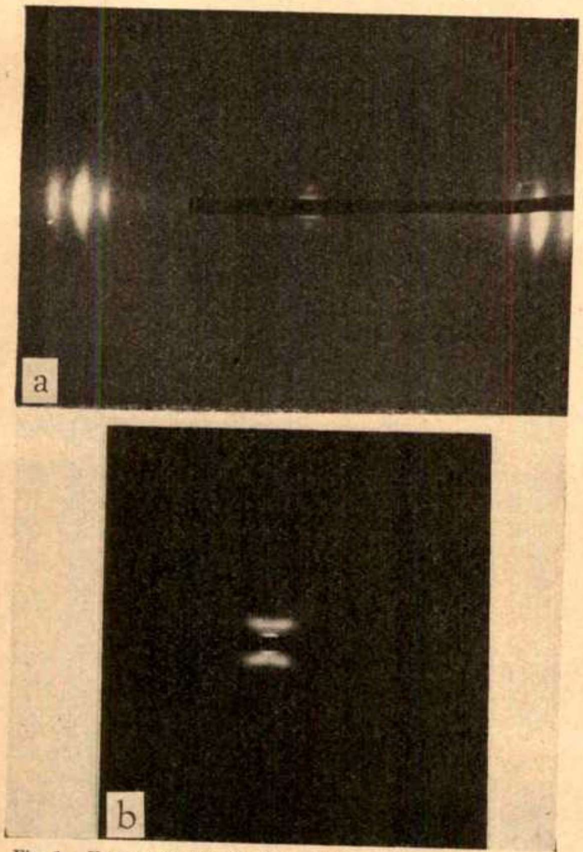

Fig. 1. X-ray photographs of polyethylene filaments drawn at 20° C and annealed at 120° C. *a*, Wide angle; *b*, small angle, corresponding to the shielded centre of *a*

Small-angle diffraction patterns were photographed by copper *K* radiation with pin-hole slits, at distances of 22·2 cm and 7·0 cm, and exposure times of 5–10 h. Small-angle scattering curves during annealing were recorded with a Geiger–Müller counter spectrometer, equipped with a small electric furnace in order to anneal the samples.

Specimens drawn at 20° C showed the ordinary off-meridional four-point patterns, and their long period and scattering intensities could be increased as the specimens were annealed at high temperatures. Together with these ordinary long-period diffraction we observed new small-angle diffraction patterns followed by several higher-order ones on the meridian after annealing at temperatures above about 90° C. Specimens drawn in boiling water also showed the ordinary off-meridional four-point diffraction and new on-meridian diffraction after annealing at about 120° C. The new small-angle diffractions did not appear at the drawn, but unannealed, specimens. These new small-angle diffractions and the ordinary ones are shown in Fig. 1, and Bragg spacing and observed intensities of these new diffractions are given in Table 1. We can conclude that these two forms of diffraction have different origins, because the new diffraction patterns appear on the meridian and their periods are independent of the annealing temperature (Table 2), while ordinary small-angle diffraction patterns are off-meridional four points and their periods are temperature dependent.

Table 1

Order	Period (Å)	Intensity (observed)
1	48·1	8
2	24·1	1
3	16·2	2
4	11·9	Weak
5	9·2	Weak

Table 2

Sample annealing temperature (°C)	Ordinary small-angle diffraction		New small-angle diffraction period (Å)
	Long period (Å)	δ*	
Drawn at 20, unannealed	163	34	—
65	178	34	
95	198	37	47·1
110	217	37	47·0
120	246	37	48·1
125	304	38	47·7

120 (contractible)	242	37	47·6
120 (not contractible)	228	Streak on meridian	48·2

* δ, Angle between diffraction spots and meridian.

Considering that the results of the new periods are independent of the annealing temperature, that several higher-order diffractions can be observed, and that their appearance are sensitively affected with the incident angle of X-ray to the specimens, we may

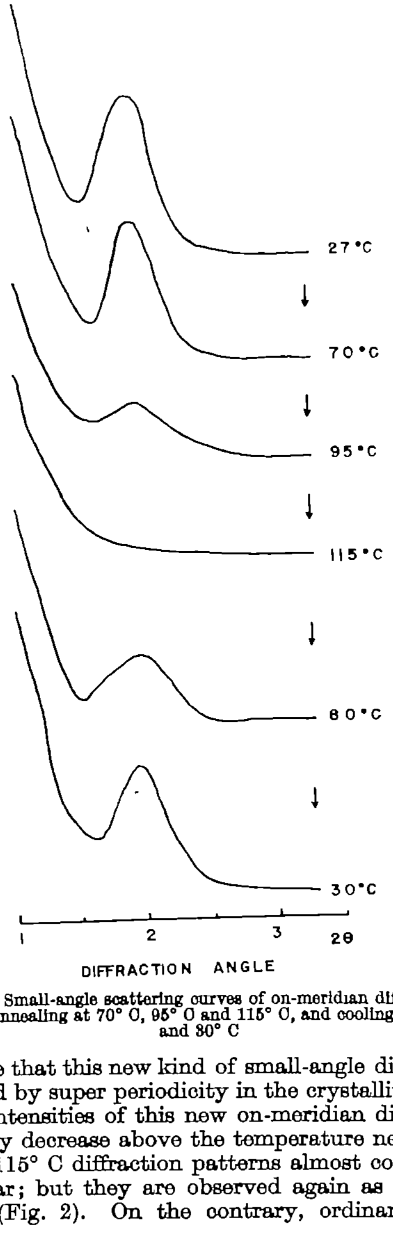

Fig. 2. Small-angle scattering curves of on-meridian diffractions during annealing at 70° C, 95° C and 115° C, and cooling at 80° C and 30° C

conclude that this new kind of small-angle diffraction is caused by super periodicity in the crystallites.

The intensities of this new on-meridian diffraction gradually decrease above the temperature near 80° C and at 115° C diffraction patterns almost completely disappear; but they are observed again as they are cooled (Fig. 2). On the contrary, ordinary small-angle diffraction patterns do not become extinct during annealing, or rather scattering intensities increase at high temperature. The extinction of Bragg diffraction patterns at high temperature are also noted on 6·10 nylon. In this case (001) diffraction becomes extinct at a temperature a little below the melting-point; but (002) diffraction does not. This means that owing to the active thermal vibrations of molecules in the crystallites, difference of electron distribution between (001) and (002) planes will disappear on the average, and consequently diffractions of odd order will become extinct.

It is well known that single crystals of polyethylene are precipitated from dilute solution, and the molecules are folded in these lamellar crystals[6,7]. We made the film by melt compression from the aggregates of single crystals precipitated from 0·02 per cent hot xylene solution of the same Ziegler polyethylene filaments. The film was drawn about seven times and then annealed at 120° C. These films did not show the new on-meridian small-angle diffractions.

The specimens used in this experiment are somewhat plasticized, but new small-angle diffractions will not be caused by the plasticizers themselves, because the diffraction patterns disappear at high temperature and they do not appear at the drawn specimens until they are fully relaxed by annealing.

From the above results and the fact that the dimensions of unit cell of these drawn and annealed polyethylene are equal to the value of normal orthorhombic structure, super-periodic structure in the crystallites, corresponding to the on-meridian diffraction, will result neither from the periodic distribution of branching nor from the pseudo-structure arising from the stretching[8], but from the periodic defects or distortions of chain in the crystallites. At present we cannot explain the detailed nature of them or the effect of plasticizer on these super-periodic structures if it is present.

We thank Prof. Horio of Kyoto University for his advice and Mr. Ban for his assistance.

INHIBITION OF BACTERIAL GROWTH BY MAGNETIC FIELDS

By VINCENT F. GERENCSER*, MADELEINE F. BARNOTHY and JENO M. BARNOTHY

University of Illinois Colleges of Medicine and of Pharmacy, Biomagnetic Research Foundation

THE results of investigations of the effect of magnetic fields on the growth of bacteria have so far been inconclusive. Leusden[1] found that the growth of coliform organisms and staphylococci was not affected by exposure to magnetic fields. Jennison[2] grew 25 species of bacteria, yeasts and moulds on solid media between the poles of an electromagnet which provided a homogeneous field of 3,000 œrsteds. After 48-h exposure, he checked the cultures for size of colony, staining reaction, pigment production, and spore formation. He found no difference between magnetized cultures and controls. However, Magrou and Manigault[3] showed that tumour production by *Bacterium tumefaciens* on a strain of *Pelargonium zonale* was retarded by magnetic fields.

The work reported here was begun by growing a nutrient broth culture of *Serratia marcescens* between the tapered constant gradient pole caps (*V*-4089-1) of a Varian 4-in. electromagnet. The average field strength was 15,000 œrsteds, having a constant gradient of 2,300 œrsteds/cm throughout the culture medium. The paramagnetic strength of this field was 34·5 mega-œrsteds^2/cm. (One mega-œrsted^2/cm exerts on 1 c.c. of a substance of a paramagnetic susceptibility of 10^{-6} an accelerating force of one dyne in the direction of the gradient vector.)

---

* Present address: Department of Microbiology, College of Medicine, West Virginia University, Morgantown.

Standard culture tubes containing 5 ml. of nutrient broth were inoculated with one drop of a 24-h broth culture from a 1-ml. pipette. One tube was incubated in the magnet and the other, serving as a control, was incubated outside the magnet. Both cultures were grown for 10 h at 27° C.

At hourly intervals, 0·1-ml. samples were taken and diluted by serial 10-fold dilutions. 0·1-ml. of the last two dilutions was surface plated on nutrient agar. The plates were incubated at 27° C for 48 h and the resulting colonies counted.

The magnetized and control cultures were found to have approximately the same number of cells and the same growth-rate up to 6 h. At 7 h the magnetized culture showed a lower plate count than the controls. This difference was greatest at 8 h and diminished up to 10 h when magnetized and control cultures had approximately the same number of cells.

A similar procedure was followed with a culture of *Staphylococcus aureus* except that the incubation temperature was 37° C. Under these experimental conditions, there was no effect on the growth of the organism. The experiments were repeated using special pole caps on the electromagnet (Fig. 1). These pole caps, consisting of a wedge, opposite to a concave piece, produced an average gradient of 5,200 œrsteds/cm. The gradient in the culture medium was nowhere less than 3,000 œrsteds/cm and reached at some parts 8,000 œrsteds/cm. The average paramagnetic strength of the field was 78 mega-œrsteds^2/cm, or more than twice as strong as the one previously used.

A difference in the number of cells was evident from 3 to 6 h, when the magnetized culture showed a higher plate count and higher growth rate than the control. However, at 6 h inhibition of this growth began and reached its maximum at 7 h, when the plate count of the magnetized culture fell below that of the control. This difference gradually diminished up to 9 h, when the magnetized and control cultures had approximately the same number of cells. Thus *S. aureus* was maximally inhibited around 6–7 h, as was *S. marcescens*.

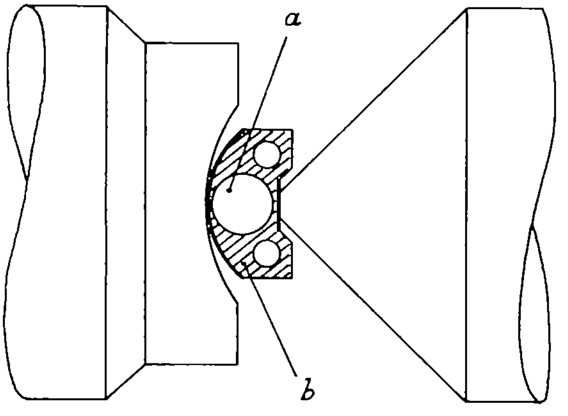

Fig. 1. Culture tube (*a*) in thermostat (*b*) between the pole caps of the electromagnet, in a field of 15,000 œrsteds and 5,200 œrsteds/cm average gradient

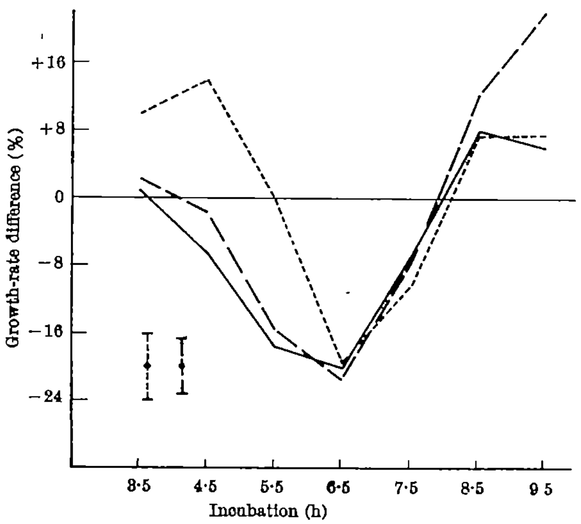

Fig. 2. Difference of the relative hourly growth-rate between magnetized and control culture. Dashed line, *Serratia marcescens*; dotted line, *Staphylococcus aureus*, full line, difference curve computed from equations (1) and (2). Standard errors are indicated

The effect of the magnetic field is more clearly seen if the difference between relative hourly growth rate of magnetized and relative hourly growth rate of control cultures is plotted, as shown in Fig. 2. The curve for *S. marcescens* is the average of three experiments; the curve for *S. aureus* is the average of two experiments. The minimum of the curve is in both cases significant to a probability-level better than 1 : 1,000,000. The higher growth rate for the hours preceding the minimum is significant for *S. aureus* but not significant for *S. marcescens*, whereas the higher growth rate shown for the hours following the minimum is significant for both cultures.

These results indicate that magnetic fields of a paramagnetic strength as used do affect the growth of bacteria. The inconclusive results of previous workers may have been due to the low paramagnetic strength of their fields.

Microscopic examination of samples taken from the magnetized cultures showed no morphological changes.

The exact physiological mechanism which causes the inhibition is unknown. Nor is it clear why *S. aureus* required a more inhomogeneous field than *S. marcescens* to be inhibited. The fact that the inhibition was observed in a highly inhomogeneous magnetic field, and particularly that the inhibition of *S. aureus* was found in a field of the same average strength as with *S. marcescens* but at a higher paramagnetic strength, indicates that the inhibition may be due to a paramagnetic phenomenon. The small magnitude of the inhibition which we observed even with fields of great inhomogeneity may be due to the fact that bacteria do change their position relative to the direction of the magnetic field and gradient vector. This constant changing of position, due to convection currents and Brownian motion, would tend to compensate all first-order reversible cumulative effects of the field, and only second-order reversible cumulative effects, or immediately permanent effects, may exert themselves. An exception would be if a bacterium as a whole were oriented through the magnetic field. This could occur if the bacterial cells were paramagnetic and, furthermore, if they were non-spherically shaped, like *S. marcescens*. This question needs further investigation.

A further interpretation of the growth-curve can be achieved through its mathematical analysis. One can describe the main part of the growth-curve of bacteria, that is the phase of logarithmic increase, the phase of negative growth acceleration, the maximum concentration, or stationary phase, the death-phase and the logarithmic death-phase by the equation:

$$N = N_0 \exp A\ [1 - \exp(-it) - \exp d(t - \delta)] \quad (1)$$

where N_0 is the number of viable cells at the onset of the logarithmic increase phase, chosen as the zero point of the time-scale (t equals incubation time less lag time); A is a constant determining the height of maximum concentration, or stationary phase, and depends among others on the total available volume; i is a parameter which determines the slope of the logarithmic increase phase and is a measure of the fission rate (minus the small proportion of cells which failed to survive); d is a parameter determining the slope of the logarithmic death-phase; it is a measure of all detrimental factors appearing during the further history of the culture and includes such factors as change in *p*H, accumulation of toxic products, exhaustion of nutrient material and others, which are the reasons for the increase in the death-rate of cells; δ is the total length of the growth-curve, after which the number of viable cells is reduced anew to N_0; it is also a measure of the time-lag, after which the effect of the detrimental factors become dominant. The growth-curve of *S. marcescens* under our experimental conditions can be well approximated with the values $A = 4$; $i = 0{\cdot}25$/h; if δ is adequately long, the second term in the exponent has no bearing on the shape of the curve up to the maximum stationary phase.

It is reasonable to assume that the magnetic field can be considered as a factor which either decreases the fission rate or increases the death rate of the cells. The circumstance that in the beginning of the logarithmic increase phase the magnetic field did not affect adversely the growth rate would indicate that its effect would be more of the nature of a detrimental factor, increasing the death rate. It manifests itself when the number of cells approaches the maximum concentration and the fission rate gradually decreases. Similar to the effect of other detrimental factors, this could be expressed through a term like the second term in the exponent in which the parameter m is a measure of the death rate caused by the magnetic field and a time-lag μ is the necessary time for the biomagnetic effect to develop. If the magnetic field is the predominant detrimental factor, the logarithmic death-phase will set in much earlier and the number of viable cells begins to drop before the usual maximum concentration is reached. It is, however, possible that while the death rate of the earlier generations increases, the new generations become better adapted to withstand the detrimental factor of the magnetic field. Depending on when, and to what degree, this resistance is building up in the later generations, it can more or less compensate the increased death rate of the earlier generations. It may be that actually the total number of viable cells will continue to increase and merely a temporary inhibition in the growth rate will be observable.

The observation that the growth rate after its minimum at 6·5 h returned quickly to its original value, and furthermore, that eventually the same maximum concentration value was reached, as without magnetic field, suggests that the adaptation of the later generation must have been more or less complete. We do not want to use the term 'magneto-resistant mutant' since no attempts were made to verify the presence of a genetic change. Mathematically, the growth-curve of these resistant cells could be described by equation (1), in which the zero point of the time-scale starts with a time ν later, which time is necessary that the number of resistant viable cells reach the starting value N_0. Assuming that the fission rate of the resistant cells is the same as that of the original population, the total number of viable cells is given by the equation:

$$\begin{aligned} N_m = {} & N_0 \exp A\ [1 - \exp(-it) - \exp m(t - \mu)] \\ & + N_0 \exp A\ [1 - \exp\ -i(t - \nu) - \exp d(t - \delta)] \quad (2) \end{aligned}$$

The first term in this equation describes the growth-curve of the original population, the second term that of the magneto-resistant population with the meaning of the parameters as discussed here, whereby it was assumed that the effect of the magnetic field on the death rate, overrides all other detrimental factors. From equations (1) and (2) we can compute the relative difference in growth rate between magnetized and control cultures. This is shown in Fig. 2, where the full line was computed using the previously given values for A and i and taking $\nu = 1$ h; $\mu = 5{\cdot}5$ h and $m = 1$/h. As we can see it follows well the experimental curve of *S. marcescens*. The *S. aureus* curve, which in the beginning shows a somewhat enhanced growth rate in the magnetized culture, can be explained by a slightly higher fission rate of the resistant cells.

We wish to stress that in both cultures the increase of the growth rate after the minimum can only be explained if magneto-resistant cells are formed. From the fitted values of the parameters we may conclude that after 5·5 h of incubation in the field, the number of resistant and non-resistant viable cells became equal and that after 7·5 h of incubation the number of non-resistant viable cells was again reduced to N_0. The other possible solution, as already mentioned, would be that the magnetic field does not kill the cells, but merely temporarily inhibits their division until they become adapted to the new environment, the magnetic field. We could think of a process similar to that occurring during the lag phase when cells inoculated from an old culture do not start to divide at once, but first grow in size and are rejuvenated and fitted for reproduction.

However, the analogy ends here. At the time when the first signs of inhibition appear, the majority of the population consists of 5th–8th generation cells. It is somewhat difficult to understand that cells multiplying in the field for 5–8 generations without being affected should abruptly cease to divide in order to adapt themselves to the field and thereafter resume their original fission rate. In our opinion the first solution is more probable: the magnetic field does not affect the fission rate, but has a mortal effect (presumably caused through a paramagnetic phenomenon). During the incubation in the magnetic field, a strain resistant to this mortal effect develops. The mortality rate of the non-resistant strain rapidly increases in younger generations, clearing the biological space for the multiplication of the resistant cells.

The experiments were performed at the University of Illinois College of Pharmacy and supported in part by a graduate research grant of the University of Illinois and in part by the Biomagnetic Research Foundation.

DEHYDRATION-INDUCED SYNTHESIS OF NUCLEIC ACIDS AND CHANGING OF COMPOSITION OF RIBONUCLEIC ACID: A POSSIBLE PROTECTIVE REACTION IN DROUGHT-RESISTANT PLANTS

By B. KESSLER and JUDITH FRANK-TISHEL

Department of Plant Physiology, National and University Institute of Agriculture, Rehovoth, Israel

DEHYDRATION has diverse effects on plant cells, and the extent in the response of plants to drought varies in different plants. The tolerance of a plant to dehydration changes with age[1] as well as with the rate of loss of water[2]. Recently, the existence of a relationship between a liponucleic acid fraction and relative drought resistance was demonstrated[3].

The possible relations between nucleic acids and drought tolerance have now been more closely examined. This article will be confined to the Oleaceae of which two systematically close genera were selected: the drought-tolerant *Olea europea* L. var. Souri and the drought-sensitive *Ligustrum sinensis*.

Leaves from the central part of one-year old branches were slowly dehydrated at 30° C. At various time-intervals four replicate leaf samples were removed and analysed for nucleic acids. The detailed assay procedures for nucleic acids, RNA and DNA extraction and fractionation, their hydrolysis and ion-exchange chromatography have all been described[4,5].

The RNA composition of both the olive and ligustrum leaves were found to be of the *G*–*C* type.

Fig. 1 demonstrates the changes in the nucleic acid content in olive leaves with progressing dehydration, and the same is shown for the ligustrum leaves in Fig. 2. The response of nucleic acids in olive leaves is interesting because it shows that on dehydration both DNA and RNA accumulated rather intensively. In contrast, in the ligustrum leaves, the DNA-level remained fairly constant at any level of dehydration while the level of RNA increased only slightly.

A similar increase in the RNA-level with dehydration has previously been found by Gates *et al.*[6] and Kessler[3] in intact tomato plants subjected to soil drought; but this initial increase was followed by a pronounced decrease in the RNA-level.

That in the drought-sensitive ligustrum leaves the RNA-level did not decline as in the intact tomato plants[3,6] might be related to the fact that in the present case we are dealing with an excised tissue from which no outward translocation is possible.

DNA synthesis occurs in non-dividing cells, continuing after the cessation of mitosis[8]. DNA, as well as RNA, are also synthesized in rooted leaves where growth is based only on cell enlargement and not on cell division[9]. In the present case, DNA synthesis was initiated in non-dividing olive leaves under the effect of water stress, and this 'induced' DNA synthesis was paralleled by an intensive accumulation of RNA even during a fairly high degree of dehydration.

The drought-induced synthesis of nucleic acid reminds, to a certain extent, Stocker's 'restitution' theory, in which he assumes an over-compensation of the plant metabolism during a slow water removal through which the plant enters a hardened condition[10,11].

Of particular interest was the fact that, in olive leaves, the newly accumulated RNA in the dehydrating leaves was differently composed than the RNA of fully turgorized leaves (Table 1). The $\frac{G+C}{A+U}$ ratio of ligustrum-RNA is about 1·04 in the fully hydrated leaves. On dehydration, there was a slight tendency of this ratio to decrease, being at all levels of dehydration near 1·00.

A different picture was obtained with the olive leaves. In this case the $\frac{G+C}{A+U}$ ratio increased on dehydration from 1·07 to 1·38. These data indicate that the drought-resistant olive leaves not only accumulated RNA on dehydration but also synthesized RNA molecules of different types as judged by the increasing $\frac{G+C}{A+U}$ ratio.

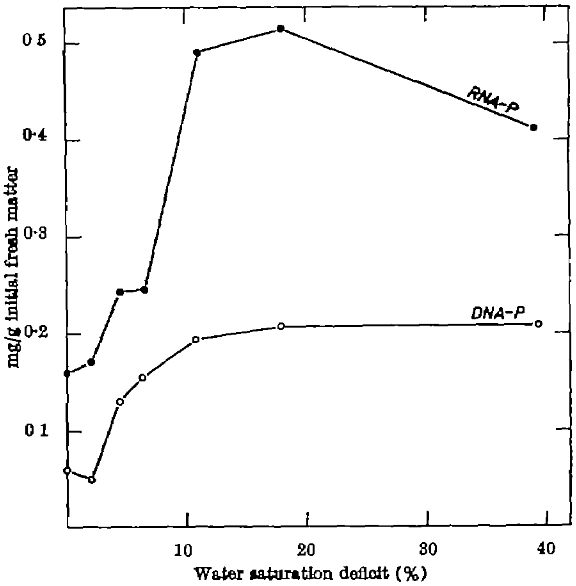

Fig. 1. Concentration of RNA and DNA in olive leaves at different levels of dehydration

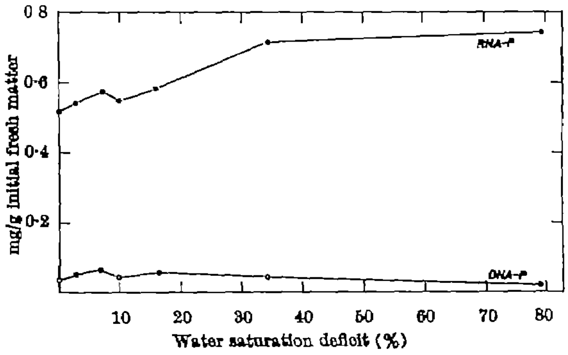

Fig. 2. Concentration of RNA and DNA in ligustrum leaves at different levels of dehydration

Table 1. NUCLEOTIDE COMPOSITION OF RNA'S FROM OLIVE AND LIGUSTRUM LEAVES AT DIFFERENT LEVELS OF DEHYDRATION

% Water loss	Mol. (%)				Purines / Pyrimidines	(Guanylic acid + Cytidilic acid) / (Adenylic acid + Uridylic acid)
	Cytidilic acid	Adenylic acid	Uridylic acid	Guanylic acid		
			(1) Olive			
0	24·2	26·5	21·8	27·5	1·17	1·07
5	24·5	25·7	20·8	29·0	1·21	1·15
11	24·6	23·6	20·8	31·0	1·20	1·25
39	24·9	21·9	20·2	33·0	1·21	1·38
			(2) Ligustrum			
0	24·1	24·9	24·1	26·9	1·07	1·04
6	24·2	25·1	24·4	26·3	1·06	1·02
11	24·1	25·5	24·4	26·0	1·06	1·00
35	24·1	25·3	24·2	26·4	1·07	1·02

The increase in the $\frac{G + C}{A + U}$ ratio indicates the formation of $(G + C)$-rich RNA molecules. The configuration of RNA in plants has not yet been fully elucidated. If we assume that leaf-RNA is double stranded then the 'dehydration-induced' synthesis of $(G + C)$-rich RNA molecules might become of particular significance. The G–C pairs, which are more hydrogen bonded, are denser[12] and have a higher thermal stability[13–15]. Their structure might, therefore, be more stable; in particular, in those cases where drought is also combined with high temperatures.

On the basis of these results it might be postulated that the extent of the resistance of plants to unfavourable conditions as drought and low temperatures is related, at least partially, to either one of the following factors: (1) a higher $G+C$ content of its RNA[7]; (2) its capacity to synthesize $(G+C)$-rich RNA molecules under the stimulus of slight stress conditions. This latter process might well constitute a basic part of hardening reactions.

Note added in proof. In a recent communication it has been reported (West, S. H., *Plant Physiol.*, Supp. 37, ii; August 1962) that, similarly to our present results, total RNA increased when water was limited.

DEVELOPMENT OF LYSOZYME RESISTANCE IN *MICROCOCCUS LYSODEIKTICUS* AND *SARCINA LUTEA*

By PROF. GERALD LITWACK and A. L. N. PRASAD

Biochemical Laboratory, Division of Cardiology, Philadelphia General Hospital,
and Department of Medicine, Graduate School of Medicine, University of Pennsylvania

THE development of lysozyme-resistance in *Micrococcus lysodeikticus* was described almost simultaneously by reports from our laboratory[1] and from Brumfitt, Wardlaw, and Park[2]. Afterwards, we demonstrated that our resistant cells were white in colour and devoid of carotenoids[3–6]. In the work described by Brumfitt, Wardlaw and Park[2], and in later work by Brumfitt[7], it was established[8] that the cells examined by the latter workers retained pigmentation and were therefore different cells than those we have obtained in the course of our experimental work. The object of this article, therefore, is to present information on how we have obtained resistant cells, to describe the means by which lysozyme develops resistance in the culture, to corroborate previous findings with regard to resistance and pigmentation in a second strain of organisms, and finally to make suggestions concerning the differences between resistant cells obtained by us and those obtained by Brumfitt and co-workers.

The conditions used for growth of cells and other manipulations have been described previously[1,3,9–11].

Fig. 1 shows the course of development of lysozyme resistance as a function of transfer (sub-culture). The level of sterile lysozyme was 0·1 μg/ml. liquid culture. It is shown that nearly complete resistance (white cells) is obtained rapidly under these conditions (in the initial culture a 40–60 h lag phase is encountered). At the stage of the 7th transfer, lysozyme was omitted from some of the cultures and these afterwards reverted to the yellow, lysozyme-sensitive strain. The resistant, white cells were morphologically identical to the lysozyme-sensitive, yellow cells as examined by Gram-staining. The resistant cells, therefore, appeared to be derived from the starting culture. Ultra-violet irradiation of the white, resistant strain gave rise to 2 yellow strains that conformed to biochemical patterns demonstrated by a strain obtained from ultra-violet treatment of the sensitive parent strain[12].

Lysozyme appears to select the resistant mutant simply by lysing the sensitive cells and permitting the white, resistant organisms to grow out (Table 1).

The value of checking this phenomenon in another strain of organisms (*Sarcina lutea*, A.T.C.C. 272)

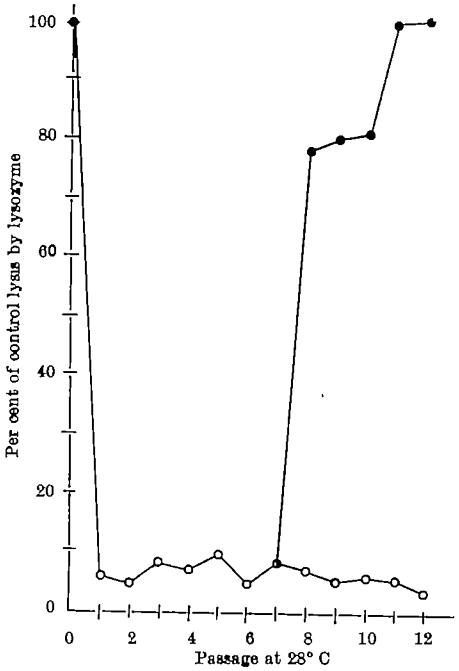

Fig. 1 Course of development of lysozyme resistance in liquid cultures of *M. lysodeikticus* and subsequent reversion to lysozyme-sensitive cells when lysozyme was withdrawn from the medium. Open circles represent cultures with lysozyme; closed circles represent cultures without lysozyme

became obvious. The features of resistance development in *S. lutea* were similar in stepwise experiments to *M. lysodeikticus* except that a more marked intermediate condition was apparent where cells remained yellow and partially resistant to lysozyme up to 1 μg lysozyme per ml. medium. At high concentrations of the enzyme, pure white cells were obtained that were not lysed by 50 μg lysozyme in the assay system. Pure white, resistant cells can be obtained using high levels of lysozyme in the culture (10 μg/ml.) in a one-step experiment and these cells grow out after a lag period when this high amount of lysozyme is combined with the yellow culture.

The content of extractable carotenoid pigments in *S. lutea* in various stages of resistance is illustrated in Fig. 2. This pattern is similar to that previously observed with *M. lysodeikticus*.

The relationship of cell whiteness to resistance and cell yellowness to sensitivity may now be discussed. In view of the facts that Brumfitt *et al.*[2,7,8] developed lysozyme-resistant cells (on agar media) and these cells lost little or no pigmentation, this question deserves some attention. Diphenylamine inhibits carotenogenesis in various organisms[13,14] presumably by interfering with cytoplasmic dehydrogenases and flavin enzymes that catalyse the oxidation of precursors to carotenoid pigments[15-17]. This activity is reversible when diphenylamine-treated cells are sub-cultured without addition of diphenylamine. We investigated the action of this compound on *S. lutea* in relation to the resistance of the resulting cells to lysozyme. Cells carried through several platings from single colonies were used ensuring that no white mutants were detectable by our procedures. Growth of this organism was studied with levels of diphenylamine from 10^{-4} to 5×10^{-4} *M*. The highest level inhibited both rate and extent of growth by about 80 per cent while the lowest level resulted in growth inhibition of 10 per cent. Table 2 shows that inhibition of carotenoid formation does not seriously alter sensitivity to lysozyme in the lysozyme-sensitive organism. This means that carotenoid *per se* is not directly related to lysozyme substrate, a conclusion which is supported by the facts that lysozyme substrate resides primarily in the cell wall and carotenoids are found in the protoplast membrane. It has now become obvious that the cultures studied by Brumfitt and co-workers did not contain the white mutant that is tenaciously associated with our cultures and with *M. lysodeikticus* A.T.C.C. 4698 and many others[13]. We therefore conclude that development of lysozyme-resistance in our case is by selection and that development

Table 1. DEVELOPMENT OF LYSOZYME RESISTANCE BY LYSOZYME IN LIQUID CULTURES OF *M. lysodeikticus*

	Type of inoculum used	Development of white, lysozyme-resistant cells
I.	*M. lysodeikticus*, yellow, lysozyme-sensitive, wild strain	yes
II.	2 replatings of single colony from I, yellow, lysozyme-sensitive	yes
III.	5 replatings of single colony from I, yellow, lysozyme-sensitive	no
IV.	Pure replated white, lysozyme-resistant strain	yes
V.	Pure replated yellow, lysozyme-sensitive cells mixed and equilibrated with pure replated, white lysozyme-resistant cells (10 sub-cultures)	yes (50% smaller lag than I)

Table 2. LYSABILITY BY LYSOZYME AND CONTENT OF CAROTENOID PIGMENTS IN DIPHENYLAMINE-TREATED CELLS OF *S. lutea*

Type of cell	Lysability by lysozyme Δ % *T* 30–60 sec.	Carotenoid content. Absorbancy at peak wave-lengths 413 mμ	438 mμ	467 mμ
Normal	3·0	0 33	0 46	0·43
Grown in 1×10^{-4} *M* diphenylamine	3·0	0·18	0·17	0·11
Grown in 2×10^{-4} *M* diphenylamine	2·7	0 08	0 07	0·05

Absorption spectra of extracts of diphenylamine-grown cells resemble the spectrum of lysozyme-resistant cells (Fig. 2).

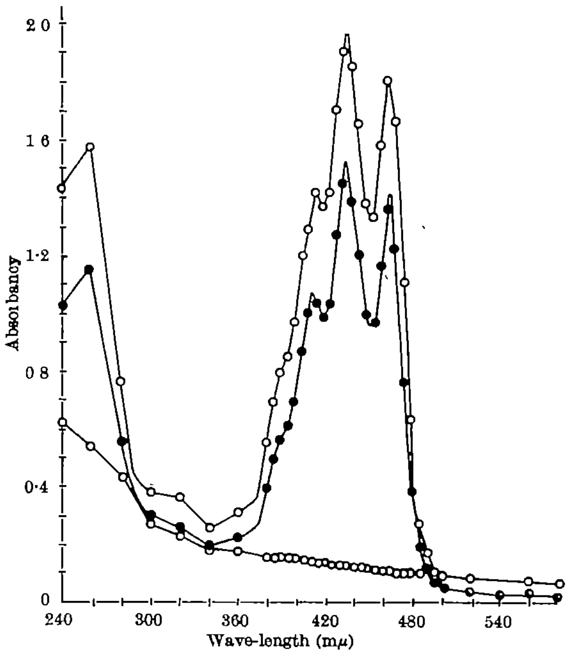

Fig. 2. Spectra of boiling methanol extracts of *S. lutea* in various stages of resistance to lysozyme. Upper curve . normal culture, no lysozyme added ; middle curve ; culture partially resistant to lysozyme ; lower curve . culture fully resistant to lysozyme (no lysis observable in assay system with 50 μg egg white lysozyme added to system). Little difference in absorbancy at maxima exists between the upper curves when absorbancy is based on dry weight of cells

Table 3 EFFECT OF STREPTOMYCIN SULPHATE ON THE DEVELOPMENT OF LYSOZYME RESISTANCE IN *M. lysodeikticus*

Inoculum	Streptomycin sulphate added to culture (mg %)	Crystalline lysozyme added to culture (μg/ml.)	Result
NR*	—	—	Excellent growth–yellow culture
NR-SS†	—	—	Excellent growth–yellow culture
NR	6	—	20 h lag period–yellow culture
NR-SS	6	—	Excellent growth–yellow culture
NR	—	0 2	10 h lag–good growth–white culture
NR-SS	—	0·2	No growth in 54 h
NR	6	0·2	No growth in 54 h
NR-SS	6	0·2	No growth in 54 h

* Refers to artificially mixed pure strains of yellow, lysozyme-sensitive cells and white, lysozyme-resistant cells equilibrated through 5 sub-cultures at 30° C All reported yellow cultures are sensitive to lysozyme. All white cultures are resistant to lysozyme. All cultures were identical morphologically after Gram stain.

† Refers to equilibrated strains above trained on increasing levels of streptomycin sulphate added to the culture to a final level of 6 mg per cent followed by 3 sub-cultures at this level at 30° C.

of resistance in pigmented cells on agar medium may well occur by a biochemical effect on the cytoplasm. We have not been able to reproduce the latter phenomenon in liquid culture with pure, sensitive strains (Table 1), although the existence of coloured resistant mutants (light yellow, red, peach, and pink) of *M. lysodeikticus* has been shown and these strains have been isolated[12]. Stechschulte has shown by indirect selection by replica plating that development of lysozyme resistance on agar media was due to spontaneous mutation[12].

The effect of streptomycin sulphate on the growth of the normal and resistant strains of *M. lysodeikticus* was studied. Both the rate and extent of growth is much more severely affected by the antibiotic in the case of the white, resistant strain. It is likely that the white, resistant mutant could be quantitatively removed from the culture by the use of streptomycin in amounts (10–60 μg/ml.) that would permit considerable survival of the sensitive strain.

This observation was extended to an examination of the effects of streptomycin sulphate on the development of lysozyme resistance in the artificially equilibrated, normal yellow and resistant white strains of *M. lysodeikticus* (Table 3). This shows that streptomycin sulphate caused a long lag period in the growth of the culture not previously trained on streptomycin (formation of streptomycin resistance). This level of streptomycin virtually abolishes the white, resistant mutant. When a low level of lysozyme is added to the culture the resistant cells are rapidly obtained after a brief lag in cultures that were not subjected to streptomycin. The streptomycin-trained cells could not produce the white, resistant cells in 54 h of growth, indicating that the resistant mutant had been destroyed and that the action of lysozyme is one of selection. It is clear that when both streptomycin and lysozyme are added to the culture of trained (to streptomycin) or untrained cells that outgrowth of the white, resistant form fails to occur within 54 h. This indicates that the antibiotic interferes with selection of the mutant by lysozyme either through pretreatment or *de novo*.

In view of the findings presented here, we are re-studying the question of whether the chemical composition of cell walls obtained from white, resistant mutants compared with the yellow, sensitive organism will yield telling chemical information with regard to lysozyme action.

This investigation was supported by research grant *G*-15854 from the U.S. National Science Foundation.

INCORPORATION OF 1-O-PHOSPHORYL-2-DIMETHYLAMINOETHANOL AND PHOSPHORYLCHOLINE INTO THE PHOSPHOLIPIDS OF BRAIN AND LIVER DISPERSIONS

By DR. G. B. ANSELL and DR. T. CHOJNACKI*

Department of Experimental Neuropharmacology, Medical School, University of Birmingham

THE enzymatic reactions for the formation of phosphatidylcholine and phosphatidylethanolamine by the transfer of phosphorylcholine and phosphorylethanolamine to a D-1,2-diglyceride have been well established by the work of Kennedy[1]. Evidence for another pathway to phosphatidylcholine, probably involving the stepwise methylation of phosphatidylethanolamine, has been demonstrated by Greenberg *et al.*[2,3] and Artom and Lofland[4]. Small amounts of the intermediate monomethyl- and dimethylaminophospholipids have, indeed, been found in liver tissue[5] (see also Hall and Nyc[6]). Free 2-dimethylaminoethanol has also been observed in animal tissues[7], and since this can be phosphorylated *in vivo* and *in vitro*[8,9] it seemed of considerable interest to see if the phosphorylated ester could be incorporated into a phospholipid.

1-*O*-Phosphoryl-2-dimethylaminoethanol and phosphorylcholine labelled with phosphorus-32 were prepared by methods similar to that of Riley[10] and coupled with cytidine-5′-monophosphate to give the appropriate cytidine diphosphate base by the procedure of Kennedy[11]. The nucleotides had the expected molar ratio of cytidine to phosphorus and yielded phosphorylated base and cytidine-5′-monophosphate in a stoichiometric ratio when hydrolysed with acid.

---

* British Council Scholar. Present address: Institute of Biochemistry and Biophysics, Polish Academy of Sciences, Warsaw.

Dispersions of rat cerebral cortex and liver were prepared in potassium chloride–sodium fluoride as described by Dawson[12] and the equivalent of 100 mg of tissue incubated in the medium indicated in Table 1. After incubation the total lipids were extracted and washed by the method of Folch *et al.*[13].

Table 1. INCORPORATION OF THE RADIOACTIVITY OF CMP-^{32}PC AND CMP-^{32}PD INTO THE LIPIDS OF BRAIN CORTEX AND LIVER DISPERSIONS

Exp. No.	Tissue	Total lipid P extracted (μg)	Per cent incorporation from CMP-^{32}PC	Per cent incorporation from CMP-^{32}PD
1	Brain	125	10·6	—
		125	—	16 5
2	,,	100	8·3	—
		105	—	13·3
3	,,	80	10·5	—
		128	—	16·5
4	Liver	83	10 0	—
		80	—	19·5

Each incubation contained the equivalent of 100 mg of tissue in a medium containing: 0 053 M NaCl, 0·019 M KCl, 0·0118 M KH_2PO_4, 0·0136 M $MgCl_2$, 0·0155 M NaF, 0·025 M $NaHCO_3$, 0·049 M pyruvate, 0·054 M fumarate, $3·2 \times 10^{-5}$ M cytochrome *c*, 0·001 M adenylic acid, 7×10^{-5} M CMP-^{32}PC (367×10^3 c./100 sec/μmole) or 7×10^{-5} M CMP-^{32}PD (213×10^3 c./100 sec/μmole).

Gassed with 95 per cent O_2–5 per cent CO_2. Incubation period 1 h at 37°.

In Table 1 it can be seen that, for both brain and liver dispersions, 13–19 per cent of the radioactivity of the cytidine diphosphate 2-dimethylaminoethanol (CMP-^{32}PD) was incorporated into tissue lipids, an amount corresponding to about 0·32 μmoles of phosphorylated base/g fresh weight/h. The incorporation of the radioactivity of the cytidine diphosphate choline (CMP-^{32}PC) was somewhat lower, possibly because of dilution of the added nucleotide with endogenous material. When the free [^{32}P] phosphate esters were incubated with the dispersions the incorporation of radioactivity into lipids was only about 0·1 per cent of the material added.

Chromatography, on a column of aluminium oxide, of the lipids extracted after incubation with the two different nucleotides gave the result indicated in Fig. 1. Incubation with CMP-^{32}PC yielded a radioactive lipid quantitatively eluted with chloroform/methanol (1:1 v/v) behaving, as expected, like phosphatidylcholine[14]. With CMP-^{32}PD as substrate, the presence of 4–6 per cent water in the chloroform/methanol (1:1 v/v) was required to elute the radioactive lipid obtained. Changing the eluant to ethanol/chloroform/water (5:2:2 v/v/v)[15] brought off non-radioactive phospholipid which was a mixture of ethanolamine and inositol-containing lipids. The behaviour on an alumina column of the lipid obtained on incubation of tissue with CMP-^{32}PD was that expected of a phosphatidyl-2-dimethylaminoethanol. In further experiments an amount of this lipid material containing 2 μg phosphorus and 1,860 counts/100 sec was mixed with an amount of synthetic distearoylphosphatidyl-2-dimethylaminoethanol ≡ 20 μg phosphorus (kindly supplied by Prof. E. Baer). After adsorption on alumina (Fig. 2) all the radioactivity and added phospholipid were eluted almost coincidentally with methanol–chloroform–water; the slight difference might be due to the saturated fatty acids in the synthetic material.

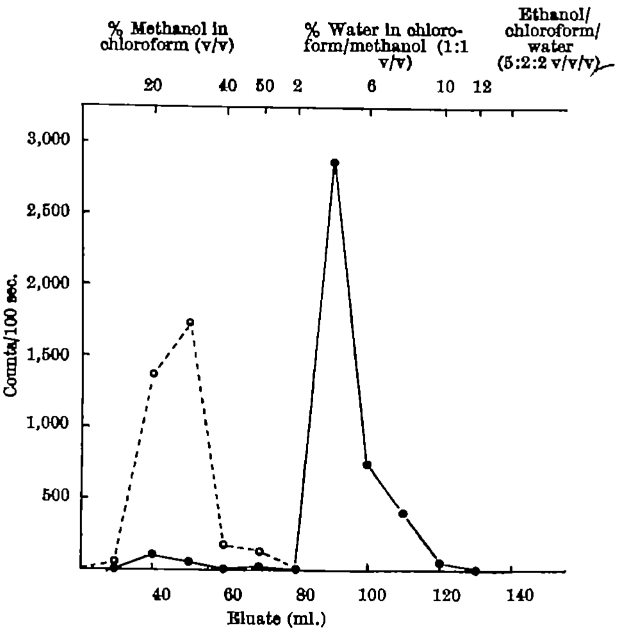

Fig. 1. Chromatography on alumina of the lipids obtained after the separate incubation of brain tissue with the radioactive nucleotides (Table 1, Exp. 1). An amount of lipid ≡ 60 μg phosphorus was applied to a 1-g column (0 6 × 15 cm) and the elution carried out in a step-wise fashion. Broken line, incubation with CMP-^{32}PC; full line, incubation with CMP-^{32}PD

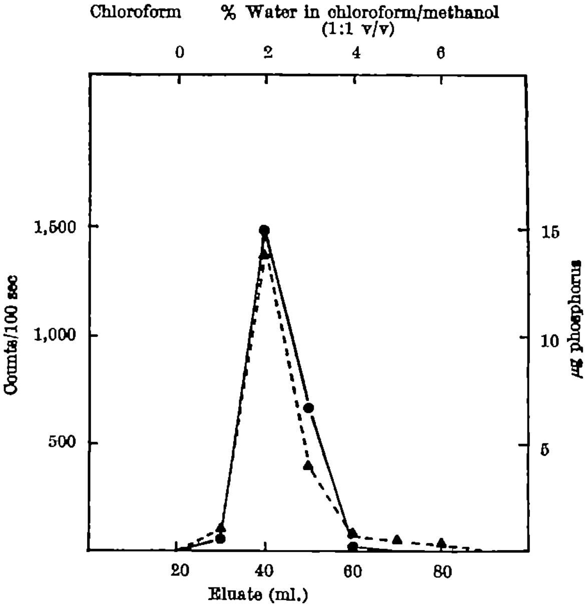

Fig. 2. Chromatography on alumina of synthetic distearoyl phosphatidyl-2-dimethylaminoethanol with the radioactive lipid obtained after incubation of brain tissue with CMP-^{32}PD. The radioactive fraction (2 μg phosphorus and 1,860 c./100 sec), obtained in an experiment similar to that shown in Fig. 1, was mixed with synthetic lipid (20 μg phosphorus), re-adsorbed on a column (0·5 g and 0·6 × 7 cm) and eluted as indicated. Full line, μgP; broken line, counts/100 sec

Paper chromatography of the total lipid extract on the silicic acid paper in the chloroform/methanol (4:1 v/v) solvent of Lea, Rhodes and Stoll[16] or the di-isobutylketone/acetic acid/water (40:20:3 v/v/v) solvent of Marinetti[17] gave only one radioactive spot which behaved similarly to the synthetic lipid. 'Thin layer' chromatograms run on plates of 'Silica gel *G*' (Merck) by Mr. J. Chamberlain of the Department of Anatomy gave similar results. When the radioactive fraction obtained from an alumina column (Fig. 2) was freed from cerebrosides with 'Florisil' and run in these chromatographic systems with increasing amounts of the synthetic lipid, the results were again consistent with the conclusion that incubation of CMP-^{32}PD with a dispersion of brain or liver leads to the formation of radioactive phosphatidyl-2-dimethylaminoethanol.

These findings strongly suggest that phosphatidyl-2-dimethylaminoethanol can be formed in tissues by a pathway analogous to that described for lecithin by Kennedy. It may have some bearing on the observation of Artom[9] and Bremer and Greenberg[3] that, although such a dimethylaminophospholipid could be methylated in the presence of liver microsomes to yield lecithin, methylation of the ethanolamine-containing lipids was not observed.

ROD RECEPTOR POTENTIAL FROM THE RETINA OF THE NIGHT MONKEY

By Dr. KENNETH T. BROWN and Dr. KOSUKE WATANABE

Department of Physiology, University of California Medical Center, San Francisco, California

METHODS of isolating and identifying receptor potentials in monkey retinæ have been reported[1]. The most general method of isolation is insertion into the eye of a polished steel rod, which is pressed on the retinal vessels where they enter the eye at the optic disk; the retinal circulation may thus be completely clamped, leaving the choroidal circulation intact. This method was first applied in *Cynamolgus* and *Rhesus macaque* monkeys[1], which are diurnal species with a pure cone fovea. Intraretinal microelectrodes were used for recording the local ERG(LERG) from a small retinal area immediately surrounding the electrode. This LERG, like that of the cat, proved to consist of four major components[1–3]. When the retinal circulation was clamped, both the *b*-wave and DC component were completely abolished. These components are from cells of the inner nuclear layer[1,3]. The *c*-wave from the pigment epithelium was not abolished, but in diurnal monkeys the *c*-wave is quite small; thus essentially complete isolation of the fourth component was attained. This component was stably maintained by the choroidal circulation and was identified by rigorous criteria as a receptor potential. The pure cone receptor potential was obtained by recording from the central fovea, while stimulating with small light spots. This pure cone response rises rapidly to a plateau, which is well maintained during long stimuli, and after the stimulus this response decays rapidly to the baseline. The leading edge of the rising cone potential contributes the *a*-wave of the LERG, while the decay of the cone potential contributes the initial phase of the *d*-wave.

Similar isolation of the pure rod receptor potential was next desired. Preliminary investigation of the cat indicated that the time-course of the rod potential is slower than that of cones, particularly in the decay phase[1]. The cat retina is not ideal, however, for this problem; the *b*-wave is not entirely eliminated by clamping the retinal circulation, the *c*-wave is exceptionally large, and cones are present in addition to the rods. Thus the South American night monkey, *Aotus trivirgatus*, a strictly nocturnal species, was investigated.

Experiments were performed on 20 adult animals. Although the body-weight was only 0·5–1·0 kg, the eye diameter was about 18 mm, which was more than adequate for our procedures. Recording methods were basically as described for microelectrode work in the retina of the intact cat eye[4]. Anæsthesia was maintained by intraperitoneal injections of thiopental sodium. A device was used for insertion of three needles into the eye. One needle was used for a tungsten microelectrode, with tip diameter less than 0·5μ, the retinal depth of which was controlled by a hydraulic electrode advancer. A chlorided silver reference electrode was inserted through the second needle into the vitreous humour. The steel rod for clamping the retinal circulation was inserted through the third needle. A light stimulator provided retinal stimuli which were well focused and readily controlled in size and position. Responses were led to a cathode follower and amplified by conventional direct-coupled methods.

Fig. 1 shows responses under normal conditions, and with the retinal circulation clamped, when the electrode was near the retinal side of Bruch's membrane. The normal record shows a positive *a*-wave and negative *b*-wave. When the stimulus terminates there is no *d*-wave, defined as a negative deflexion followed by a positive deflexion. Instead there is only a positive deflexion, as found in the cat, which has been shown due to termination of the negative DC component from the inner nuclear layer[2,3]. There is also a slow positive potential which long outlasts the stimulus, consisting partly of the *c*-wave.

When the retinal circulation was clamped, the *b*-wave was abolished. The positive deflexion after the stimulus was also abolished, indicating elimination of the negative DC component. The remaining response was a summation of the positive receptor

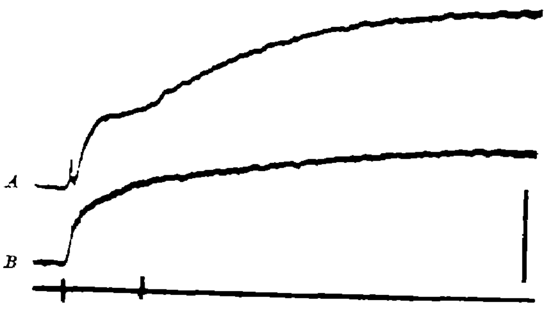

Fig. 1. LERG's recorded by a microelectrode adjacent to the retinal side of Bruch's membrane. Record *A* made under normal conditions, and in *B* the retinal circulation was clamped. The retinal stimulus spot was about 1·5 mm in diameter, focused and centred on the electrode. Stimulus intensity was maximum for the optical system, stimulus duration was 320 msec, and the repetition-rate was one every 30 sec. Positive potentials shown upward, both here and in Fig. 2. following the convention for ERG work. Calibrating voltage signal 1·0 mV

potential and positive *c*-wave. This response shows a rapid initial rise, the latency of which corresponds to that of the *a*-wave in the normal LERG. When the stimulus terminates, however, there is no sign of a rapid negative deflexion; thus the rod potential must decay very slowly. Since the receptor potential and *c*-wave are both positive in polarity with this method of recording, the general form of the rod potential is not entirely clear. This may be shown better by recording the ERG of the entire retina with extra retinal leads. For this type of recording the active electrode was a chlorided silver wire in the vitreous humour, and the reference electrode was a chlorided silver wire in the mouth. It has been shown previously that the same basic components are found in the LERG and ERG[3]. It has also been shown that all components except the *c*-wave invert polarity between the LERG and the ERG[3]. Thus in the ERG the receptor potential is negative, but the *c*-wave is positive.

Fig. 2 shows that the normal ERG consists of a negative *a*-wave, positive *b*-wave, and a negative deflexion after the stimulus. There is also a slow negativity during and following the stimulus. When the retinal circulation was clamped, both the *b*-wave and the negative deflexion after the stimulus were abolished. The remaining potential shows an initial rapid rise of negativity, the leading edge of which corresponds in time to the *a*-wave of the ERG. The negativity throughout this response must be due to the receptor potential, which is sufficiently large to mask the positive *c*-wave. Thus the rapid initial rise is clearly the rising phase of the rod potential. It is also clear that when the stimulus terminates this rod potential has considerable magnitude and decays very slowly. Fig. 2 likewise shows that the rod potential appears to increase in amplitude when the retinal circulation is clamped. This effect is particularly noteworthy in the decay phase, where results of eliminating the *b*-wave and DC component should be minimal, but it is not clear whether clamping the retinal circulation produces a true increase of the rod potential. Evidence for such an effect is much clearer for cones, especially in the fovea, where a tentative interpretation has been offered[1]; these effects are of special interest and require further study.

After the initial rapid rise of the rod potential in Fig. 1, the secondary phase of slow rise is probably due at least partly to the *c*-wave. An even more marked phase of secondary slow rise is evident in Fig. 2, where it is undoubtedly due partly to recording a summation of receptor potentials which have different latencies because of variations in stimulus intensity to different retinal areas[3]. It is not yet known whether a secondary phase of slow rise is a true characteristic of the rod potential. During stimuli of several seconds duration, the amplitude of the rod potential is well maintained; this is true in both intraretinal and extraretinal records. The time-course during long stimuli appears more variable, however, than that of the cone potential. The *c*-wave must be eliminated to determine further details concerning the time-course of the rod potential.

Identification of the rod potential of the night monkey, as a true response of the receptors themselves, has been made by the same criteria used for cones[1]. The only exception is that the night monkey has no fovea, for comparison of receptor potential amplitudes between the fovea and periphery. It is also pertinent, from the point of view of identification, that the same procedure has been used for isolating both rod and cone responses. *S*-potentials of mammalian retinæ, which are single unit slow potentials from the inner nuclear layer[5], have now been found to survive clamping of the retinal circulation in all four species studied. Receptor potentials are readily distinguished from *S*-potentials, however, since the latency of the receptor potential has been shorter than that of the *S*-potential in all cases noted. Apparently the cells which generate *S*-potentials are unique, among cells of the inner nuclear layer, in the ability to maintain their functions from the choroidal circulation. A previously considered possibility, that the *b*-wave and DC component of the LERG might arise from the same cells which generate *S*-potentials[3], must therefore be abandoned.

Svaetichin has concluded, from work in fish and frog, that the receptor potentials of rods and cones are opposite in polarity[4]. This conclusion was based on evidence interpreted to indicate that the *a*-wave was a cone response and the *b*-wave was a rod response. This conclusion must be rejected, at least for the mammalian retina. The *b*-wave does not arise from receptors[1,3]. With any given method of recording, the polarities of rod and cone potentials are the same; also in both cases there is an initial rapid rise, the leading edge of which contributes an *a*-wave. Both types of receptor potential are likewise well maintained during long stimuli. After the stimulus, however, the cone potential decays rapidly while the decay of the rod potential is delayed

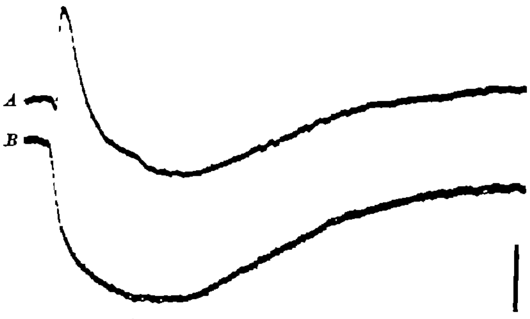

Fig. 2. ERG's recorded between an active electrode in the vitreous humour and a reference electrode in the mouth. Record *A*, normal conditions; record *B*, retinal circulation clamped. Stimulus was a retinal spot about 4·0 mm in diameter, of maximum intensity for the optical system, 320 msec in duration, and repeated once every 30 sec. Calibrating voltage signal 0·3 mV.

and very slow. It may therefore be noted that the mammalian retina is another example of a sensory system containing both fast and slow receptors. In this case the fast receptors are the cones, while the slow receptors are the rods, and the distinction is clearest in terms of the decay rates. Similar principles may be expected in retinæ of lower vertebrates, and some recent observations suggest they pertain in fish[7].

The rapidly rising phase of the rod receptor potential inverts polarity within the retina during electrode withdrawal. Maximum amplitude of this rapidly rising phase, of positive polarity, is found near the distal tips of the receptors. During electrode withdrawal this response declines to zero, becomes negative, and maximum amplitude of the negative response is found near the proximal receptor terminals. Similar findings have been reported for the cone potential[1]. The time-courses of the positive and negative potentials, at different retinal levels, appear to be identical; this is true in both rod and cone cases. These findings provide the key for a working hypothesis concerning the electrical activity of rods and cones. Assuming that the receptor potential is due to a depolarization, which seems required by general principles of receptor action, these findings indicate that the depolarization is initiated at the presynaptic membrane of the receptor-bipolar synapse. The positive potential of identical latency, recorded from near the distal tip, may be explained as resulting from the electric field which this depolarization produces along the receptor axis. Depolarization of the presynaptic membrane may be assumed to be associated with release of a transmitter from the synaptic vesicles which have been described at the receptor-bipolar synapse[8]. Hence this depolarization is probably the electrical end-product of receptor activity. The minimum latency of the receptor potential, as determined to date, is about 1·7 msec. This is too long for a response which directly reflects photochemical isomerization, and indicates an intervening process. The mode of conduction from the outer segment to the proximal receptor terminal must therefore be considered. Evidence for impulse activity in mammalian visual receptors has been sought, under a variety of theoretically favourable conditions, but no sign of impulses produced by any portion of the receptor has ever been obtained. The possibility of a depolarization which is electrotonically conducted in the orthodromic direction also seems definitely excluded by the findings reported here. Thus neither of the known modes of conduction, involving the outer membrane of the cell, appears to apply in the case of retinal receptors. Serious consideration must therefore be given to the possibility that conduction from the outer segment to the proximal terminal is by some type of activity in intracellular fibrils oriented along the receptor axis. Such fibrils have been described in monkey rods and cones by Cohen[9], who also finds them in mouse rods and speculates concerning a conductive function[10]. The conduction time in these fibrils may account for the latency of the receptor potential.

In the night monkey slender 'rudimentary' cones have been found scattered among the rods[11]. Walls considers that this retina evolved from a diurnal type, and that these receptors are in a transitional stage of evolution from cones to rods[11]. Since no rapid decay phase can be detected in the isolated receptor potential of the night monkey, its receptor potential must be due entirely to rod activity. Thus the 'rudimentary' cones may be responding with the rod type of potential, although retaining some histological characteristics of cones. On the other hand, typical cone responses may occur in receptors which are too sparsely scattered to give a detectable contribution to the massed receptor potential. In either case the night monkey appears to be an excellent animal for the study of pure rod activity by means of the isolated but massed receptor potential. Whether scattered functional cones are present must be determined by other methods.

It has also been found that the pure rod and pure cone forms of receptor potential are the extremes between which many combinations may be obtained. In a response from a mixed population of receptors, the relative contributions of cones and rods should be indicated by the relative amplitudes of the rapid and slow decay phases of the receptor potential. The cat retina is dominated by rods, but also contains cones[12]. The cat's receptor potential is predominantly like that of the night monkey, but after the stimulus a small phase of rapid decay has now been detected. Although small in amplitude it has proved entirely reliable and undoubtedly represents decay of the cone potential in this animal. In diurnal monkeys the relative contributions of cones and rods to the response may be varied readily by comparing foveal with peripheral responses, and by varying the stimulus spot size while recording from the fovea These methods of altering the proportions of responding cones and rods have produced the predicted effects on relative amplitudes of the fast and slow decay phases of the receptor potential. The described form of rod potential has therefore been detected in all four species studied, and the described form of cone potential has been found in all of these except the night monkey. This makes it very likely that the reported differences in decay rate, of rod and cone potentials, represent fundamental and quite general differences between the receptor potentials of rods and cones. It is also evident that relative amplitudes of the rapid and slow decay phases, in the isolated receptor potential, provide a method for study of relative cone and rod activity.

The major qualitative differences between rod and cone ERG's occur in that portion of the response following termination of the stimulus. These differences may now be understood from the decay rates of rod and cone potentials. In typical cone ERG's, after the stimulus there is a rapid positive deflexion preceding a negative deflexion (the *d*-wave)[13]. This *d*-wave is found in the retinæ of diurnal monkeys, where it has been shown due to rapid decay of the receptor potential, followed by decay of the DC component from the inner nuclear layer[1]. In Fig. 2 the initial positive deflexion does not occur; this absence of the *d*-wave is typical of rod ERG's (ref. 13), and is undoubtedly because there is no rapidly decaying phase of the rod potential. On the other hand, the long-lasting negativity following the stimulus, as noted in Fig. 2, appears to be found only in rod ERG's. This is clearly due to the prolonged decay phase of the rod potential.

The problem of how off-responses are generated, in neurones of the second order and higher levels, may also prove related to the decay rates of receptor potentials. In the night monkey the dominant response of ganglion cells, evoked by large stimuli, is an on-response. Off-responses have been observed in the light-adapted state, but these are rare by comparison with the cat. These rare off-responses may be mediated by scattered functional cones, and future study of this problem is required.

The different decay rates of rod and cone potentials are probably the basis for certain functional differences between rods and cones which have long been known from psychophysical studies. The rapid decay of the cone response is theoretically advantageous for following flickering light stimuli. It is probably the physiological basis of the well-known fact that the fusion frequency of cones is higher than that of rods, which means that cones have a superior ability to resolve stimuli in time. Considering the fact of physiological nystagmus, this superior time resolution of cones may also confer some degree of superiority for spatial resolution. On the other hand, the very slow recovery of the rod potential must contribute to the greater susceptibility of rods to light adaptation, as determined by the elevation of threshold for a stimulus delivered shortly after terminating the adapting light.

Since some of the functional differences between rods and cones appear to be determined by the decay rates of rod and cone potentials, the form of the receptor potential suggests itself as a criterion for determining whether receptors are functionally rods or cones. In certain cases such a criterion may be crucial. For example, duplicity of function has recently been demonstrated in the retina of the nocturnal gecko[14]. This animal shows no Purkinje shift; also the receptors appear to be a single histological type, and are believed to be rods which have evolved from cones[14]. The ERG of this animal shows a well-developed *d*-wave, however, and the functional duplicity includes a higher fusion frequency in the photopic state[14]. Interpretation of these facts, in view of the decay rates of rod and cone potentials, suggests that functional differences may occur among receptors which show no differences in structure or contained photopigments.

This work was supported by grant No. *B*-1903 from the National Institute of Neurological Diseases and Blindness, U.S. Public Health Service.

INDEPENDENCE OF WHOLE BLOOD AND HÆMOGLOBIN SOLUTION OXYGEN DISSOCIATION CURVES FROM HÆMOGLOBIN TYPE

By J. J. P. SCHRUEFER*, C. J. HELLER, DR. F. C. BATTAGLIA and DR. A. E. HELLEGERS†

Department of Gynecology and Obstetrics and the Department of Pediatrics, Johns Hopkins University and Hospital, Baltimore, Maryland

IN the transfer of oxygen across the placenta of the human being and of a variety of animal species an important role has been ascribed to the differences in the oxygen affinity of fœtal and maternal blood. The higher affinity of fœtal blood for oxygen has been considered an advantage in the transfer of oxygen from the maternal to the fœtal circulating blood streams across a barrier, the placenta.

It is commonly assumed that the differences in the physiological characteristics of two different populations of red cells are adequately accounted for by finding differences in the amino-acid sequence of the two hæmoglobins within the cells. In point of fact, this assumption has not been restricted to discussions of adult and fœtal hæmoglobin types alone. In spite of the general acceptance of this assumption evidence has accumulated that does not warrant unquestioned acceptance of such an explanation for the difference in the positions of maternal and fœtal whole blood oxygen dissociation curves.

This evidence can be summarized as follows:

(1) Oxygen dissociation curves of solutions of hæmoglobin obtained from cord blood and from normal adults showed no difference between the oxygen affinities of such solutions[1].

(2) In one report, superimposable oxygen dissociation curves were found for fœtal bloods in which the relative amounts of hæmoglobin F-A varied from 1 : 1 to 4 : 1, providing such curves were constructed at identical *p*H. The proportions of fœtal to adult hæmoglobin were measured in the same blood samples with which the dissociation curves were determined[2].

Results are reported here on the oxygen dissociation curves of hæmoglobin solutions prepared from bloods containing hæmoglobins AA, AF and SS at various *p*H values. They confirm and extend the findings described in sub-heading (1).

It may be argued that in the course of the preparation of hæmoglobin solutions from whole blood the different hæmoglobin types are so altered as to cause elimination of the differences in their oxygen affinities. For this reason we are reporting the oxygen dissociation curve of whole blood obtained from an adult with 69 per cent fœtal and 31 per cent adult hæmoglobin showing this curve to be markedly different from that of cord blood with the same proportion of the two hæmoglobins, and in fact identical with that of normal adults whose bloods contain 100 per cent hæmoglobin A. This patient is the propositus R. M. in a report previously published from this hospital[3] and the details of her medical history can be found in that report.

The adult and fœtal blood used for these investigations was obtained from patients delivered on the obstetrical service of the Johns Hopkins Hospital. Sickle-cell whole blood and blood from the patient R. M. were obtained through courtesy of the Hæma-

---

tology Clinic of this Hospital. Construction of oxygen dissociation curves was performed by the technique previously described by Hellegers *et al.*[4]. Hæmoglobin solutions were obtained from whole blood as follows: the blood was centrifuged for 30 min at 3,300 r.p.m. in centrifuge cups previously chilled on dry ice. The plasma was removed and the cells washed 5 or 6 times with an approximately 4-fold volume of cold 0·9 per cent saline. The final packed red cells were then frozen for 30 min on dry ice and allowed to thaw at room temperature. The disrupted cell stroma was centrifuged at 4,500 r.p.m. for 10 min and the supernatant hæmoglobin solution filtered in the cold through activated charcoal (6–14 mesh) previously wet with cold 0·9 per cent saline. The approximate hæmoglobin concentration in the resultant solution was determined either by use of a hand protein refractometer (Hitachi) or colorimetrically. The solutions were then diluted accordingly with physiological saline to a final concentration of 4·4 g per cent.

The hæmoglobin solutions were buffered at pH's of 6·9 and 7·4 with 0·1 M phosphate buffer and at pH 7·90 with *tris*(hydroxymethyl) amino-methane (THAM) buffer. Curves at pH 7·40 were constructed alternatively with phosphate or THAM buffer. The use of either buffer produced identical dissociation curves, even in the one case buffered by a THAM–hydrochloric acid mixture at a 1·1 M concentration. The final hæmoglobin solution–buffer mixture was at a concentration of 4 g per cent.

Blood gas analyses were performed by the technique of Van Slyke and Neill[5], gas analyses by the method of P. F. Scholander[6] and pH measurements on the Beckman model *G*, pH meter. The sickle whole blood values obtained were corrected to 38° C by means of Rosenthal's factor[7]. The pH measurements for the hæmoglobin solution dissociation curves and for the whole blood dissociation curve of the adult R. M. were carried out on a radiometer pH meter, model *pHM 4C*, at a temperature of 38° C.

Tables 1, 2 and 3 contain the P_{O_2}, percentage saturation, and pH of each point of the dissociation curve for adult, cord, and sickle hæmoglobin solutions.

By means of the least-square method, a regression analysis was carried out on these results to obtain the oxygen tensions required to half-saturate the three different hæmoglobin solutions at pH 6·9, 7·4 and 7·9 respectively.

The standard deviations from the regression for the data of hæmoglobin solutions AA, FA and SS were 0·035, 0·034 and 0·033 respectively.

In Table 4 the oxygen tensions required to half-saturate the respective hæmoglobins at the various pH's are given.

It will be noted that the different hæmoglobin solutions have identical oxygen affinities at the three stated pH values. In addition, since these identical affinities hold true at all pH's, the Bohr effects of the three hæmoglobin solutions must be identical within these pH limits.

In Table 5 are given the P_{O_2}, percentage saturation, and pH of an eight-point oxygen dissociation curve constructed with the blood of the adult patient with 69 per cent persistent hæmoglobin F. In the fourth column of the same table the P_{O_2} given denotes that (obtained from the nomogram of Hellegers and Schruefer[8]), which would produce the same percentage saturation at the same pH, if the blood of the patient had contained only AA hæmoglobin. The P_{O_2} given in column 5 denotes that which would have been required to produce the same saturation at the same pH, similarly obtained, if the blood sample were of umbilical cord origin.

It is thus obvious that the oxygen dissociation curve of the particular patient's blood corresponds

Table 4. P_{O_2}/MM MERCURY REQUIRED TO HALF-SATURATE HÆMOGLOBIN SOLUTIONS AA, FA AND SS AT pH 6·90, 7·40 AND 7·90

	pH 38° C 6·90	7·40	7·90
Adult	24·15	14·69	8·95
Cord	23·55	14·29	8·67

*From nomogram

within the limits of experimental error with that obtained in normal adults, and is significantly different from that obtained with blood of fœtal origin.

In a previous report from this laboratory[9] we have shown that the oxygen dissociation curves constructed with blood from non-pregnant and pregnant patients are identical, providing the curves are constructed at identical pH.

In another report[4] it was shown that any point on the oxygen dissociation curve of whole blood could be obtained by the use of the equation:

$$\log P = K_1 - K_2\,p\mathrm{H} + K_3 \log \frac{S}{100\text{-}S}$$

This equation yields constants K_1, K_2 and K_3 for maternal and fœtal blood respectively. For human maternal blood the three constants are 4·734, 0·45 and 0·351 respectively, and for fœtal blood 5·748, 0·60 and 0·389 respectively. In this equation the constant K_3 describes the slope of the oxygen dissociation curve and is identical with the reciprocal of the constant n in Hill's equation[10]. It is not statistically significantly different for adult and fœtal whole blood.

The constant K_2 reflects the magnitude of the Bohr effect, describing the amount by which the position of oxygen dissociation curves shifts per unit pH change. It is significantly different for adult and fœtal whole blood of humans and also for adult and fœtal blood of goats[4]. Applying the constants in this equation, half saturation of maternal whole blood at a pH of 6·9, 7·4 and 7·9 is produced at a P_{O_2} of 42·6, 26·2 and 15·1 mm. mercury respectively. Comparative P_{O_2}'s calculated for umbilical cord blood would be 40·6, 20·3 and 10·2 respectively.

Numerous other workers have also shown half saturation of maternal and fœtal blood to be produced at P_{O_2}'s of about 26 and 20 mm mercury respectively providing the blood is at pH 7·40[11-14].

It will be seen, therefore, that despite the wide variety of percentages of fœtal and adult hæmoglobin reported to exist in the bloods of fœtuses at birth, the reported oxygen dissociation curves for whole blood of fœtuses are remarkably constant at identical pH's. On a statistical basis it would therefore be unlikely that the percentage of fœtal hæmoglobin contained in the erythrocytes would, by itself, be the sole determinant of the position of the oxygen dissociation curve. Indeed, Allen, Wyman and Smith[1] reported that cord blood and adult blood hæmoglobin solutions showed identical oxygen affinities at pH 7·20. Their points were corrected to this pH on the assumption of a K_2 of 0·60. Thus, even assuming this K_2 to be applicable to hæmoglobin solutions, their results provided no information on the magnitude of the Bohr effect in hæmoglobin solutions. Our data clearly demonstrate that the differences between the affinities of SS, AA and FA hæmoglobin, normally present when these hæmoglobins are in their red cell environment, disappear on their removal from the erythrocytes. In this respect our results therefore confirm those of Allen, Wyman and Smith. The results also show that the difference in the Bohr effect of fœtal and maternal blood disappears when the hæmoglobin is removed from its erythrocyte environment. For the hæmoglobin solutions then constant K_2 does not differ from that applicable to the whole blood of adults, that is, 0·45.

It might be argued that differences between adult and fœtal hæmoglobin should not be equated with differences between other hæmoglobin types, considered pathological, since the presence of fœtal hæmoglobin in cord blood is an invariable natural finding, not seemingly related to a specific genetic mechanism. It was for this reason that we also sought to study hæmoglobin solutions obtained from blood of patients with electrophoretically proved sickle-cell anæmia. This was done in the knowledge that the oxygen dissociation curves of sickle-cell whole blood obtained by the above method are displaced to the right of those of normal adult blood[15], while conflicting data for sickle hæmoglobin solutions exist[16,17]. It will be noted that sickle hæmoglobin solutions have the same oxygen affinity as hæmoglobin solutions AA and FA.

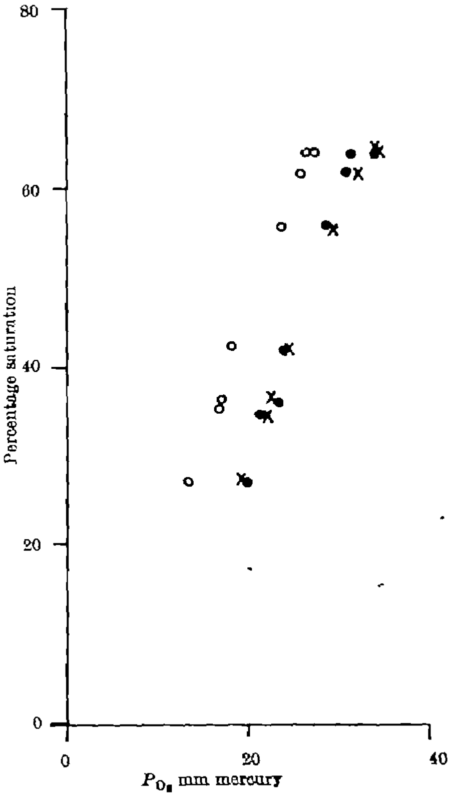

Fig. 1. Oxygen dissociation curve for the blood of patient R. M. (●), normal adult blood (×) and cord blood (○).

Previously it was shown that blood of fœtal origin, containing 69 per cent fœtal hæmoglobin and 31 per cent adult hæmoglobin, gave a whole blood oxygen dissociation curve which was in no way distinguishable from that of fœtal blood with other widely varying proportions of adult and fœtal hæmoglobin. Since a whole blood, obtained from an adult, but containing the same proportion of fœtal to adult hæmoglobin as many cord bloods, yields an oxygen dissociation curve (Fig. 1) identical with that of blood containing 100 per cent adult hæmoglobin—and different from that of cord blood with the identical proportion of the two hæmoglobins—it can only be concluded that the hæmoglobin type, *per se*, is not the determinant of the position of whole blood oxygen dissociation curves.

Some other factor or factors, operating in conjunction with or independently of the hæmoglobin type within the erythrocyte, must therefore be the determinant of the position of whole blood oxygen dissociation curves.

The results from experiments designed to elucidate the role of such other factors will be the subject of a future report.

We thank members of the Division of Hæmatology, Department of Medicine, the Johns Hopkins Hospital, and in particular Dr. C. Lockard Conley, Dr. Samuel Charache, and Dr. David Weatherall, for their co-operation.

TRICHOBEZOARS (HAIR BALLS) IN *RATTUS ASSIMILIS*

By Prof. B. ELIZABETH HORNER

Smith College, Northampton, Massachusetts

THE occurrence of trichobezoars in the stomach is well known in certain of the ungulates and carnivores, and even in man. Among rodents hair balls have been reported from *Sigmodon*[1], *Peromyscus*[2] and *Rattus norvegicus*[3]. This article extends these findings to a native Australian rat, *Rattus assimilis*, and gives additional information regarding the cause and prevention of trichobezoars.

The nucleus of the stock of animals here described was live-trapped in the Hawkesbury River area of coastal New South Wales, Australia, in August of 1955, and flown to the United States. Here the stock was divided into two colonies. One colony was maintained at the University of California at Berkeley and the other at Smith College. The animals bred well in both colonies[4], producing a total of several hundred offspring. Routine autopsies disclosed the presence of stomach hair balls in 16 specimens, 15 of these animals being in the California colony and one in the Smith College colony.

These hair balls are shown in Fig. 1, the missing one having been destroyed by moths. In shape the bezoars varied from semi-spherical and ovoid to broadly curved forms resembling the cavity of the stomach. All were dark brown, hard and compact. That they were composed largely of hairs and hair fragments was determined by microscopic examination of bezoar sections. The hairs formed a felt-like mass of similar texture throughout the interior of the hair ball. The surfaces of all the hair balls were fairly smooth, with the smoothness enhanced in some instances by a thin and incomplete lacquer-like coat. The smallest bezoar measured 13 × 8 mm and had a dry weight of 0·16 g; while the largest measured 26 × 13 mm and weighed 1·21 g. Within the stomach some were pyloric in position, some were cardiac and some extended into both areas, the largest hair ball (Fig. 1) filling almost the entire stomach and forming a virtual stomach replica with regard to size and shape.

With the exception of their diet the animals in the two colonies were kept under essentially the same laboratory conditions in that the rats were maintained almost continuously as mated pairs, with at least one cubic foot of space per pair, and with food, water and nesting material available at all times. The California animals were fed on 'Diet I' (ref. 5) with a small bi-weekly supplement of sunflower seeds and greens or apple. 'Diet I' consists of: 67·5 per cent ground whole wheat, 15·0 per cent technical casein, 7·5 per cent skimmed milk powder, 6·75 per cent hydrogenated vegetable oil, 1·5 per cent calcium carbonate, 0·75 per cent iodized sodium chloride, and 1·0 per cent fish oil (vitamin A–D concentrate). The animals in the Smith College colony were kept on a more varied diet. Carrots, apples, pears, grapes, oranges or greens were supplied daily. Wheat germ was provided at bi-weekly intervals, as also were one or more of the following: whole milk, oatmeal, liver meal, sunflower seeds and hemp seeds. 'Purina' laboratory chow was always available but was seldom eaten when other foods were present.

In both colonies the animals reproduced well and attained the adult size characteristic of field-caught animals[6]. The animals in which the hair balls were

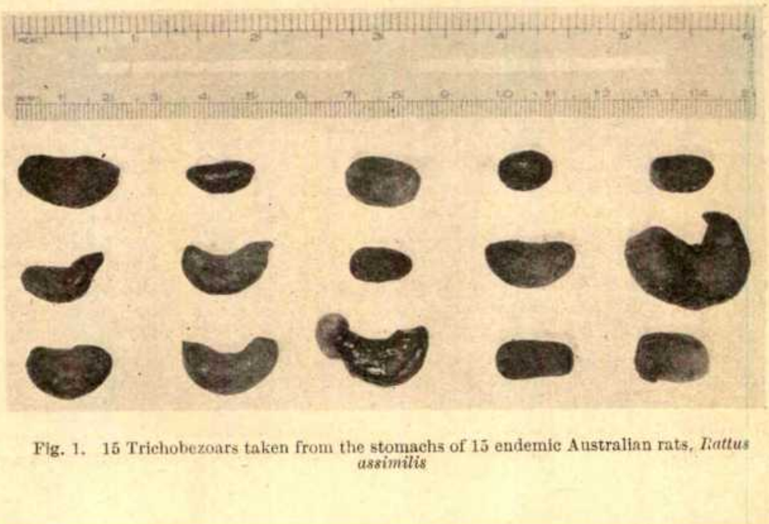

Fig. 1. 15 Trichobezoars taken from the stomachs of 15 endemic Australian rats, *Rattus assimilis*

found showed no convincing malnutrition nor prolonged debility prior to death, and all equalled or exceeded the average life span of 16 months for *Rattus assimilis* born in captivity[6]. Although the hair balls may have been a contributing factor to death, they never filled the entire stomach, even the largest hair ball permitting a small amount of material to pass through the stomach, and there was no evidence of ulceration.

Among the differences in the diets of the two colonies were at least two which may be related to the greater incidence of trichobezoars in the California colony: the somewhat greater percentage of fat and the considerably smaller percentage of roughage in the California diet. Mitchell *et al.*[3], working with white rats (*Rattus norvegicus*), found that animals receiving paste foods of high fat content (25–27 per cent) show a high frequency (90 per cent) of hair ball formation, while those receiving food of low fat content in either a dry diet or a liquid diet show no hair balls. These authors postulate that the paste-like fatty food left in the cage all day accumulates hair on its sticky surface and that when eaten it coats and cements together the additional hairs ingested as a result of grooming activities. 'Diet I', a moist powder fed to the *Rattus assimilis* of the California colony, although lower in fat content than the paste food described by Mitchell *et al.*[3], was higher than their non-bezoar-forming diets. 'Diet I' contained also a higher percentage of fat than did the diet supplied to the Smith College *Rattus assimilis*, only one of which exhibited hair ball formation. Although it is possible that 'Diet I' was conducive to hair ball formation in the California rats, the smaller percentage of roughage in their diet seems far more important.

The work of Howell *et al.*[1] on *Sigmodon hispidus* gives convincing evidence that supplemental rations of cellulose inhibit trichobezoar formation, and the present study supports this finding. The Smith College colony, with a very high percentage of cellulose in its diet, produced only one hair ball; while the comparable colony at California, with a relatively low amount of cellulose in its diet, produced 15 hair balls. Furthermore, once the supplement to 'Diet I' of the California animals was altered, as it eventually was, to include daily, rather than bi-weekly, rations of greens and fruits, no hair balls were encountered in animals raised on the additionally supplemented diet.

Another factor contributing to hair ball formation in the *Rattus assimilis* studied was the extensive grooming associated with sexual behaviour. This aspect of behaviour was well developed in the caged animals, often to the extent that one or both animals of a pair showed conspicuously epilated patches, commonly in the mid-shoulder region[6]. *Rattus norvegicus* reared in the same laboratory under identical dietary conditions groomed one another to a considerably less extent, and there was no evidence of denudation (Taylor, J. M., *in litt.*).

In summary, it appears that in the case of the laboratory-maintained *Rattus assimilis* here described, hair ball formation is facilitated by the ingestion of large amounts of hair in association with a relatively low intake of cellulose-containing food materials. A relatively high fat content in the diet may also be important. To what extent these factors are operative under natural conditions is unknown. However, since *Sigmodon*, *Rattus* and *Peromyscus* are predominantly herbivorous, one would suspect that the large amounts of cellulose normally ingested would amply compensate for the effects of grooming and occasional meals of high fat content. Certainly of the many *Rattus rattus* and *Rattus assimilis*, as well as a wide variety of other rodents examined in the field, no hair balls have been encountered by me; and to the best of my knowledge no such trichobezoars have been reported by other authors.

INTRA-SUB-SPECIFIC VARIATION IN RETINAL STRUCTURE IN *SEBASTES MARINUS MENTELLA*

By DR. I. HANYU and PROF. M. A. ALI

Département de Biologie, Université de Montréal

DURING the course of an investigation of retinal structure in fish found in moderately deep waters of the western North Atlantic, a marked variation in the size of the retinal cones was observed in *Sebastes marinus mentella*. This difference is evidently related to the depths from which the specimens were collected.

One specimen of *Sebastes marinus mentella* was collected from a depth of 150 fathoms near the coast of Labrador (54° 42′ N.; 53° 50′ W.) on August 7, 1960. Another specimen belonging to the same sub-species was taken from an adjacent area (54° 47′ N.; 53° 32′ W.) on the same day, but from a much deeper habitat (300 fathoms).

The following description of the retinæ from both the specimens pertains to the region near the central part of the fundus. This is being done in order to minimize the descriptive part of this communication. It is felt that although there are differences among the various regions of the retina, as has been reported in the case of many teleosts[1-3], the basic consideration to be presented here is adequately supported by the evidence from this region alone.

The general features of the retinæ of the two specimens are given in Table 1. Figs. 1*B* and 1*C* show the photomicrographs of cross-sections of these retinæ. As can be seen, they differ in several respects. A striking difference between the two is demonstrated by the visual cell layer. Here, the cone ellipsoids of the specimen from the less-deep waters are much larger, being twice as long and twice as wide as those of the fish from the deeper environment. Their volume is therefore some eight times greater. Accordingly, the outer segments of these two differ considerably in their diameters although they are approximately the same in length. The entire visual cell layer (composed of the cones and the rods) is thinner in the retinæ of the fish from 150 fathoms. This indicates that the rods of the fish from the deeper waters are longer than the rods of the fish from 150 fathoms. It is also observed that the internal nuclear layer and the internal plexiform layer from the retinæ of the fish from 150 fathoms are thicker in general than those of the fish from 300 fathoms. This can be related to the differences between the visual cell layers.

In the vertebrate retina, cones are the photopic elements while the rods are scotopic. In the case of the teleostean retina this is adequately demonstrated by the pronounced photomechanical changes undergone by these receptors[4]. It has also been shown that the cones are larger in size and greater in numbers in a diurnal and surface water species than in a nocturnal one[2]. On the other hand, they are smaller and fewer while the rods are longer, more slender and numerous in the nocturnal and deep sea forms[5]. These differences are interspecific and are related to differences in habitats. This is the first time that intra-specific variation of a similar nature related to habitats has been observed.

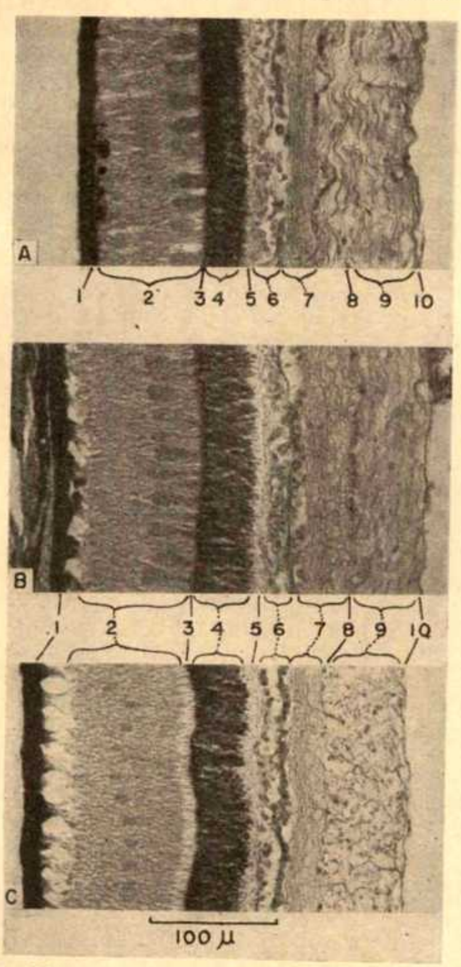

Fig. 1. Photomicrographs of transverse sections of retinæ. *A*, *Sebastes marinus marinus* from 150 fathoms; *B*, *S. m. mentella* from 150 fathoms; *C*, *S. m. mentella* from 300 fathoms. 1, Retinal epithelial pigment; 2, visual cell layer; 3, external limiting membrane; 4, external nuclear layer; 5, external plexiform layer; 6, internal nuclear layer; 7, internal plexiform layer; 8, ganglion cell layer; 9, nerve fibre layer; 10, internal limiting membrane

Table 1. DETAILS OF RETINAL STRUCTURE OF THE TWO SPECIMENS FROM TWO DEPTHS

	S. m. mentella from 150 fathoms	*S. m. mentella* from 300 fathoms
Retina	300–325µ	300–315µ
Retinal epithelial pigment layer	15–18µ. Contracted proximally. Some pigment in the epithelial cell processes	Similar to that of other specimen
Visual cell layer	88–100µ. Cones bulky, about 5–7 per 100µ length of the section. Most are twin. Cone ellipsoids 25µ long, 12–15µ in diameter. Outer segments 10–13µ high. Rods, small and numerous	105–108µ. Tiny cones; almost all twins; cone ellipsoid 10–13µ long, 7–8µ in diameter. Outer segments 10–13µ high. About 5–6µ cones per 100µ length of the section. Rods, small and numerous
External nuclear layer	45–50µ. Well packed. 8–10 rows	45–50µ. Well packed. 8–10 rows
External plexiform layer	5–8µ	5–8µ
Internal nuclear layer	32–38µ. Poorly developed. Much less packed than E.N.L. Nuclei increasing in size from outer to inner region	30–32µ. In other respects similar to that of other specimen
Internal plexiform layer	40–43µ	35–40µ
Ganglion cell layer	1 row of scattered cells. About 5–7 cells per 100µ length of the section	Similar to that of other specimen
Nerve fibre layer	63–75µ	63–75µ

Although some information is available regarding the habits and ecology of this bottom dwelling species[6,7], it is not sufficient to explain the cause or causes for this intra-sub-specific variation. However, it may be suggested that this variation might be caused by the separation of populations. This separation may be expected to bring about, over a period of time, certain differences such as those enumerated here. On the other hand, there may not be genetically fixed populations and the retina of a larva, regardless of the depth of its origin, may develop in such a way as to function best in the conditions obtaining in the depth at which it establishes itself. It is possible that the cones of those fish which establish themselves in deep waters do not attain the proportions attained by those in less deep waters. Similarly, the rods of the deeper water fishes may become longer than those of the others. In either case, we consider light to be the principal factor responsible for bringing about this variation.

It is of interest to compare the features enumerated here with those of *Sebastes marinus marinus*, a very closely related form, taken from the same locality and depth as the *S. m. mentella* from 150 fathoms. The retina of the former (Fig. 1*A*) appears considerably similar to that of the latter (Fig. 1*B*). However, its cones are a little larger, the rods shorter and the external nuclear layer narrower. The last feature indicates fewer rods. As Templeman and Sandeman[8] observe, "While both are deep water forms, *Sebastes marinus mentella* . . . occurs in deeper water than *Sebastes marinus marinus*. *Mentella*-type redfish are to be found in small numbers deeper than 400 fathoms (730 m) and they often have their centre of abundance between 200 and 300 fathoms (370–550 m), whereas the *marinus*-type usually does not occur in abundance deeper than about 160–180 fathoms (290–330 m)". The variation in retinal features enumerated here is supported by this information.

Another feature which warrants mention is the position of the cones in relation to the contracted state of the retinal epithelial pigment. The latter being in a contracted state would seem to indicate that the retina is in a dark-adapted state. However, the position of the cones, at least in the retinæ of the fish from 150 fathoms, indicates a light-adapted state. The cones of the fish from the deeper habitat appear to be in a semi-adapted state. However, since the function of the retinal epithelial pigment in the teleostean eye is to control the amount of light impinging on the cones[9] it may be argued that in these deep water forms which live in areas where light is scarce the ability of the retinal epithelial pigment to undergo photomechanical changes may be considerably reduced or even lost altogether. Or, it may be that since the ventral part of the retina is directly exposed to light, at least in the fish from 150 fathoms, it may retain somewhat the ability to undergo photomechanical changes. This is supported by the fact that, in the fish from 150 fathoms, the ventral part of the retinal epithelial pigment is expanded, at least sufficiently to cover the rod outer segments.

This investigation was supported by the National Research Council of Canada through an operating grant (*A*-996) to one of us (M. A. A.) and by the Paulhus Foundation in the form of a post-doctoral fellowship awarded to the other (I. H.). We thank Dr. W. Templeman, director, Fisheries Research Board of Canada, Biological Station, St. John's, Newfoundland, for collecting the specimens and to our chief, Dr. E. Pagé, for the criticism of this manuscript.

REACTIVATION OF POXVIRUSES: FATE OF REACTIVABLE VIRUS WITHIN THE CELL

By DR. W. K. JOKLIK*

Department of Microbiology, John Curtin School of Medical Research, Australian National University, Canberra

MILD treatment with heat or urea converts poxvirus particles into a state in which they can only multiply in cells which are in addition infected with infectious poxvirus[1-4]. Poxvirus behaving in this manner is said to be in the reactivable state[2]. More extensive denaturation or interference with the structure of the reactivable particle leads to loss of reactivability[5].

The progeny of reactivable virus is indistinguishable in all respects from the original virus[6]. Reactivable virus therefore contains intact DNA. This DNA, like that of infectious particles, is not accessible to the action of DNase[5].

The reactivation phenomenon extends throughout the whole poxvirus group. Any poxvirus strain can be converted to the reactivable state, and is then capable of being reactivated by any other poxvirus. However, no virus outside this group is capable of acting as the reactivating virus[6]. Infection with reactivable virus and reactivating virus need not be simultaneous: reactivable virus can infect as much as 72 h before the other, and is then still capable of being reactivated. Similarly reactivating virus may precede by at least 12 h[2].

Mild denaturation of the virus particle therefore does not prevent the uptake into, or at least the adsorption to, the cell. Yet the particles are altered sufficiently to render viral DNA incapable of exercising its executive function within the cell. It is clear that the presence of reactivating virus in some way restores this ability, so that the genome of reactivable virus can then replicate and organize the synthesis of such proteins as are required for mature virus to be produced.

The lesion in the reactivable particle appears to be the denaturation of an essential protein. This hypothesis was strengthened when it was found that it was not necessary for reactivating virus to contain functionally intact DNA, but rather functionally active protein: virus completely inactivated with nitrogen mustard (which binds preferentially to DNA) is capable of reactivating virus completely inactivated by heat or urea, and the genotype of the progeny is then exclusively that of the latter[7].

The present model to explain the phenomenon of poxvirus reactivation is then that mild treatment with either heat or urea denatures a protein which is essential if the viral genome is to express itself within the host cell. This protein can be carried into the cell by any other poxvirus particle, which may itself be damaged in the genome. It follows that this protein is a common component of all poxviruses, or that all poxviruses contain a protein component with the same biological function.

Nothing is known concerning the interaction between reactivable poxvirus particles and the cell. Information on this point could well be valuable in defining at the molecular level the component inactivated during denaturation.

We have recently developed a method[8] for preparing very highly purified poxvirus labelled with phosphorus-32 or leucine-1-^{14}C and have used such virus preparations to determine the fate within the infected cell of viral DNA, phospholipid and protein[9]. It has thus become possible to test directly how the fate of reactivable virus differs from that of infectious virus. It is clear, however, that this direct biochemical approach would only be successful if a sizeable proportion of virus particles in a given preparation are in fact in the reactivable state. Early estimates of this proportion gave values of about 1 in 1,000 (1 per cent of the infectious particle titre)[5]. Recently, however, we have obtained evidence that this is a gross underestimate and that in fact well over one-tenth, and possibly more than one-half, of the particles may be in the reactivable state after suitable treatment (Joklik, W. K., to be published). The contemplated approach is thus feasible.

The fate of viral DNA, phospholipid and protein was thus determined for infectious and reactivable radioactively labelled rabbitpox virus. The procedure was to infect cells for 15 min, remove unadsorbed virus and then sample the infected cells at intervals. The following results were obtained:

* Present address: Department of Cell Biology, Albert Einstein College of Medicine, New York 61, N.Y.

(*a*) *DNA*. When rabbitpox virus labelled with phosphorus-32 (20 atoms of phosphorus-32 per particle, 70 per cent in DNA and most of the rest in phospholipid) was used as the infecting agent, its DNA gradually became accessible to the action of DNase (tested after breaking open the cells). As shown in Fig. 1, the fraction of DNA accessible to DNase rose from a background-level of about 3 per cent to some 50–60 per cent 6 h after infection. Certain features of this phenomenon have already been discussed[8], and a full report will follow elsewhere. For the present purpose, the significant feature is that within a period of some 6 h 50–60 per cent of the infecting virus particles are altered in such a way that their DNA becomes accessible to the action of DNase, that is, they are uncoated. When reactivable virus, similarly labelled, is subjected to the same experiment, it is found that none of the DNA is uncoated.

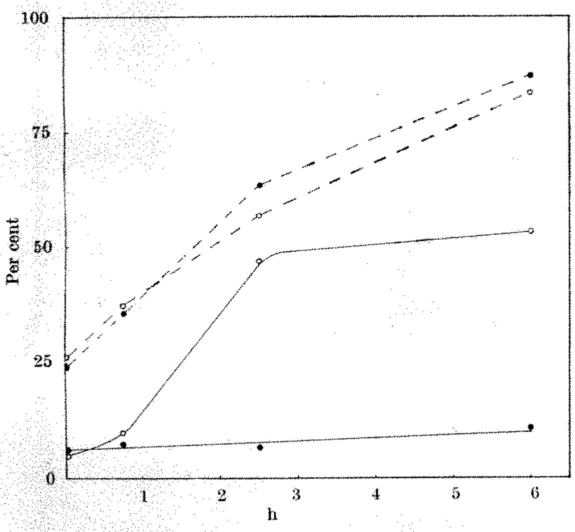

Fig. 1. Breakdown of infectious and reactivable rabbitpox virus, labelled with phosphorus-32, following adsorption to HeLa cells. Open circles: infectious virus; filled circles; reactivable virus; solid curves; viral DNA accessible to DNase; broken curves; viral phospholipid rendered acid-soluble. Multiplicity of infectious virus, 25; multiplicity of reactivable virus, 45. Reactivable virus was prepared by heating infectious virus suspended in sodium chloride (0·15 M)–sodium citrate (0·015 M) at 55° for 2 h. No detectable infectious virus was then present

(*b*) *Phospholipid*. In similar experiments some 50 per cent of the phospholipid of infectious virus is rendered acid-soluble within the first 2 h after infection, and up to 85 per cent within 6 h (Fig. 1). This is also the case when labelled reactivable virus is the infecting agent; the degradation of the phospholipid of both infectious and reactivable virus proceeds *pari passu*.

(*c*) *Protein*. Information concerning the fate of the protein moiety of reactivable virus has been obtained by the use of virus labelled with leucine-1-^{14}C (Table 1). At the end of the infection period virtually all label is associated with the cells and is, after breaking them open, depositable in centrifugal fields sufficient to deposit more than 95 per cent of intact virus (20,000*g* for 20 min). Label is gradually lost from this fraction and appears as (*a*) cell-associated label no longer depositable under these conditions, but still acid-insoluble ('sub-units'); (*b*) similar material in the medium; and (*c*) acid-soluble material in the medium. When reactivable virus is used in this way the overall pattern is virtually the same.

Table 1. FATE OF ADSORBED RABBITPOX VIRUS LABELLED WITH LEUCINE-1-^{14}C*

Time (h)	Cell-associated Depositable fraction	 Sub-unit fraction	Medium Sub-unit fraction	 Acid-soluble fraction
0	96	2·5	< 1	< 1
1	88	7	4	< 1
2	75	12	7	5
3	65	15	11	8
4	57	17	16	10
5	50	18	19	11

* The multiplicity was 66. The figures represent the percentage of label recovered in the various fractions.

The conclusions are: the DNA of reactivable virus is not uncoated. However, the phospholipid (the major part of which is probably located near the surface of the particle) of reactivable virus is treated in the normal manner, as is at least a large part of the protein. It should, however, be stated that the experimental technique was not sensitive enough to detect the possible presence of a minor protein fraction, more or less closely associated with the DNA, and perhaps structurally a component of the nucleoid, which is not broken down when reactivable virus is the infecting agent.

The failure of the DNA of the reactivable particle to express itself is thus most probably due to the fact that it is not uncoated. It would therefore be expected that reactivation would result in the DNA of the reactivable particle being uncoated. This has been tested. Cells were infected with unlabelled infectious rabbitpox virus for 5 h and then superinfected with reactivable virus labelled with phosphorus-32. A significant portion of the DNA was rendered accessible to DNase (Fig. 2). This fraction did not reach the 50–60 per cent attained in the case of infectious virus: the reason for this is most probably that only a certain proportion of virus particles were in the reactivable state, the rest probably being denatured beyond the point at which they could still be reactivated. However that may be, it is clear that an appreciable fraction of reactivable particles is

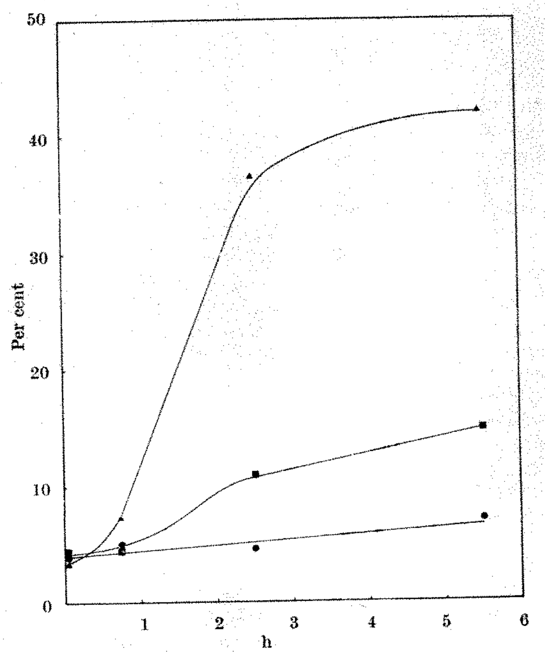

Fig. 2. Partial uncoating of reactivable virus in pre-infected cells. Triangles, infectious virus, multiplicity, 28; circles, reactivable virus, multiplicity 35, no pre-infection; squares, reactivable virus, multiplicity 31, in cells pre-infected with unlabelled rabbitpox virus for 5 h. The ordinate is expressed as the percentage of viral DNA accessible to DNase

uncoated in cells simultaneously infected with infectious poxvirus.

The manner in which the reactivating virus causes the DNA of reactivable virus particles to be uncoated is at present under investigation.

RELATIONSHIP BETWEEN SPLENOMEGALY, RUNTING AND TOLERANCE TO SKIN HOMOGRAFTS IN CHICKEN

By J. B. SOLOMON

Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, Fulham Road, London, S.W.3

WHEN immunologically competent chicken cells are transferred to the chick embryo an early symptom of their immunological reaction to the host antigens is an increase in spleen weight[1]. This splenomegaly consists of proliferation of both donor and host cells[2] but the extent of splenomegaly under given conditions is proportional to the dose of donor cells[3,4]. It was noted that in the experiments of Terasaki[3,5] that the doses of whole blood which were required to produce splenomegaly in the chick embryo were similar to those required to produce tolerance to skin homografts from the blood donor. This suggested a causal relationship between splenomegaly and the degree of tolerance to subsequent adult skin homografts. As the tolerant state requires the persistence of antigen[6] (in this case, the donor cells) the survival of skin homografts may provide information about the life-span of the donor cells which were initially active in producing splenomegaly.

Citrated whole blood (0·1 ml.) or dilutions of blood (from 1/80–1/2) from adult Rhode Island Red (RIR) hens was injected intravenously into White Leghorn (WL) or Light Sussex (LS) embryos at 15 days of incubation. The embryos were injected at this age, first to avoid the tremendous mortality resulting from injection at an earlier age, and secondly, 15 days is near the optimum time for the production of splenomegaly because the embryo is still apparently immunologically unreactive at this age[7–9]. Five days after injection half the embryos (about 20) in each group were killed and their spleens weighed. The remainder were hatched and then skin-grafted 2–3 days later. The technique of Cannon and Longmire[10] for skin grafting was followed except that adhesive dressings were used to protect the grafts during the first week. Tolerance was measured by the percentage of homografts surviving at 30 days after grafting[11]. In embryos injected with Ringer solution no homografts survived at 30 days. In the experiments described 282 embryos were used for spleen weight assay and 142 chickens were used in the analysis of homograft survival.

Szenberg and Warner[12] have suggested that the large lymphocyte is responsible for these transplantation reactions in chicken. The dose range in these experiments of 0·1/80–0·1/2 ml. whole blood corresponds to an average dose-range of about 5×10^2 to 2×10^4 large lymphocytes. This narrow dose-range includes the threshold dose for splenomegaly and the induction of tolerance and the dose which produces severe runting with 60–80 per cent mortality.

When 15-day-old LS embryos were injected with adult whole blood (0·1/60–0·1/2 ml.) there was a close correlation between the log of the host mean spleen weight five days after injection and the subsequent tolerance to skin homografts in each group (Fig. 1). When WL embryos were similarly injected the degree of tolerance was directly related to the mean spleen weight only for doses from 0·1/80 to 0·1/10 ml. RIR blood. This relationship broke down completely with larger doses of RIR blood. When 0·1/7 ml. RIR blood was injected the spleen assay on half the group gave a mean weight of 90 mg; three weeks after hatching there was an 83 per cent reduction in mean body-weight and only 26 per cent of the birds were tolerant at 30 days after hatching. Larger doses of blood (0·1/2 ml.) produced greater mean spleen weights (140–190 mg), more severe runting (60–70 per cent reduction of body-weight) and virtually complete breakdown of tolerance to skin homografts (Fig. 2, Table 1). At these doses of blood from 0·1/10 to 0·1/2 ml. there is considerable mortality both just before and after hatching (Table 1). However, such deaths do not apparently result in selection as the highest mortality occurred in two experiments one with the greatest and the other with the least degree of tolerance (Table 1). It appears

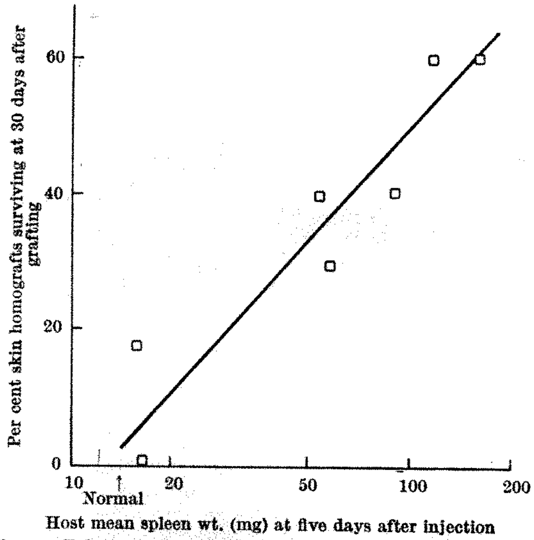

Fig. 1. Tolerance proportional to mean spleen-weight of Light Sussex recipients after injection of adult blood

Table 1. INVERSE RELATIONSHIP BETWEEN THE DEGREE OF TOLERANCE AND THE SEVERITY OF RUNTING AND SPLENOMEGALY

Dose of RIR blood (vol. (ml.)/ dilution)	Per cent survival from injection to 3 weeks of age	Per cent reduction in body-wt.	Per cent tolerant after 30 days	Mean spleen wt. (mg) 5 days after injection
0·1/10	17	100	66	67
0·1/7	50	83	26	90
0·1/3	18	60	16	193
0·2/5	35	71	0	138
0·1/2	15	64	0	167

that runting is associated with a breakdown of tolerance in WL. In one experiment with LS recipients in which slight runting occurred there was no breakdown of tolerance, but there are, at present, insufficient data from LS recipients to determine whether the degree of runting is inversely proportional to the degree of tolerance. This result with WL is contrary to expectation as larger doses of blood would be expected to provide a larger antigenic dose and therefore a greater degree of tolerance to skin homografts would be anticipated. The degree of tolerance in WL chicken at all dose-levels appears to be associated with the percentage incidence of host spleen weights in the 25–100 mg range at 5 days after injection, despite the occurrence of runting in some of these experiments (Fig. 3). The proportion of host spleen weights within the 25–100 mg range at five days after injection determines the subsequent tolerance to skin homografts. As splenomegaly is proportional to the blood dose and at high dose-levels (> 0·1/10 ml.), when runting (and breakdown of tolerance) occurs, there are few small spleens at five days after injection. If there is a low incidence (below 50 per cent) of spleen-weights within this range at five days after injection of the donor blood then only slight tolerance to subsequent skin grafts can be predicted (about 20 per cent grafts surviving at 30 days). On the other hand, the greatest tolerance (66 per cent homografts surviving at 30 days) was obtained in WL when 85 per cent of the sample of host spleen-weights at five days after injection were within 25–100 mg. (Fig. 3).

Blood doses of 0·1/80–0·1/10 ml. do not produce runting in WL, and within this range the degree of initial splenomegaly is proportional to the subsequent extent of tolerance to skin homografts. This relationship appears to hold over a wider dose-range in LS recipients (0·1/60–0·1/2 ml. blood) because there is little runting. However, in WL recipients runting (and mortality) progressively increases with increasing blood doses from 0·1/7 to 0·1/2 ml. and there is also a progressive breakdown of tolerance to skin homografts (Table 1). It therefore appears that at these higher blood doses the donor cells, while producing greater splenomegaly, also attack the organs concerned with growth. In this process the donor cells in the spleen probably suffer an accelerated death so that insufficient donor cells remain in the spleen to maintain the antigenic stimulus necessary for tolerance to continue. This effect may be similar to the 'allergic death' of immunologically competent cells postulated by Gorer and Boyse[13].

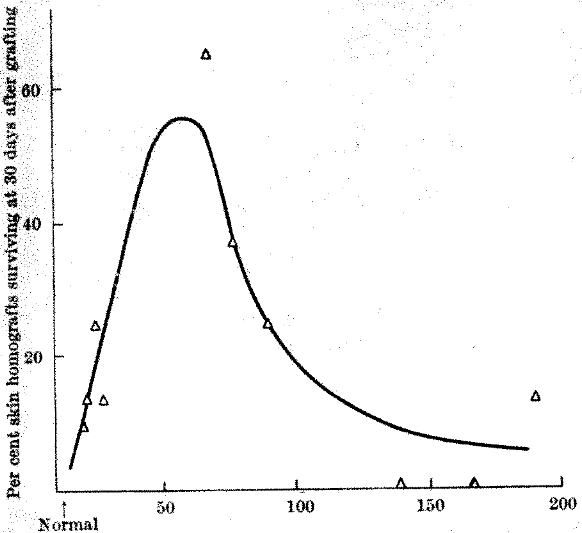

Fig. 2. Tolerance and spleen-weight of White Leghorn recipients after injection of adult blood

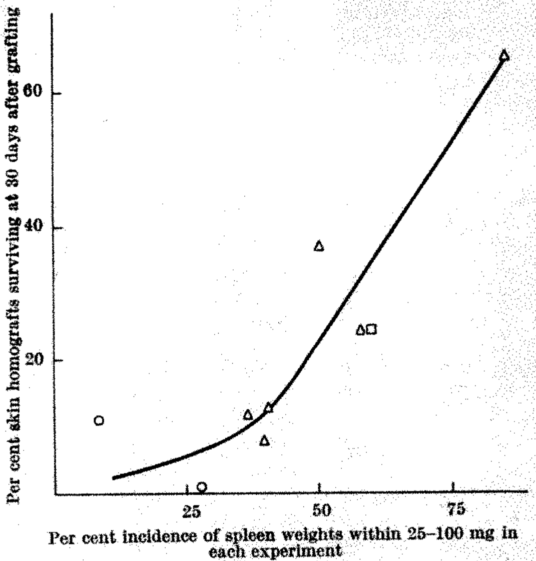

Fig. 3. Tolerance proportional to the incidence of low spleen weights in White Leghorns. △, no reduction; □, 83 per cent reduction ; ○, 60–70 per cent reduction in mean body-weight

Other workers have obtained similar results. Closer examination of Terasaki's results[5] revealed that, whereas 0·1/9 ml. blood produced a relatively high degree of tolerance, 0·1/3 ml. gave much weaker tolerance. Runting has been observed in mice which were not tolerant[14,15], particularly when thymocytes were injected[14]. Rats which had recovered from runt disease were not tolerant when afterwards skin grafted[16]. Trentin and Session[17] found that the degree and duration of tolerance to skin grafts in mice was inversely proportional to the severity of runting.

The close relationship between the dosage of donor cells required to produce tolerance and that required to produce splenomegaly that was inferred from separate experiments in Terasaki's work[3,5] has now been established when LS were used as recipients and when only slight splenomegaly and no runting was produced in WL embryos. Recently, Hasek and Puza[18] showed that some proliferation of the inoculate of donor cells is necessary to establish tolerance in ducklings. Billingham and Silvers[19] have suggested that the proliferation of donor cells injected into mouse neonates of a different strain increases the antigenic dose of donor cells by graft against the host reaction and thus produces a high degree of tolerance. In this way only small doses of adult lymphocytes would be necessary to establish large colonies of donor cells in the spleen at the critical time when the host's lymphocytes are appearing in the spleen and are thus able to accept the donor cells as 'self'. Splenomegaly is apparently an essential initial process in the induction of tolerance to skin homografts by adult lymphocytes. Owing to the rapid growth of the spleen immediately after hatching, splenomegaly cannot be detected after about 10 days. However, as the survival of skin homografts suggests, donor cells are known to survive in the spleen of tolerant birds[20].

I thank Prof. Alexander Haddow for his encouragement and Miss Dorothy Hogben for her technical assistance. This work was supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Anna Fuller Fund and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

A RELATIONSHIP BETWEEN SKIN TEMPERATURE AND AMOUNT OF WOOL GROWN ON VARIOUS POSITIONS ON THE NEW ZEALAND ROMNEY MARSH SHEEP

By F. COCKREM

Massey College, Palmerston North, New Zealand

HENDERSON[1], in an investigation of fleece development in Romney Marsh lambs, found gradients in the amount of wool grown on different positions of the body. He suggested that differences in blood supply to these positions might account for the differences in the amount of wool grown on them. Ryder[2] was unable to find evidence that the patterns of the blood vessels in the skin of the sheep could account for the gradients in the amount of wool grown, which were found by Henderson. However, Cockrem and Wickham[3] pointed out that the actual blood supply will depend on factors such as the size of the vessels and their distance from the heart as well as their distribution. These factors were not considered by Ryder and, as Ferguson[4] had demonstrated an effect of blood supply on wool growth, further investigation seemed desirable.

An indirect method of estimating blood supply is by measurement of skin temperature. This measurement will depend on the volume of blood-flow, the deep body temperature, the ambient temperature and the insulation of the skin. However, if a series of temperatures of different positions are measured on the one animal within a short period of time on one day, then those effects other than blood flow will be reasonably constant. In this case, any differences found in temperature can largely be attributed to differences in blood supply.

In the present experiments two groups, each of nine New Zealand Romney Marsh yearling ewes, were used for measurements of skin temperature and wool growth in various positions.

The first group (*A*) averaged 12 months of age and had eight months fleece growth. The second group (*B*) averaged 14 months of age and, for this group, skin temperatures were measured immediately after shearing and again 14 days later when wool growth samples were also taken. The means of these two series of skin temperatures were used for analysis. This second group had had a unilateral cervical sympathectomy at the age of 10 weeks in order to increase the blood flow to the right side of the face (position *B*).

The positions measured for each group are shown in Table 1. Those main fleece positions used were similar to those sampled by Henderson[1]. Skin temperatures were measured with a 'Thermophil' (trademark of Ultrakust, Ltd., West Germany; a direct reading thermistor instrument) and the methods used and their accuracy and interpretation have been described[3,5].

Table 1. MEAN SKIN TEMPERATURES (°F) AND WOOL GROWTH (MG/CM²/14 DAYS) FOR EACH POSITION OF EACH GROUP OF NINE SHEEP

	*A**	*B*	*L*	*K*	*C*	*F*	*H*	*G*
Group *A*								
Wool growth	2·76		—	—	18·8	19·7	—	25·2
Skin temperature	90·2		—	—	95·4	96·2	—	96·6
Group *B*								
Wool growth	2·01	2·69	10·4	12·1	16·2	23·5	22·3	23·7
Skin temperature	86·8	89·7	90·6	90·9	89·2	90·0	90·9	91·3

* Positions *A*, *B*, left and right side of nose; *L*, cheek left side; *K*, ventral, below *C* (belly) — Extremities
C, mid-side; *F*, thigh, posterior to *H*; *G*, upper shoulder; *H*, back dorsal to *C* — Main fleece area left side

For the present experiment two readings were made on each body position, in random order, on each of three days. The sheep were allotted to three groups at random and each group was measured at a different time each day. The effects of the day, time of day and group were allowed for in a simple 3 × 3 Latin square design. The purpose of this design was to minimize effects from diurnal trends in temperatures as it required about 15 min to measure each sheep.

Wool growth was measured by clipping a measured area and the resulting wool was scoured and weighed at a constant humidity and temperature. Wool growth was expressed as mg/cm^2/14 days.

Initial plotting of the data indicated that the relationship of wool growth to skin temperature was curvilinear. Hence the data were analysed as the regressions of $\log_e$ wool-weight on mean skin temperature (°F) from the three days' readings. Groups *A* and *B* were analysed separately. For Group *A* only, the mean of positions *A* and *B* was used. For Group *B* regression coefficients were estimated for the main fleece position (*CFGH*), the extremities (*ABLK*) as well as for all the positions together. All the regression coefficients were estimated as the pooled regression coefficients within sheep, that is, these are the average relationships of the individual sheep in a group.

The results of the analyses are shown in Table 2 and the mean temperature and amount of wool grown (arithmetic scale) for each position are shown in Table 1.

The results in Table 2 indicate that, on average, a significant amount of the variation of wool growth over the body of the individual sheep can be attributed to differences in skin temperature. In so far as skin temperature differences reflect blood supply differences over the body of the individual sheep under the conditions of this experiment, then the gradients of wool growth in part arose from differences in blood supply to the different positions.

The regression coefficients over all positions were very similar for Groups *A* and *B* although the periods over which the wool was grown were very different. The differences between the amount of wool grown at a given skin temperature (Table 1) for Groups *A* and *B* probably reflect differences in deep body temperature resulting from the shearing of the latter group. Group *A* had higher rectal temperatures, which could mean that the higher skin temperatures reflected similar relative blood-flows to that of Group *B*, which had lower rectal and skin temperatures, in that Bligh[6] has shown that there is a reasonable correspondence between rectal and deep body temperatures under uniform conditions (for the calf). If relative blood-flows were similar, then the result suggests that the substrate made available by the blood supply is of greater importance than an actual temperature effect on reactions within the follicle bulb.

Table 2. THE POOLED REGRESSION COEFFICIENTS WITHIN SHEEP OF LOG_e WOOL WEIGHT (MG/CM^2/14 DAYS) ON MEAN SKIN TEMPERATURE (°F) OF VARIOUS POSITIONS

Group	Positions	Regression coefficient	Standard error	d.f.	Per cent sums of square due to regression
A	*ABCFG*	+0·29	0·025	26	84
B	*CFGH*	+0·13	0·036	26	33
	ABLK	+0·34	0·063	26	53
	All	+0·30	0·040	62	48

For Group *B* the regression coefficient is lower for the main fleece areas than for the extremities. In addition, it can be seen from Table 1 that a particular skin temperature on the extremities leads to less wool growth than on the main fleece area. In particular, sympathectomy, while markedly increasing skin temperature, did not increase wool growth proportionally. These results considered together suggest that an inherent factor associated with the skin or with its follicle population is also involved in the determination of the amount of wool grown on a particular position.

Overall these results suggest that about 50 per cent of the variation in wool growth over the body of the New Zealand Romney Marsh sheep is the result of variation in substrate available to the follicle. The remainder of the variation is likely to be the result of inherent differences in the follicle populations themselves. That is, in follicle size, density of follicles or in the ratio of secondary to primary follicles.

I thank Mr. J. C. Newhook, who performed the sympathectomies, and Messrs. B. Thatcher, D. G. F. Orwin and D. A. Evans, who assisted with the measurements, and the New Zealand Wool Board for finance.

INSTABILITY OF PULSE ACTIVITY IN A NET WITH THRESHOLD

By PROFS. W. R. ASHBY, H. Von FOERSTER and C. C. WALKER

Electrical Engineering Research Laboratory, University of Illinois, Urbana

FOR half a century, threshold has been known to be important in the activities of nerve cell and synapse, but little is known of the general properties that so ubiquitous a feature must impose on the system's behaviour in the large. Beurle[1], in his investigations of the transmission of waves of activity over a conducting net, noticed that a net with threshold would have a marked tendency to be unstable, but his assumptions were complex, and the origin of the instability is not easily identified. Here we propose to show that an instability, similar to his, can readily be traced from a simpler origin.

The instability we refer to would soon show itself if one made an artificial nerve-net with unspecified, rich connectivity, with threshold at the junctions, and then attempted, as the net transmitted pulses, to keep the net's activity at a moderate value. The net would tend to run either down to a state of total inactivity, from which one could scarcely get it to stir, or up to a state of total activity, which would lessen only at the onset of exhaustion or some other extraneous factor.

The origin of this instability can be traced as follows. Suppose the whole net is composed of a large number of interconnected units which handle information represented everywhere by identical pulses of some physical activity. Each of these units has n identifiable inputs. A unit 'fires' in time interval t to $(t + \Delta t)$—emits a pulse of duration $\delta t \ll \Delta t$—if and only if at least θ of the inputs have received a pulse within the preceding time interval $(t - \Delta t)$ to t. The following argument is applicable both to nets with essentially one-directional information flow (from a network-input to a network-output) and also to nets with rich internal cross-connexions (provided none of the feed-back loops is short).

We shall describe the activity on the inputs of a particular unit by first associating a probability p with the occurrence of a pulse in a particular time interval Δt on a specified input. We define:

$$p = \lim_{t \to \infty} \left(\frac{N}{L} \cdot \frac{\Delta t}{t} \right) \qquad (1)$$

where N is the number of pulses counted in time t which have passed through a sufficiently large bundle of L randomly selected inputs. From this we have the probability p_i that precisely i inputs on a particular unit receive a pulse in the time interval Δt:

$$p_i = \binom{n}{i} p^i (1 - p)^{n - i} \qquad (2)$$

Consequently, the probability p that at least θ inputs are active in this time interval, that is, that the unit fires, is given by the cumulative binomial probability function[2]:

$$p' = \sum_{i=\theta}^{n} \binom{n}{i} p^i (1 - p)^{n - i} = \frac{n!}{(\theta - 1)!\,(n - \theta)!} \int_0^p x^{\theta - 1} (1 - x)^{n - \theta}\, \mathrm{d}x \qquad (3)$$

The instability arises when we allow the resulting pulse frequency $f' = p'/\Delta t$ to be itself the generator of a further frequency $f'' = p''/\Delta t$, and so on. Under these conditions we ask what will happen in the net as time goes on. Equilibrium is reached if the pulse activity on each input equals the pulse activity on each output, that is, if:

$$p' = p = p^* \qquad (4)$$

The equilibrium will be stable at the activity p^* if an increased activity at the input leads to a lesser activity at the output; that is, if:

$$\left| \left(\frac{\partial p'}{\partial p} \right)_{p^*} \right| < 1 \qquad (5)$$

However, differentiating expression (3) once and twice with respect to p shows that for all cases where solutions for (4) with $0 < p^* < 1$, and $n > 1$, exist, $p'(p)$ starts at the origin with zero slope and exhibits a single inflexion at the point:

$$p = \frac{\theta - 1}{n - 1} \qquad (6)$$

Thus the stability criterion (5) is satisfied only where $p^* = 0$ or $p^* = 1$.

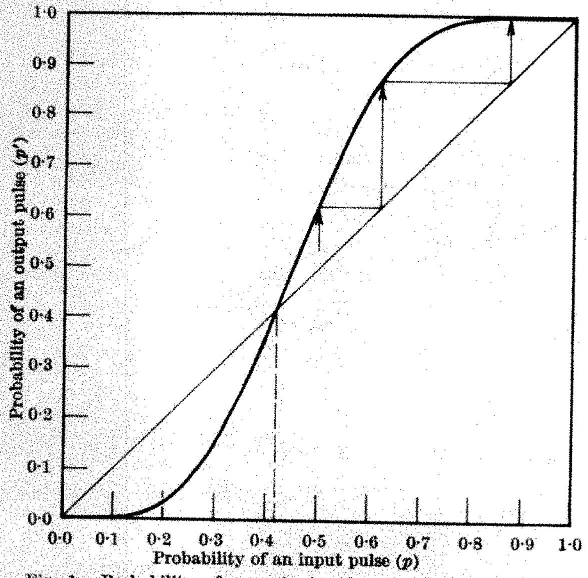

Fig. 1. Probability of an output pulse, as a function of the probability of an input pulse (threshold 5, 10 inputs)

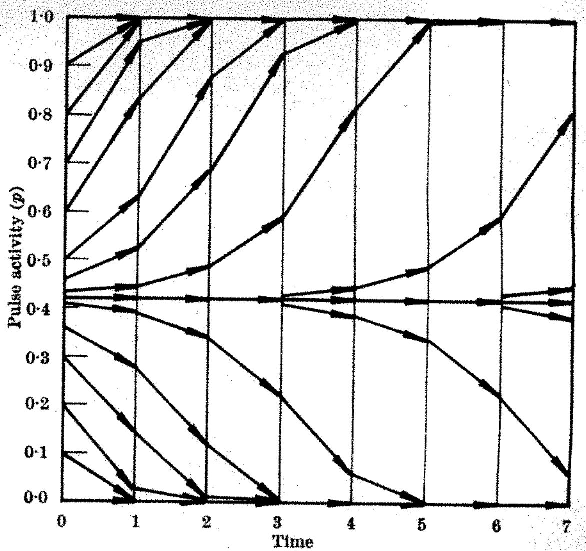

Fig. 2. How pulse activity changes with time, from various initial activities (threshold 5, 10 inputs)

Fig. 1 illustrates the situation in a simple case where p' is plotted against p for $n = 10$ and $\theta = 5$, using (3). The equilibria p^* are the three points where $p'(p)$ intersects $p' = p$: 0, 0·42 and 1. Those at 0 and 1 are stable; that at 0·42 is unstable in the sense that the slightest perturbation from this value is followed by the system going to one of its extreme values. (In Fig. 1 the change in p from an initial value of 0·5 is indicated by the stairway.) Fig. 2 shows how various perturbations provoke a runaway to an extreme value.

It seems, therefore, that the more richly organized regions of the brain offer us something of a paradox. They use threshold intensively, but usually transmit impulses at some moderate frequency, seldom passing in physiological conditions into total inactivity or maximal excitation. Evidently there must exist factors or mechanisms for stability which do not rely on fixed threshold alone.

One such mechanism that offers itself readily is the non-linear dependency of threshold on output that is sometimes referred to as 'inhibition by depletion'. If this dependency is of the form:

$$\theta = \mu^{-1/\lambda} (p')^m$$

with:

$$1 < \frac{1}{\lambda} \leqslant m$$

(λ, μ and m being constants), stability criterion (5) is fulfilled if:

$$\left(\frac{\partial p'}{\partial p} \right)_{p^*} \leqslant \lambda < 1$$

RADIO ASTRONOMY

Measurement of Magnetic Fields in Interstellar Clouds

PREVIOUS attempts[1-3] with the 250-ft. radio telescope at Jodrell Bank to measure magnetic fields in interstellar clouds in the Milky Way by observing the Zeeman splitting of their neutral hydrogen line profiles failed to show any clear evidence for fields greater than 10^{-5} gauss. The observations of February 1962[3] indicated a possible Zeeman splitting in some clouds, but with the sensitivity of the receiver and the band-width of 5 kc/s used in that work the result could not be verified in a significant manner. This communication describes a new and successful attempt to measure the magnetic field.

These observations were made in September and October, 1962, with the 250-ft. telescope using a parametric amplifier (*AIL* Type 1930) and a radio frequency switch incorporating varactor diodes as switching elements which gave an overall system noise temperature of about 200° K. Crystal filters having a square bandpass response 3 kc/s wide at the 6 db. points were used for giving the frequency resolution required. Six of these channels simultaneously monitored adjacent 3 kc/s bands and were used for measuring both the hydrogen line intensity and the difference between right and left hand circular polarization. Two methods of observation were used. In the first the channels were fixed in frequency, connected to integrators and set alternately on the hydrogen line profile and off the profile. Only narrow absorption features were studied in this way. In the other method the channels were swept in frequency through the line profile, and the output was fed on to punched tape. Two of these channels were monitored on a pen recorder.

The strongest indication of Zeeman splitting was shown by the narrow deep feature of Taurus *A*. The normal line profile is shown as *C* in Fig. 1*a*, where the optical depth τ is plotted as a function of frequency difference from the frequency of the line centre. With the 3 kc/s band-width used in the present work this feature has been shown to be double and has been resolved into two absorbing clouds with profiles given by *A* and *B* in Fig. 1*a*. In Fig. 1*b* the difference between right and left hand polarization is plotted as a percentage of the profile depth observed in one polarization. These results were obtained by the first method (the integration technique) described here. Preliminary analysis of the records using the second method (frequency sweep technique) confirms the form of Fig. 1*b* but the full punched-tape data have not yet been analysed.

The observed Zeeman splitting curve of Fig. 1*b* cannot be interpreted as the result of a uniform field in the two clouds, but it is compatible with a field directed away from the observer of $2 \cdot 5 \times 10^{-5}$ gauss in the cloud giving the profile *B*. The expected Zeeman profile is shown as a dotted line in Fig. 1*b*. The field in the cloud giving the profile *A* appears to be less than 5×10^{-6} gauss. In retrospect it is clear that this Zeeman curve was visible in data from previous observing programmes, but because its shape was not that to be expected from a uniform field through the whole feature it was suspected to be caused by some systematic effect in the equipment.

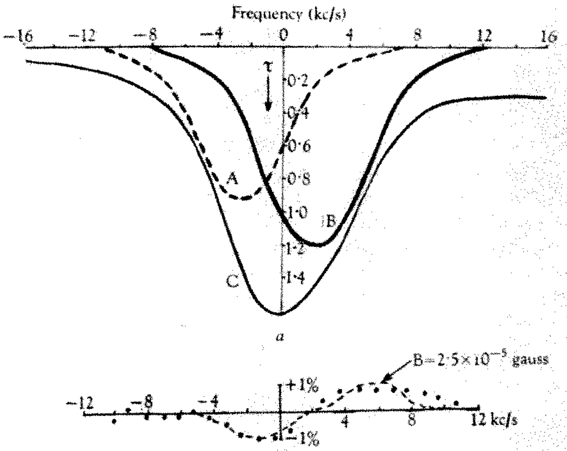

Fig. 1. *a*, The absorption profile (*C*) of the deep narrow feature in the Taurus *A* spectrum, as observed with a 3-kc/s band-width. It is plotted in optical depth (τ) as a function of frequency, and the diagram also shows the profile resolved into two components *A* and *B*
b, The Zeeman profile plotted as right hand minus left hand circular polarization amplitude. The ordinate is expressed as a percentage of the profile depth as it would be observed on one polarization. The dots are the observed points and broken curve is the Zeeman profile expected for a field of $2 \cdot 5 \times 10^{-5}$ gauss directed away from the observer in component *B*

Similar but weaker Zeeman features have been found in the absorption spectra of Cassiopeia *A* and Cygnus *A*. The interpretation of these data and of the emission data awaits the complete analysis of all the 6 channel Zeeman and hydrogen line observations. Nevertheless several important conclusions can be drawn. The absorption and emission profiles seen with the 12 min of arc beam of the 250-ft. radio telescope and with a 3 kc/s square bandpass are much more complex than previously suspected. For example, the narrow feature in the Cygnus *A* spectrum at about + 400 kc/s has three main components. The data already analysed suggest that each component may have a different magnetic field component in the line of sight. The maximum components of the magnetic field seen in the clouds of the Cassiopeia *A* and Cygnus *A* directions are about 5×10^{-6} gauss. In other clouds the field is below the level of detection and is significantly less than 5×10^{-6} gauss. These preliminary results suggest that the general galactic magnetic field is of the order of 5×10^{-6} gauss.

PHYSICS

Growth of Positive Channels in Non-uniform Fields during Impulse Breakdown

In a rod–plane gap subjected to 1/50-µsec impulse voltages (rod positive–plane negative) the breakdown is initiated by a corona discharge at the rod which is then followed by a positive channel crossing the gap. The main discharge of the breakdown occurs after the bridging of the gap by the channel. Investigations concerning this phenomenon are reported by Allibone[1] and recently by other workers[2-9].

This communication concerns an investigation of the positive channel propagation in a plane to sphere gap from 10 to 20 cm in length and is aimed at a physical approach of this phenomenon. The plane is charged negatively from an impulse generator, and the positive channels starting from the earthed electrode (5 mm diameter) were investigated by chopped impulse voltages so they do not reach the high-tension negative electrode. Photographs of the discharge and simultaneous current recordings by means of a double-beam oscillograph are used for investigating the propagation of the channel. The upper beam of the oscillograph is used for recording the whole current variation up to the end of the chopping, while the lower one registers, at a higher sensitivity and at a faster sweep, only a part of the upper current trace. This is done by using, as described here, a model 555 'Tektronix' oscillograph. Figs. 1 and 2 are examples of channel photographs and of the corresponding current recordings. The lower trace of the oscillograms gives the fine structure of that part of the upper record, which appears brighter, this being a special feature of the oscillograph used.

In cases where a better discrimination of the current steps is desired in order to facilitate the correlation of the channel photographs with the detailed oscillogram, a mixed divider consisting of resistances and a small inductance can be connected at the input of the lower beam. This inductance introduces to the voltage recorded by this beam a component proportional to di/dt, so that current variations are reproduced on the oscillogram more pronounced. Obviously this method introduces a considerable distortion in the current trace and can be applied only in those cases where a faithful record of the current is not important.

Well-known investigations on long gaps, of the order of more than 1 m, have shown that leader channels are stepped and that this discontinuity of propagation is influenced by the series resistance of the gap circuit. During the investigation reported here the gap is connected directly to the front capacitor of the impulse generator so that, practically, the voltage across the gap is not changed by drops in voltage in the circuit caused by current variations. In spite of this fact and of the small dimensions of the gap, the form of the channel on Fig. 1, for example, correlated to the corresponding current oscillograms of Fig. 2 justifies the suggestion that the channel propagation is in this case also in a way stepped. It also seems that each step is preceded by a corona discharge paving the way for the next step. This stepped mechanism should rather be attributed to the nature of the breakdown phenomenon in air than to time constants of the circuit. It is hoped that the comparison of a great number of channel photographs with simultaneous current records will provide information for a better approach to the physics of the phenomenon.

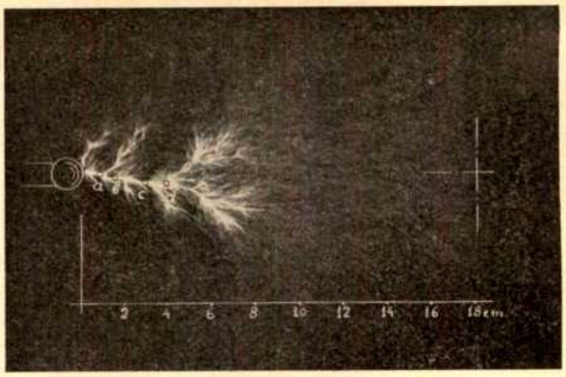

Fig. 1. Photograph of a chopped positive channel. Correlation with the oscillograms of Fig. 2 is reliable up to the branching point *d*

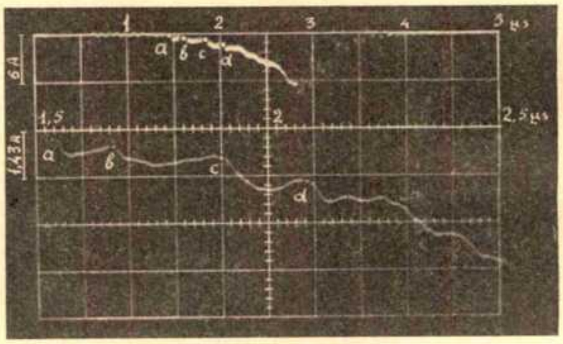

Fig. 2. Oscillograms of the current through the gap. Points *a*, *b*, *c*, *d* correspond to those of Fig. 1

By correlating photographs of the channels to current records obtained so far, the propagation velocity of the channels could be determined as being of the order of 10 cm/µsec, which is in accordance with values found by other methods. Since the channels are very often branched, the correlation is useful in those cases only where branching is restricted to a minimum.

The impulse generator used, of a single 200-kV stage, has a front capacity of 4,140 pF. The gap consists of a plane disk, 30 cm in diameter, directly connected to the output of the generator, and a small sphere, 5 mm in diameter, fixed at one end of a 75-ohm co-axial cable. At the other end of the cable, a 75/7-ohm attenuator is connected to the input terminals of the C.R.O. pre-amplifiers. The chopping device consists of two 25-cm spheres separated by a plane disk to form a three-electrode arrangement. This device is connected in series with a 100-ohm resistor across the front capacitor of the impulse generator and allows interruption of the positive channel development at any point in the gap investigated.

The oscillograph used has a rise time of 12 nsec, two beams with *L*-type pre-amplifiers and two separate time-bases. A special interconnexion of the time-base devices permits use of the upper beam to record the whole variation of a phenomenon, while a pre-selected part of the upper trace can be magnified and registered by the lower beam. The delay-time between the starting moments of the two sweeps can be adjusted at will.

The 75/7-ohm attenuator is designed in such a way that its time constant, estimated to be less than 10^{-8} sec, is so low that practically no distortion of the current form occurs.

The gap is installed in a 90 × 90 × 90 cm^3 box of hardboard, at one side of which an $f/1{\cdot}5$ Leica camera is fixed, allowing the channels to be photographed from a distance of 45 cm.

This investigation is financially supported by the Royal Hellenic Research Foundation and is being continued. I thank Prof. G. M. Petropoulos for his advice.

Hot Resistivity of Tungsten Wires

WHILE a number of more recent papers have dealt with the variation of electrical resistivity of tungsten with temperature, it remains a not uncommon practice to refer to the tables compiled by Langmuir and Jones[1] for estimating the temperature of a heated filament. These tables, in turn, were taken from earlier work by Zwikker, Worthing and others.

In an investigation into the progress of changes to the electrical parameters of tungsten filaments in thermionic devices, which will be published later, it was soon found that the Langmuir values can lead to errors. For example, at the operating temperature of valve heaters (about 1,100° C), errors of the order of 100° C were common. Furthermore, these errors were not consistent from heater to heater so that, in experiments where heater temperatures were critical, many results could be invalidated by undetermined differences.

Apart from the conventional precautions in measuring resistances, the determination of the resistance of tungsten wires imposes the need to maintain a rigidly controlled temperature, and we have found it necessary to use an a.c. bridge with heating currents not exceeding 1 m.amp on fine wires.

Many expressions have been proposed for relating resistivity with temperature. However, most of these are applicable over but limited temperature ranges, and in our experience, for tungsten, the most useful remains the polynomial of the form:

$$R_T = R_0[1 + \alpha T + \beta T^2 + \gamma T^3]$$

For temperatures up to about 100° C, terms above α can be neglected and γ can be neglected below about 1,200° C, for a precision of about 1 per cent. If Jones and Langmuir's values are plotted, they are found to follow not a smooth curve, but a sequence of short lines, indicating perhaps that a number of the values are interpolated estimations. The 'constants' from their results are roughly:

$$\alpha = 4{\cdot}8 \times 10^{-3};\ \beta = 1 \times 10^{-6};\ \gamma = 0{\cdot}5 \times 10^{-9}$$

Examining a large number of samples of wire and wire products from a wide range of sources, we have found the values of these parameters to vary: especially α and β seem sensitive to the influential factors of purity and work hardening and α has been found to lie between 3·9 and $4{\cdot}7 \times 10^{-3}$ and β between 0·5 and $2{\cdot}0 \times 10^{-6}$: γ has averaged near $-0{\cdot}5 \times 10^{-9}$. The room-temperature resistivity, correspondingly, is higher than Langmuir's by about 10 per cent.

This makes it necessary, for really precise work, to determine the characteristics of each sample. But for temperatures up to 1,200° C if a precision close to 1 per cent is adequate, a simplified procedure can be adopted. The resistance at 0° C and 100° C is determined and an average value of $1{\cdot}2 \times 10^{-6}$ is taken for β. From this α can be derived and a good approximation up to about 1,200° C can be obtained. Inclusion of the value of γ above permits extension of this range by several hundreds of degrees. It is usually not difficult to determine R_0 and R_{100} even on a completed device, and if there is reason to believe that the characteristics may vary throughout the experiment, rechecks can be made at appropriate intervals. These serve to track changes in state of the wire—for example, by annealing, or contamination—but also to discriminate between such changes and dimensional alterations.

On no samples of fine wire have α's been found as high as Langmuir's $4{\cdot}8 \times 10^{-3}$: more commonly α has fallen between 4·1 and 4·3, and coils tend to have lower values than straight wire.

This lowering of the temperature coefficient is partly due to the consequences of working. While considerable recovery is effected by relatively low-temperature annealing, progressive changes have been observed to continue up to the highest temperatures studied (2,600° C), so that it is not safe to assume that a sample treated, say, at 1,800° C, has been stabilized.

Purity also plays a part: the deliberate addition of trace impurities made to most commercial wires influences the electrical characteristics[2], but the pick up of trace impurities inevitable in the working of materials from ingot to wire is demonstrated in a progressive fall in α (0–100) from the unworked metal (about $4{\cdot}7 \times 10^{-3}$) to fine wire (about $4{\cdot}4 \times 10^{-3}$ fully annealed). As may be expected, some increase in α is obtained if wire is heavily etched before annealing, illustrating the superficial nature of the contamination.

It is the interplay of these factors which makes imperative the actual measurement of the electrical characteristics of tungsten wire components for critical work, and this applies especially to temperature determinations.

METALLURGY

Aluminium Nitride in a Mild Steel

The presence of aluminium nitride in mild steels de-oxidized with aluminium has been suspected for many years. Various investigators have reported indirect evidence for its presence and several have attempted to identify it.

Hsiao[1] took reflexion diffraction patterns from an etched section of a mild steel, containing 0·035 per cent aluminium, that had been decarburized, nitrided, and homogenized at 675° C *in vacuo*. The analysis of the ring pattern indicated the presence of aluminium nitride and α-iron. Particles were extracted from the steel surface on a 'Formvar' replica, and it was assumed that these were aluminium nitride.

Booker and Norbury[2] used a 1 per cent aluminium steel, nitrided at 640° C, then furnace cooled. They studied extraction replicas by transmission electron diffraction with an *EM*3 electron microscope and were able to correlate their ring pattern directly with the diffracting precipitate, which was identified as aluminium nitride.

Dahl *et al.*[3] in more recent work claimed to have identified aluminium nitride from single crystal patterns but give no details of '*d*' values or lattice constants. Wright and Quarrell[4] have recently published work identifying plate-like and dendritic precipitates in steel castings as aluminium nitride. They attribute the variance in morphology compared with the better-known 'needle-shaped precipitates' to the fact that their dendritic precipitates have been extracted from fracture surfaces. It must also be added that their '*d*' values for these dendrites differ from those in the *A.S.T.M.* index by more than 5 per cent.

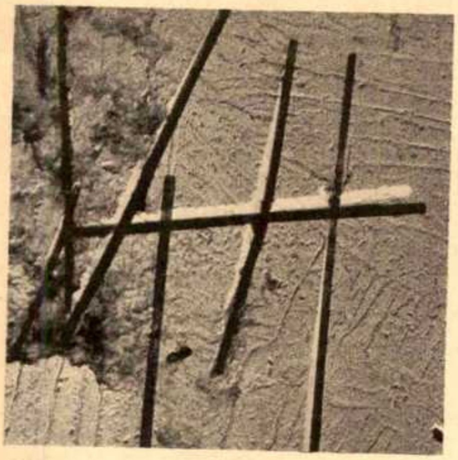

Fig. 1. Carbon extraction replica. (× 10,000)

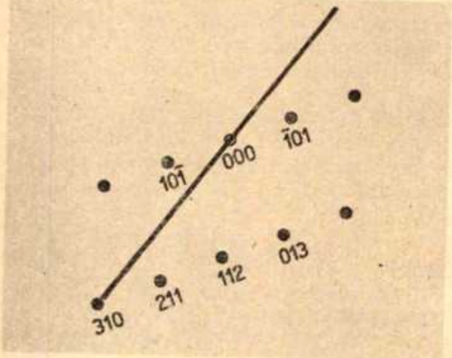

Fig. 2. Reciprocal lattice-$1\bar{3}1$ plane

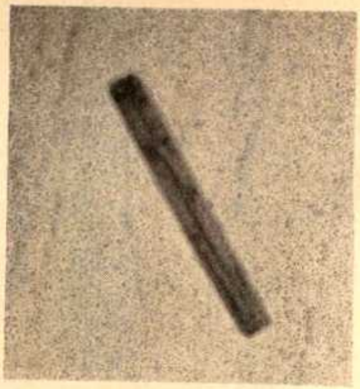

Fig. 3. Carbon extraction replica (× 20,000)

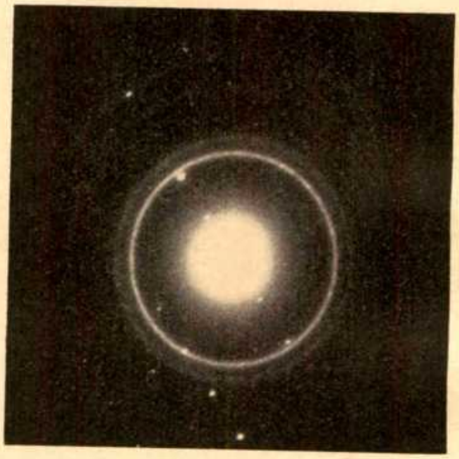

Fig. 4. Electron diffraction pattern of needle shown in Fig. 3 with superimposed gold standard

The investigation reported here was carried out to try to obtain a positive identification of aluminium nitride precipitates in a synthetic steel of the following composition (per cent): carbon 0·19, manganese 0·80, aluminium (insoluble) 0·001, aluminium (soluble) 0·08, nitrogen 0·0078, oxygen 0·0008, sulphur 0·01, phosphorus 0·001, silicon 0·01.

This steel was kindly provided by the British Iron and Steel Research Association, and details of melting, casting and heat treatment are given by Sage *et al.*[5]. This particular specimen was finally water-quenched from 900° C.

Carbon replicas were taken from polished sections by electrolytically etching in 20 per cent perchloric–alcohol solution for 1–2 min and were then examined in the Siemens Elmiskop I and Metropolitan Vickers *EM*3*A* type electron microscopes.

A large number of electron micrographs of needles (Fig. 1) with their corresponding single crystal diffraction patterns have been obtained. The most frequently occurring diffraction patterns were indexed as the (010) and (110) reciprocal lattice planes. Fig. 3 shows a typical needle and Fig. 4 the corresponding

Table 1

	a	*c*	*c*/*a*
(110)	3·084 ± 0·035	4·98 ± 0·035	1·61 ± 0·01
(010)	3·114 ± 0·03	5·00 ± 0·05	1·60$_5$ ± 0·01
A.S.T.M.	3·114	4·986	1·61

diffraction pattern. The (010) and (110) planes give the two patterns expected from a hexagonal structure, both being perpendicular to the *c* axis. The lattice constants were calculated from these patterns.

Taking into account lens rotation when changing from image to diffraction pattern, it was found in both patterns that the needle axis was parallel to the [001] direction. To support this fact, a third pattern, indexed as $(1\bar{3}1)$, not containing the (001) spot in its plane was used. The intercept common to both (001) and $(1\bar{3}1)$ is in the [310] direction. Allowing for the same lens rotation, the needle axis was again perpendicular to the intercept shown in Fig. 2.

To summarize, in aluminium-killed steels, needle- or lath-shaped precipitates have been found which give single crystal diffraction patterns. Lattice constants calculated from the indexed patterns correspond within 1 per cent with the A.S.T.M. index for aluminium nitride, while the *c*/*a* ratio, which is independent of calibration, has an agreement better than 1 per cent. The patterns were consistent with a hexagonal lattice system having its *c* axis parallel to the length of the needle.

I thank the British Iron and Steel Research Association for providing the steel and the Chairman of Tube Investments, Ltd., for permission to publish this communication.

Dendritic Structure in the Nedagolla Ataxite

Present versions of the Rose-Brezina system of meteorite classification include a Nedagolla group (D_n) of nickel poor ataxites which show a granulated structure[1]. The Nedagolla mass was observed to fall in 1870 and the main mass is preserved in the British Museum[2]. The nickel content is reliably established as 6·2–6·1 per cent[3,4], which is exceptionally low in relation to the other known members of Brown's gallium–germanium group IV (ref. 5). The presence of small amounts of silicate have been suspected[3] and Nedagolla shares with Tucson, the other silicate-containing member of gallium–germanium group IV, an exceptionally high chromium content[4,5].

I have made a metallographic examination of a 15-g slice taken perpendicular to the surface of the British Museum specimen *B.M.* 51184. A photograph of this specimen after etching in 4 per cent aqueous nitric acid is shown in Fig. 1, where a distinct pattern of slender dendrite skeletons may be seen in the heat-altered zone. The dendrite skeletons in the heat-altered zone are easily revealed by both aqueous and alcoholic nitric acid etchants and are seen to be least distinct at the ablating surface. Thus the dendrite structure in the heat-altered zone is being destroyed by the inflow of heat from the ablating surface of the meteorite, and we must conclude that the macrostructure of the unaltered mass of Nedagolla is dendritic. It is not easy to obtain an etching treatment which simultaneously reveals the dendritic structure in both heat-altered and -unaltered regions, but there is an area (opposite to the least-curved edge of Fig. 1) in which the dendrite skeletons of the heat-altered zone may be seen to merge into the more corpulent dendrites of the unaltered region.

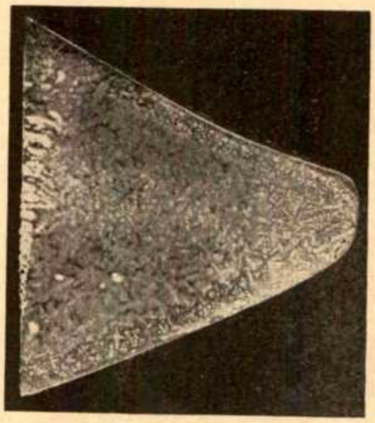

Fig. 1. A macro-etched fragment of the Nedagolla meteorite. The true length of the straight saw-cut edge is 3·0 cm. Curved edges are ablation surfaces below which a heat-altered zone is visible

Microscopic examination of the surface when reprepared and etched in 2 per cent 'Nital' revealed a number of minute globules of silicate but no identifiable phosphide. The unaltered region shows a dendritic pattern of clear kamacite areas in a duplex ground mass. The clear kamacite areas correspond to the iron rich cores whereas the duplex areas arise by precipitation from the alloy enriched outer regions of heavily cored dendrites produced during the solidification of an iron–nickel melt containing 6·1 per cent nickel. It is noteworthy that the γ–δ peritectic of the iron–nickel system is likely to be involved in the solidification process.

Progressing from the exterior inwards, the heat-altered zone shows a gradation of structures from the completely martensitic at the very edge; through a broad region of low nickel dendrite spines in a matrix of martensite and a transition zone of dendrites in a matric of non-acicular alteration product; to the unaltered structure of dendrite spines in a duplex groundmass. This sequence is consistent with the pattern of phase resolution and α–γ transformation events to be expected of cast iron–nickel material when it is reheated in a temperature gradient.

Thus Nedagolla appears to be an extreme example of a nickel-poor ataxite which has been produced by the complete melting and resolidification of material which is normally encountered as hexahedrites. It would be valuable to have gas content and radio-dating studies of this material. Similarly the metallographic examination suggests an appreciable carbon content and it would be valuable to have an analytical value for this element.

I thank Drs. Max Hey and A. A. Moss for making the specimen available and for helpful discussion.

METEOROLOGY

Pseudo-whiskers of Ice, grown from Clouds of Supercooled Water in an Electric Field

INTERESTING effects of ice formation in an electric field and from a supercooled water fog have been observed by Schaefer[1] and later confirmed by Marshall and Gunn[2], who pointed out at the same time that electrical charging of a suitable support which is immersed in a supercooled cloud greatly accelerates growth of supercooled droplets (and later crystals) on the sustaining medium. Schaefer's report mentions, in fact, very rapid growth of whisker-like aggregates from the tips of which, at high electrical gradients, supercooled water appears to be projected outwards.

Fragile 'ice-whiskers' could, if formed in a cloud and in an electric field, become, after subsequent mechanical fragmentation, the source of relevant quantities of ice nuclei, and information towards their growth and structure thus appeared to be of interest. Since, furthermore, the possible role of electrical effects in ice-nucleation has again recently been stressed[3], it was decided to carry out an experiment similar to those quoted in refs. 1 and 2, but in conditions of dense fogs artificially produced for short periods of time. Relatively intense electrical fields were used in this experiment and the potential was applied on copper wires which were insulated with plastic, in order to reduce the possibility of fragmentation of 'whiskers' by electrostatic wind and corona.

'Whisker' growth experiments were carried out in a plastic, tubular container, 40 cm in diameter and 50 cm high, the bottom part of which was closed. A similar container, but of 30 cm in diameter and made from a black mat carton, was introduced concentrically into the plastic tube, and the side interspace filled with 'dry ice' up to about 30 cm. A standard 1-l. beaker, containing about 600 c.c. of distilled water at 25° C, was placed centrally on the bottom of the assembly; the water was stirred using a magnetic stirrer drive which was situated under the plastic container. Two concentric rings of 6 and 17 cm in diameter, respectively, and made in standard, vinyl-insulated copper wire 2 mm thick, were suspended horizontally about 5 cm above the beaker, and brought to a potential difference of 6 kV using a stabilized d.c. supply. A large amount of supercooled fog was then produced in the apparatus by fast introduction of about 200 c.c. of liquid nitrogen into the beaker. Temperatures at the level of the electrodes usually fluctuated between −6° and −17° C during experimentation. Observation of the dense, thin 'whiskers' was carried out after the fog had subsided. Invariably, large amounts of hair-like ice-particulates were found to extend between electrodes (Fig. 1).

In contrast to the structure of 'normal' metal or salt whiskers, which appear to be of a somewhat unusual but none the less definitely developed crystalline form (see, for example, a recent contribution by L. D. Calvert, A. F. Sirianni and I. E. Puddington[4]), the ice particles obtained in this experiment consist of very thin microcrystalline dendritic aggregates, the agglomeration of which is oriented in the direction of the electric field (Fig. 2).

It can be seen that the 'fibres' consist of particulates more than about 20μ thick: closer examination reveals the existence of minute, frozen ice spherules, which are intermingled with the microscopic dendrites. The photographs were taken using a suitable, microscopic covered cold stage and transmitted light: no particular effects could be detected by use of polarized illumination.

The growth of dendrites is not surprising here, considering the order of magnitude of the temperature in

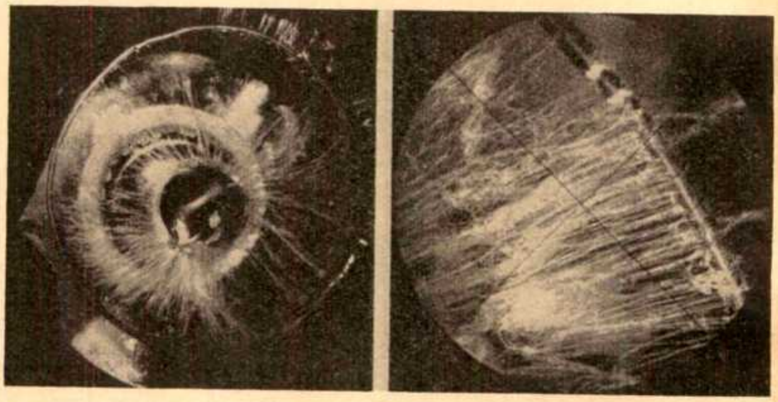

Fig. 1. Photographs of 'ice whiskers' grown between charged electrode wires. One picture was taken directly, while the other was taken through a cathetometer telescope

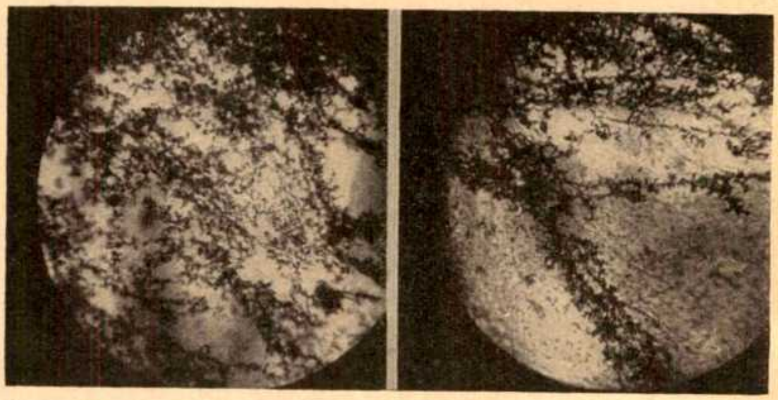

Fig. 2. Two different photomicrographs of dendritic 'ice-whisker' material. Visual field is 0·78 mm in diameter

e region of the electrodes[5]. The speed of growth of e agglomerates in the direction of the electric field, well as their thinness and fragility, are, however, of onsiderable importance. If, in line with Schaefer's bservations, the presence of an ice-forming nucleus s required to initiate 'ice-whisker' growth, and if such rowth is afterwards favoured by a local strong tmospheric electric field, and occurs in a dense under-ooled cloud, then it may easily be expected that the delicate material formed will soon be broken up by atmospheric turbulence into many minute fragments of ice, which will in turn act as individual nuclei. It is therefore thought that a process of a chain-multiplication of ice nuclei, such as that suggested here, could, if occurring in Nature in conditions otherwise suitable, have a bearing on some aspects of precipitation phenomena from congested clouds.

We thank Prof. V. Caglioti for his interest in this work, and the Cassa per il Mezzogiorno and the Società Generale Elettrica della Sicilia for financial assistance.

GEOLOGY

Possible Relation of Tuff in the Jackson Group (Eocene) to Bediasites

King and Rodda[1] have described rhyolitic tuffs in the Jackson Group; the first report of rhyolitic tuff from the Texas Gulf Coastal Plain. Analysis of tuff from the Jackson Group (Table 1) differs from analyses of unaltered tuffs from the Gueydan Formation (Miocene) in South Texas[2].

Table 1. Analyses of Tuff and Tuffaceous Siltstone from the Manning Formation of the Jackson Group, Walker County, Texas

This locality is known locally as the 'Chalk Pit' (from King and Rodda (ref. 1))

	Upper tuff	Middle tuffaceous siltstone
SiO_2	73·13	73·08
Al_2O_3	13 26	15·23
Fe_2O_3	0·57	3·16
MgO	0·39	0·53
CaO	0 65	1·08
Na_2O	1·33	1 89
K_2O	6·02	2·68
TiO_2	0·19	0·59
P_2O_5	0 02	0·12
MnO	0·06	0·04
Ignition loss	3·62	1·52
H_2O	0·79	0·37
	100 08	100·22

Most bediasites have been found on rocks of the Jackson Group, and analyses of Jackson tuff and tuffaceous rock (Table 1) are similar to some published analyses of bediasites[3,4], especially when water and ignition loss are removed and percentages recalculated to 100 per cent.

Tuff, tuffaceous rocks and bentonite (altered tuff) are abundant in the Jackson Group[5] and are present at or near many bediasite localities. The Purswell Lease of the Baroid Division, National Lead Co., is a recently discovered example.

The Purswell property, situated approximately 5 miles south-east of Waelder, Gonzales County, Texas, contains 2 large pits from which bentonite has been commercially recovered. The old pit, to the west, is abandoned. The new pit, approximately 100 yards east of the old pit, is being worked for bentonite. Mr. E. S. Dorsey, of Flatonia, Texas, mine superintendent of the Purswell Lease, found a bediasite on top of the waste pile immediately north of the old pit. This specimen is now in the possession of Mr. R. E. Offeman, of Houston, Texas, who furnished a fragment to me for examination. Mr. Dorsey states that material in the waste pile on which he found the bediasite came from well below the ground-surface, approximately 6–10 ft., and that this waste material was loaded from the bottom of the pit, hauled to its present location and dumped there. There seems to be only a slight possibility of mixing with surface gravel. The waste pile contains abundant gravel, and gravel is in place in the rock exposed in the east wall of the old pit, although most of the old pit is now flooded. Mr. Dorsey also noted that almost all the gravel in the waste pile on which he found the bediasite occurred in lenses very close to the top of the 6–8-ft.-thick strata of bentonite which was mined. At least 2 other bediasites have been found on waste piles to the north and west of the old pit.

It is probable that the 3 bediasites from this locality came from gravel lenses overlying the bentonite. This locality supports the conclusion that there is a geographical association, as well as a probable stratigraphic association, of bentonite (altered tuff) and bediasites. The stratigraphic position of this locality within the Jackson Group is unknown. There are several faults in the area, outcrops are scarce, and dips within the pit are 4°–6° south-west instead of the 1°–2° south-east which is the regional trend.

Two experimental dry fusions of tuff from the 'Chalk Pit' locality, Walker County, were performed in a Hevi Duty globe-type furnace at one atmosphere pressure in covered Denver fire clay crucibles.

Fusion 1 was heated to 1,420° C over a period of 4 h, cooled to 1,200° C, held at that temperature for 72 h, cooled to 850° C over a period of 6 h and removed from the furnace. Fusion 2 was heated to 1,450° C over a period of 5 h, held at that temperature for 30 min, then was removed from the furnace and immediately quenched in room temperature tap water. The glass resulting from both of these fusions is identical. The glass is transparent, vesicular, greenish yellow-brown, devoid of microlites, and has an index of refraction of 1·490 ± 0·001. The specific gravity of this glass could not be determined accurately because of the numerous vesicles, but because most of the vesicles are spherical or nearly spherical a fair approximation of the specific gravity can be made allowing for the total volume of the vesicles. One such determination was made on a small fragment of glass from fusion 2. The vesicles in the specimen were counted and measured, and their approximate volume calculated. The corrected specific gravity of this glass is 2·351 at 74° F. These properties are very similar to those of some bediasites[3].

Preliminary comparison of the composition of tuff samples from the 'Chalk Pit' with bediasites by X-ray fluorescence analysis does not indicate any marked qualitative differences. However, this remains to be investigated in detail.

Pinson and Schnetzler[4] found 'marked similarity' in rubidium/strontium ratios of bediasites and a sample of 'clayey sand' from the Wellborn Formation of the Jackson Group. The strontium-87/strontium-86 ratios were found to be identical within experimental error, but the chemical composition of the 'clayey sand' that Pinson and Schnetzler analysed did not resemble bediasites. Isotope investigation of the tuffs and tuffaceous rocks in the Jackson Group seems desirable because of their compositional similarity to bediasites.

If bediasites are of terrestrial origin, it is probable that tuffs or tuffaceous rocks in the Jackson Group are the parent material of, or are genetically related to, bediasites.

GEOCHEMISTRY

Trace Elements in Tanganyika Carbonatites

Von Knorring and du Bois[1] have given analyses for a vesicular carbonate lava from Fort Portal, Uganda, showing close geochemical affinities with intrusive carbonatites. Only two other occurrences of extrusive equivalents of carbonatites have been reported, namely, Kerimasi[2] and Oldoinyo Lengai[3]. Dawson[3] has described both *pahoehoe* and *aa* carbonate lava from Lengai which were extruded from an active vent on to the floor of the northern crater. Analyses of samples of the lava have been completed at the Tanganyika Geological Survey Laboratories together with the trace elements. At the same time, samples of Kerimasi sövites and Oldoinyo Dili sövites were analysed to compare the trace element data of both extrusive and intrusive carbonatitic occurrences. These values, obtained by a semi-quantitative spectrographic method using anode excitation and by comparison with synthetic standards, are listed in Table 1.

Kerimasi, Oldoinyo Dili and Oldoinyo Lengai[3] are situated in an area which extends from the Serengeti Plains in the west to Kilimanjaro in the east, and from the Kenya border in the north to Lake Manyara the south. Kerimasi and Oldoinyo Lengai associated with volcanoes of a highly explosive ty in which lavas are subordinate to pyroclastics, wh Oldoinyo Dili represents an eroded eruptive centre.

BD.118 and 114, carbonate lavas collected by J. B. Dawson. *JG*.1523, 1266, 2349 and 2356, sovites collected by N. J. Guest.

The only characteristic trace element occurring i all three localities is lanthanum, with the values f Oldoinyo Lengai and Oldoinyo Dili approaching th for the vesicular carbonatitic lava from Fort Port (600 p.p.m.). Other rare-earth elements have not ye been sought, but yttrium with geochemical properties similar to the rare-earth group, particularly ytterbium, is only found in appreciable quantity at Oldoinyo Dili. The concentration of strontium i higher than the concentration of barium in the two extrusives Lengai and Kerimasi, a characteristic property of carbonatites noted by Higazy[4] and observed by von Knorring and du Bois[1]. However, in contrast, barium is more concentrated than strontium at Oldoinyo Dili. Niobium, an element often thought to indicate the presence of carbonatite, is notably low for Lengai and Kerimasi but reaches 800 p.p.m. at Oldoinyo Dili. Significantly, the carbonate lavas from Lengai contain up to 400 p.p.m. rubidium and 100 p.p.m. lithium, a marked indication of the alkalinity. Wyllie and Tuttle[5] have commented that if alkali-bearing carbonatitic magmas can persist down to pressures of 1 bar, then the eruption of vesicular carbonate lava is possible. The specimens from Oldoinyo Lengai may thus approach the composition of a carbonatite magma.

It may be tentatively concluded that lanthanum i a characteristic trace element in Tanganyikan carbc atites. Further evidence of this is indicated by recent analysis of a brecciated fenite from Wigu Hi some 300 miles south-south-east of the three north localities, having a concentration of more than 5,0 p.p.m. lanthanum. The presence of lithium a rubidium confirms the alkaline nature of carbona lava from Oldoinyo Lengai.

I thank Mr. J. W. Pallister, commissioner for Geological Survey, Tanganyika, for criticism and permission to publish this short communication.

CRYSTALLOGRAPHY

Crystal Structure of Peroxochromates, $CrO_5.C_5H_5N$

WORK on the crystal structures of peroxochromates has been going on in this laboratory for some years. The addition compound $CrO_5.C_5H_5N$ was prepared according to Hofmann and Hiendlmaier[1] and was recrystallized in ether, which yielded well-developed needle-like crystals. The compound decomposed in one or two days. $CrO_5.C_5H_5N$ was investigated by the usual X-ray methods. It was found to have monoclinic symmetry, corresponding to the non-centrosymmetric space group $P2_1$ (No. 4).

The dimensions of the elementary cell are: $a = 5{\cdot}107$ Å; $b = 16{\cdot}31$ Å; $c = 11{\cdot}29$ Å; $\beta = 128{\cdot}35°$. The cell contains four formula units. Parameter values for all the atoms have been determined by three-dimen-

sional Fourier summation (Table 1). The reliability index R is calculated to be as follows: $R_{hk0}=0{\cdot}15$, $R_{h0l}=0{\cdot}21$, $R_{0kl}=0{\cdot}19$ and $R_{hkl}=0{\cdot}21$.

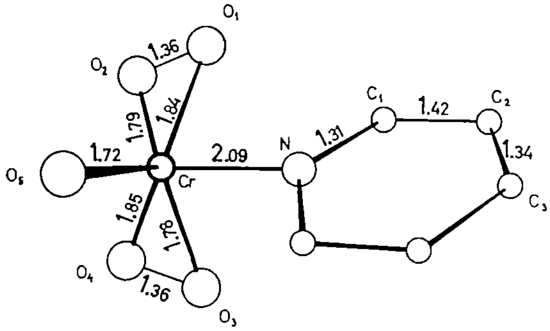

Fig. 1

The constitution of the peroxo complex can be seen om Fig. 1. Thus the chromium atom is 6-co-inated, and the geometrical configuration is that of omewhat distorted pentagonal pyramid with the le oxygen at the top of the pyramid. The bond-ances have been taken as the mean values of the responding distances found in the two non-sym-try-related molecules. It is estimated that the romium to light atom distances are probably eliable to ± 0·05 Å and the light atom to light atom istances reliable to ± 0·10 Å. The distances between the oxygen atoms in the O_2-groups are remarkably short.

A least-square refinement of the structure has been undertaken, and a complete report of the structure nvestigation will be published elsewhere.

CHEMISTRY

Resolution in Gas Chromatography

THE comparison of columns used for gas chromatographic separation is almost invariably based on the experimentally determined number of theoretical plates (n). A major practical limitation of this concept is that it can only be calculated for isothermal operation; in addition, its use for comparing the performances of different columns is misleading. Although capillary columns have been developed with several hundred thousand theoretical plates, as opposed to the several thousand plates of ¼-in. diameter packed columns, the performance of the apillary columns (in terms of ability to separate omponents) is only a few times better than that of the acked columns. The comparison between distillation and gas chromatographic efficiencies is similarly misleading[1].

Peak resolution has been suggested[2] for assessing the performance of a column in separating any pair of components. This term can be used irrespective of the way in which the column is operated; but it does not provide a clear overall picture of the separating capabilities of the column, nor does it afford a means of comparing column performances.

We therefore propose the concept of the 'effective peak number' (EPN).

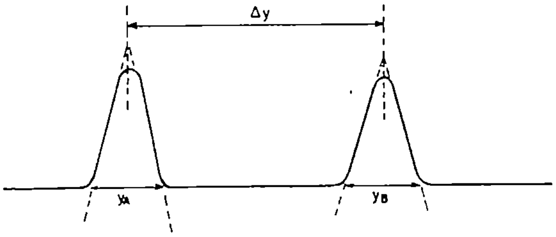

Fig. 1

Fig. 1 represents a chromatogram of two consecutive members of a homologous series. The nomenclature is that recommended by Ambrose, Keulemans *et al.*[2]. We define effective peak number as:

$$\text{EPN} = \frac{2\Delta y - (y_A + y_B)}{(y_A + y_B)}$$

This is obviously related to peak resolution (r), which is given by:

$$r = \frac{2\Delta y}{(y_A + y_B)}$$

$$\text{that is, EPN} = r - 1$$

We emphasize that this holds only where r is calculated for consecutive homologues.

We suggest that the two homologues, by which effective peak number is defined, are specified. For example, if n-octane/n-nonane be the pair, then the appropriate value would be EPN_{nC_8/nC_9}, similarly $\text{EPN}_{\text{bz/tol}}$ for the benzene/toluene pair.

The value of effective peak number lies in the fact that it is the maximum possible number of peaks which can be completely resolved between two homologues with a given set of operating conditions. The effective peak number can, of course, be calculated for any type of column, operated either isothermally or with any form of programming. By the same token,

Table 1. VALUES OF THE EFFECTIVE PEAK NUMBER AND NUMBER OF THEORETICAL PLATES FOR SOME REPRESENTATIVE COLUMNS

Stationary phase, dimensions and mode of operation of column	Component	EPN	No. of theoretical plates
Silicone gum, 2′ × ¼″, programmed temp., 60°–300° C	nC_{23}	1·0	400 (isothermal)
	nC_{24}		
'Apiezon *L*', 30′ × ¼″ isothermal (125° C)	benzene	8·4	10,240
	toluene	9·1	—
	ethylbenzene		—
programmed, 60°–220° C	toluene	9·2	
	ethylbenzene		
2,5-Hexanedione, 45′ × 1/8″ isothermal (0° C)	C_3	6·5	26,400
	nC_4	14·4	23,410
	nC_5		20,770
'Apiezon *L*', 60′ × 1/8″ isothermal to nC_6, then programmed	nC_5	16·6	30,000
	nC_6	23·1	—
	nC_7	25·3	
	nC_8	20·3	
	nC_9		
Squalane, 120′ × 0·01″ isothermal (70° C.)	nC_{18}	26·6	160,500
	nC_{19}		—

The effective peak number of the best of the above columns (the efficiency of which is good by any standards) puts into perspective the limit of separation (for example, of isomers) obtainable by gas chromatography. It appears that EPN values above say, 40, are unlikely to be obtained easily so that, should a mixture contain more than this number of components between any pair of homologues, they could not be completely resolved, however ideal the stationary phase.

it can be used for comparing the performance of any two columns, even though they may be operated in completely different manners.

In Table 1, some values of effective peak numbers and, where applicable, the numbers of theoretical plates, are given for a range of column types and modes of operation.

Note added in proof. Since this communication was originally submitted, we have become aware of a publication by Kaiser[3], in which he defines a "separation number" (TZ) in almost exactly identical terms to our definition of EPN. The two concepts are equivalent.

In a recent paper[4], resolution, with respect to consecutive normal alkanes, was specified for a high efficiency column. Besides emphasizing the very limited utility of theoretical plate numbers, the actual value of resolution (68 for nC_6/nC_7) obtained was strikingly high.

Transmission of Electronic Effects in Transition Metal Complexes

AN interesting aspect of transition metal chemistry relates to the influence which one ligand partner, in a mixed complex, may exert on another. The importance of electronic effects transmitted through a central metal ion is demonstrated, for example, by the directing influence of certain ligands in substitution reactions[1]. We report here some preliminary results on the influence of certain anionic ligands on the nature of the metal–pyridine bond in mixed complexes of cobalt(II). Our evidence for transmitted electronic effects in these complexes rests on certain striking differences in the influence of X on the position of equilibrium in the following configurational transformation:

$$\underset{\text{(tetrahedral)}}{\text{Co py}_2X_2} + 2\text{ py} \rightleftharpoons \underset{\text{(octahedral)}}{\text{Co py}_4X_2} \qquad (1)$$

in chloroform solution. Py = pyridine and X = Cl$^-$, Br$^-$, I$^-$, OCN$^-$, SCN$^-$ or SeCN$^-$. Co(II) complexes are well suited to configurational equilibria investigations of this kind because of the relatively high crystal field stabilization energy expected for the d^7 configuration in a tetrahedral field[2], and experimentally, because of the separate well-defined visible spectral characteristics of the two stereo-chemical arrangements. Equilibrium constants derived from spectrophotometric measurements were coupled with enthalpies determined calorimetrically and the associated entropy changes calculated. Since chloroform is relatively non-co-ordinating, the derived thermodynamic quantities refer, fairly closely, to the actual association reaction as represented in equation (1).

We direct attention to two features of the results: (1) the marked difference in the effect of the halide and OCN$^-$ ions on one hand, and SCN$^-$ and SeCN$^-$ on the other, on the equilibrium constant (K); (2) the predominant importance of the entropy term. The negative entropies are of the order of magnitude expected for an association reaction in which two of the three reacting molecules lose independent translational motion. It is the differences in ΔS, however, which are of greater interest, and to account for them we suggest that the pyridine ligands lose, in addition, a certain amount of rotational freedom (about the cobalt–nitrogen bond) to an extent determined by X. Potential barriers to rotation may arise from steric interactions or from multiple bonding. While some steric interaction must be expected in all the octahedral complexes, steric factors alone cannot be responsible for the dependence of ΔS on X; for example, there is unlikely to be a greater steric effect in Co py$_4$(NCO)$_2$ than in Co py$_4$(NCS)$_2$. Double bonding would arise from back-co-ordination of electrons in non-σ-bonding metal d orbitals to an anti-bonding π-orbital of pyridine; considerable evidence for multiple bonding in metal–pyridine complexes already exists[3]. On this basis, then, it is possible to arrange the ligands X in order of their capacity for inducing dative π-bonding in the Co–pyridine bond. From the ΔS values this order is:

$$\text{I}^- > \text{Br}^- > \text{Cl}^- \gg \text{OCN}^- \gg \text{SCN}^-$$

with SeCN$^-$ probably placed after SCN$^-$.

It seems that both inductive and mesomeric effects are involved. The order of effectiveness of the halide ions indicates that in the halide complexes it is the charge transferred to the metal in the cobalt–X bond that is important in the first instance. This electron drift, since it will decrease the effective electron affinity of the metal, might be expected to have two consequences; (1) decrease the attraction of the meta ion for the electrons in the cobalt–pyridine σ-bon (2) enhance the overlap of the non-σ-bonding metal orbitals with pyridine π-orbitals. By either mean the metal atom becomes partially relieved of excessive electron density close to it. If the inducti effect (1) were the dominant one, the changes in would be reflected mainly in ΔH, which should fall o on passing from chloride to bromide to iodide. In fact not only is a small trend in the opposite sense observed but the entropy of reaction becomes more negative also. This is strong evidence for a transmission of effects by means of both π- and σ-bonding metal orbitals. The much less negative ΔS found for the thiocyanate suggests either very little covalency in the Co–NCS bond (relative to Co–Cl) or a substantial measure of dative π-bonding of the type $d\pi \rightarrow p\pi$ (in Co–NCS) which would render the metal t_{2g} orbital less available for overlap with pyridine π-orbitals The former postulate, however, would conflict with other properties of the SCN$^-$ ion, for example, its reducing character which is comparable with that of Br$^-$ and its position in the nephelauxetic series[4]. Thus it seems that SCN$^-$ (and probably SeCN$^-$ also) when bonded via the nitrogen atom, as is the case here[5], may have a moderately high π-acceptor capacity, OCN$^-$ being less effective in this respect.

These conclusions, which are being tested in further experiments, demonstrate the different ways in which charge may be distributed within a complex molecule so as to maintain the metal atom in a condition close to electrical neutrality.

It is noteworthy that K, which is a sensitive indicator of the tendency of the metal to increase its co-ordination number from 4 to 6, correlates fairly well with the preferred co-ordination number in the solid complex Co py$_2X_2$ (Table 1). Only Co py$_2$(NCO) seems anomalous. However, we believe this anomaly to be apparent rather than real, since the adoption o

Table 1

Complex	K	$-\Delta H$ (kcal mole^{-1})	$-\Delta S$ (cal deg^{-1} mole^{-1})	Preferred configuration in solid state

All data refer to measurements at 20° C.

* A reliable value was not obtained because of the low solubility of this complex.

a bridged octahedral configuration depends, among other factors, on the capacity of the anion X for bifunctional linkage. The suggestion[5] that OCN$^-$ might have a low co-ordinating power through the oxygen atom is thus supported by the data presented here. It is probably significant, in this connexion, that while organic thiocyanates are known in both the normal and iso-forms, organic normal-cyanates have not been isolated[6]. It seems that before OCN can be made to bridge in complexes of the kind described here the electron density around the metal atom must be further reduced. One obvious way of attempting this is to replace pyridine by a poorer σ-donor. We have done this using 4-cyanopyridine and find that cobalt(4-cyanopyridine)$_2$(NCO)$_2$ is pink in colour and has a magnetic moment of 5·3 *B.M.* at 18° C, a value in accordance with expectation for 6-co-ordinate Co(II)[7]. The complex is therefore presumed to contain bridged OCN$^-$.

Electron Affinities of Organic Molecules

ABSOLUTE values of the electron affinity, E, of organic molecules have not been determined experimentally except in a few cases[1,2], and in most of these the uncertainty is several tenths of an electron volt or even more. Some theoretical values have also been calculated[3]. Since the electron affinity is a fundamental molecular property and also is[4] of considerable importance to modern biology it is desirable that more and better values be found.

The deduction of relative values of E from the data of charge-transfer spectra has been possible in principle for some time but absolute values have been unobtainable[2]. However, Jortner and Sokolov[5] have recently used experimental results to relate the affinity of I_2 to the well-known value for atomic iodine. In this way $E(I_2)$ was found to be 1·8 eV. Mulliken had previously estimated[6] 1·8 eV for $E(I_2)$ and indeed such a theoretical value for E could have been made the basis of a table of electron affinity values, which however, to our knowledge, has not been done.

Since I_2 acts as an acceptor in charge-transfer spectra, E of other acceptors can be related to $E(I_2)$. The simplest relationship between the E's of two acceptors depends on a number of assumptions and follows from the expression for the energy, $h\nu$, of the maximum of the charge-transfer band being given by the expression (1).

$$h\nu = I(D) - E(A) + \varphi_{AD} \qquad (1)$$

where $I(D)$ is the ionization potential of the donor molecule D; $E(A)$, the electron affinity of the acceptor, A.

The difference in E for two molecules, i, and j, for a given donor is then:

$$E(A_i) - E(A_j) = h\nu_j - h\nu_i + \varphi_{iD} - \varphi_{jD} \qquad (2)$$

The assumption that the right-hand side of equation (2) is approximately equal to $h\nu_j - h\nu_i$ can be tested by determining $E(A_i) - E(A_j)$ for a series of donors. Data are available for tetrachlorophthalic anhydride with 7 donors; 1,3,5-trinitrobenzene with 12 donors; chloranil (presumably p-chloranil) with 14 donors; and tetracyanoethylene with 14 donors. The affinities of these acceptors relative to $E(I_2)$ are calculated in eV to be respectively $-0·03 \pm 0·10$; $+0·06 \pm 0·13$; $+0·79 \pm 0·17$; $+1·09 \pm 0·10$. The spread of the values so determined is thus only about 0·2 eV in each case and the simplifying assumption accordingly finds some justification.

However, $(\varphi_{iD} - \varphi_{jD})$ need not be zero, but may be a constant with respect to changing the donor, D. We now make the simplest assumption, which was also

† In the case of donors 19–22, values are based on that of trinitrobenzene, taken as 1·86 eV.

‡ There is disagreement in the literature about the experimental result for the perylene–maleic anhydride complex.

§ This value was used to fix the zero of the energy of scale.

implicit in the work of Jortner and Sokolov, that this constant is zero. Consequently, it is possible to compile a table of electron affinities (Table 1) for molecules which act as acceptors in charge-transfer spectra. The above assumption is expected to hold quite well for molecules which form complexes with similar intermolecular separations. For planar molecules such as chloranil, 1,3,5-trinitrobenzene, and for tetracyanoethylene the contribution to $(\varphi_{iD}-\varphi_{jD})$ from a change in intermolecular separation is probably less than 0·2 eV and so may be ignored. For iodine, $(\varphi_{iD}-\varphi_{jD})$ may or may not be significantly larger than 0·2 eV. Since iodine is the basis of the scale it is therefore possible that the electron affinity values given in Table 1 differ from the true values by a constant which, however, is possibly not more than a few tenths of an electron volt. Furthermore, φ_{iD} must vary with the polarizability of the donor and the acceptor. The contribution of such a change to $(\varphi_{iD}-\varphi_{jD})$ for the acceptor pair *p*-chloranil and *p*-bromanil or the pair *p*-chloranil and 1,3,5-trinitrobenzene is no greater than 0·4 eV. In many other cases the contribution must be less than 0·4 eV. The electron affinity values in Table 1 are labelled 'approximate' because it has not been possible to take account of the corrections for lack of sufficient data on polarizabilities and intermolecular distances. In Table 1 $E(\mathrm{I}_2)$ has been taken as 1·80 eV. Those values which are derived from the spectrum with a single donor are subject to a greater uncertainty than those for which many donors have been studied.

Other values of E have been derived from charge-transfer spectra by Briegleb and Czekalla[2] using a different procedure which yields, according to the authors, a lower limit for E. Briegleb and Czekalla's results are: tetracyanoethylene, 1·6 eV; chloranil, 1·35 eV; 1,3,5-trinitrobenzene, 0·6 eV; iodine, I_2, 0·8 eV, and maleic anhydride, 0·5 eV. Compared with values in Table 1, Briegleb and Czekalla's results are indeed lower, as they expected, and by an amount of about 1·2 eV. Our results confirm their relative values.

Radiation-induced Solid-State Polymerization of Acrylonitrile and Acrylamide in the Presence of an Electric Field

CERTAIN monomers, when irradiated in the solid state, polymerize only to a limited conversion. When acrylonitrile is irradiated with γ-rays at −196° C it appears impossible to polymerize the monomer beyond a conversion of approximately 5 per cent[1–3]. If, however, the irradiated monomer is allowed to melt and then resolidified, a stepwise conversion curve is obtained on further irradiation, with yields of approximately 25 per cent[1]. One explanation of this phenomenon is that initiation occurs at crystal defects and termination occurs at grain boundaries or other surfaces.

It has been reported that during the polymerization the reaction vessels became electronically charged, and subsequent discharging with a grounded electrode caused polymerization to proceed further[4]. A linear conversion of up to 23 per cent was achieved when the solid monomer was irradiated with X-rays in a grounded steel vessel[1]. These results were interpreted as indicating that some electronically charged species are the precursors of the active centres responsible for the initiation of polymerization.

An extension of this work[4] showed that if the positive pole of a cell (1·5–80 V) was placed in the solid, with the negative pole unconnected, yields of up to 40 per cent could be obtained. We have investigated the effect of high electric fields (approximately 1 kV/cm) on the radiation-induced solid-state polymerization of acrylonitrile. The results obtained are summarized in Table 1.

Table 1. POLYMERIZATION OF ACRYLONITRILE AT −196° C BY COBALT-60 γ'S (560 krads/h)

Dose (megarads)	Conversion (percentage polymer)		Voltage (kV)
	No field	Plus electric field	
0·5	—	1·2	1·2
1·0	2·2	1·9	1·4
2·0	7 7	7·8	1·4
3·0	—	5·2	1·4
4·0	3·7	3 9	0·9

Field applied between two parallel platinum plates, about 1 cm apart.

These results show that the electric field has little or no effect on the conversions of acrylonitrile. It has been shown that the polymerization of acrylonitrile at −196° C proceeds by an ionic mechanism[5]. It is felt, therefore, that the results from our experiments show that charge separation cannot be a contributory factor in the electric field enhancement of the polymerization in the case of acrylonitrile.

Similar experiments were performed with acrylamide, this monomer being crystalline at room temperature. 100 per cent conversion of the monomer can be obtained by irradiation with higher doses of γ-radiation at this temperature.

It has been assumed that polymerization of this monomer in the solid state proceeds by a radical mechanism; however, electron spin resonance techniques have shown that observed radicals are not those responsible for polymerization[7]. Further evidence indicates that if a radical mechanism is operative then it is not of a similar nature to that observed in liquids[8].

Table 2. POLYMERIZATION OF ACRYLAMIDE AT ROOM TEMPERATURE BY COBALT-60 γ'S (560 krads/h)

Dose (megarads)	Conversion (percentage polymer)		Voltage (kV)
	No field	Plus electric field	
1·0	10·4	9·6	3·0
1·3	11·1	17·0	1·5
1·6	16·3	16·3	1·3
2·0	40·5	39 5	1·35

The results found in the presence of an electric field are summarized in Table 2.

In the presence of an electric field there is no enhanced conversion; thus it may be assumed that there is no charge separation operative in the polymerization of acrylamide.

BIOCHEMISTRY

Monoamine Oxidase Inhibition by Ethanol *in vitro*

HYPNOTIC doses of ethanol have been reported by Rosenfeld[1] to prolong the metabolic inactivation of exogenous serotonin (5-hydroxytryptamine) in mice. Olson, Gursey, and Vester[2] found the urinary excretion of 5-hydroxyindolylacetic acid (5–HIAA) to be significantly below normal in alcoholics, even after 6 months of abstinence on rigidly controlled diets. These findings suggest that ethanol may act as a monoamine oxidase (MAO) inhibitor. On the other hand, Gursey and Olson[3] have reported depression of brain-stem serotonin and *nor*epinephrine in rabbits after both acute and chronic ethanol administration; suggesting that ethanol may act to release stores of bound amines. Pscheidt, Issekutz, and Himwich[4] were unable to confirm this finding. In our laboratories, we have found that a single dose of ethanol, given orally to human volunteers, produces a marked, but transitory, increase in the urinary excretion of tryptamine[5].

These reports, although somewhat contradictory and confusing, appear to indicate that ethanol does influence the metabolism of the biogenic amines. The possible importance of such an influence in understanding the pharmacology of ethanol, and in the problem of alcoholism, has been emphasized by Westerfeld and Schulman[6]. As the first part of a systematic study of the effects of ethanol on the biogenic amines, we have investigated the influence of ethanol on mouse liver and brain MAO *in vitro*.

The tissues were homogenized in ice-cold potassium phosphate buffer, *p*H 7·4, 0·1 M. Tryptamine, tyramine, and serotonin (1·0 μmole) were used as substrates. Ethanol was added in the following concentrations: 100, 150, 200, 300, and 400 mg/100 ml. Potassium phosphate buffer, *p*H 7·4, was added to bring the total volume to 3·0 ml. Glass-stoppered flasks, 25 ml. vol., sealed with silicone grease, were used. It was necessary to keep all reagents and glassware chilled until the flasks were sealed, to prevent evaporation of the ethanol. After sealing, the flasks were incubated for 70 min at 37° C in a Dubnoff metabolic incubator. The disappearance of the substrate was measured spectrophotofluorometrically after a butanol extraction procedure modified from that of Udenfriend, Weissbach, and Clark[7]. Duplicate samples were run on the controls and on each of the ethanol concentrations.

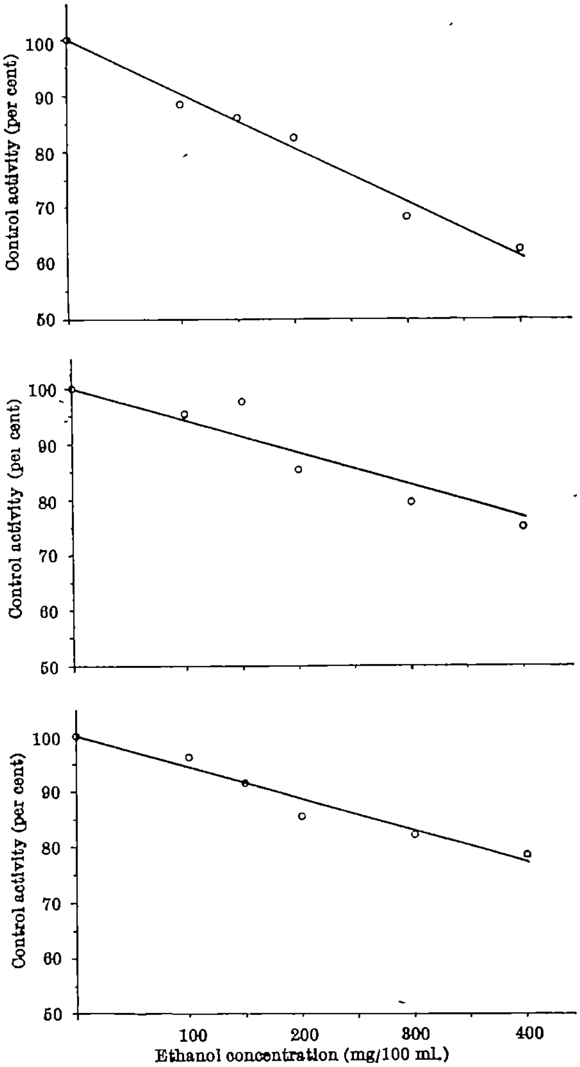

Fig. 1. Inhibition of mouse liver MAO by ethanol *in vitro* using as substrates serotonin (top), tryptamine (middle), tyramine (bottom)

The results obtained, using mouse liver homogenate as the enzyme source, are presented in Fig. 1.

Each of these curves is the average of a minimum of three runs. Straight lines were fitted by the method of least squares. The slopes of these lines are as follows: serotonin, – 0·097 per cent; tyramine, – 0·057 per cent; tryptamine, – 0·058 per cent. The standard deviations of these slopes were calculated. Application of the *t* test indicates that all the slopes differ significantly from a zero slope, *P* being less than 0·01, but do not differ significantly from each other.

Attempts to duplicate these results with brain MAO failed to demonstrate any inhibition of MAO by ethanol, despite the use of a variety of enzyme and substrate concentrations. Purified mitochondria from mouse brain likewise failed to exhibit any inhibition of MAO, although mouse liver mitochondria responded in a manner identical to that of whole liver homogenate (Fig. 1).

These results demonstrate definite and reproducible inhibition by ethanol of mouse liver MAO, but not of mouse brain MAO, when serotonin, tyramine, and tryptamine are used as substrates. The degree of inhibition is of a low order, and its biological and pharmacological significance is questionable. The sharp rise in urinary tryptamine excretion following ethanol ingestion[6] would seem inexplicable on the basis of this degree of MAO inhibition alone. We are therefore led to postulate that ethanol may have an effect on the biogenic amines not unlike that of reserpine, that is, that it can release stores of amines from the bound, inactive state into the free, active state. The depletion of brain-stem serotonin and *nor*epinephrine after the administration of ethanol to rabbits[3] supports this hypothesis. It is intriguing to speculate that ethanol may have a dual action, that of low order MAO inhibition, and that of releasing stores of bound amines. We are investigating this postulated amine releasing action of ethanol.

Lactate Dehydrogenase Isozymes in the Developing Rat Brain

THE immaturity and the lack of differentiation of the rat brain at birth has been shown some fifty years ago by Sugita[1] in a classic paper on the postnatal morphogenesis of the brain in this animal. The sequence of physiological and biochemical changes which parallel the histological maturation of the rat brain has been investigated, however, only recently.

Biochemical quantitative studies on brain lactate dehydrogenase (LDH) during the post-natal development of the rat have been performed in 1956 by Kuhlman and Lowry[2], who showed that LDH doubles from birth to maturity in the whole rat brain.

A different biochemical approach to the study of the developing brain was made in 1960 by Flexner *et al.*[3] LDH's of cerebral cortex and liver from adult and new-born mice gave different elution patterns when chromatographed on DEAE-cellulose. However, because of variability in loss of activity on the columns, it was impossible to obtain accurate relationships between total anionic and cationic components of the enzyme.

This communication is a preliminary account of quantitative data on LDH isozymes from the whole brain (in the following, the brain without the diencephalon will be referred to as whole brain). Kinetic properties of the enzyme during the ontogenesis will be described elsewhere.

The separation of LDH isozymes was obtained through agar-gel electrophoresis for 3·5 h, at *p*H 8·4, and with a continuous current of 48 m.amp. All other conditions of migration and elution from agar have been previously described by Bonavita and Guarneri[4]. That the technique of elution allowed an almost complete recovery (95 per cent or more) of the enzyme submitted to electrophoretic migration need only be mentioned. In these experimental conditions, LDH from the brain of the adult rat gives the isozymatic pattern illustrated in Fig. 1. This pattern is highly reproducible so far as the migration of the single components and their percentage values are concerned. Table 1 summarizes data on the individual variation of the single components.

The enzyme from the brain of the adult rat gives a pattern quite different from that observed in the new-born animal. Two days after birth, only minor

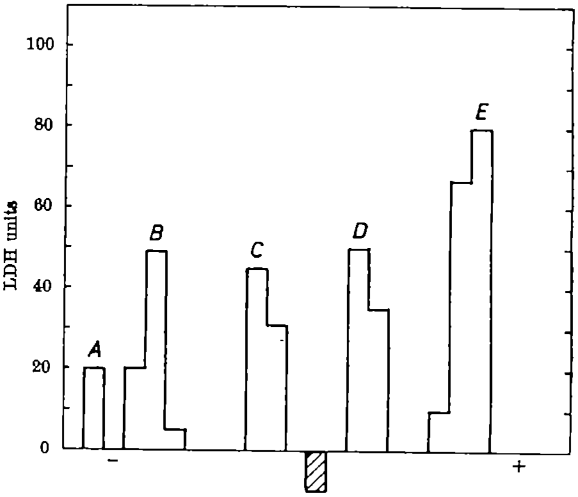

Fig. 1. LDH isozymes from adult rat brain as separated by agar-gel electrophoresis. The starting point is shown below the graph. One LDH unit is the amount of the enzyme which gives an absorbancy decrease of 0·001 in 1 min at 340 mμ

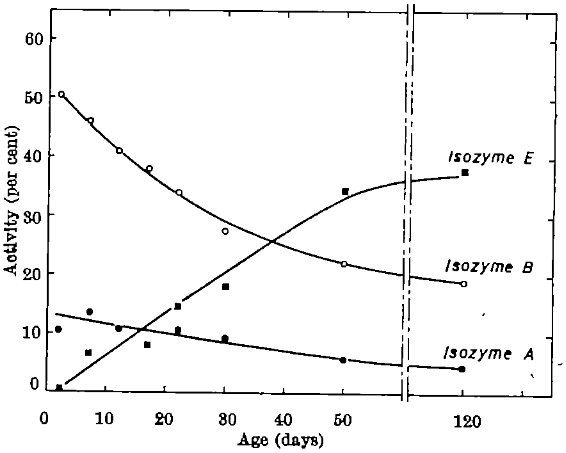

Fig. 2. Changes in the percentage activity of three LDH isozymes from the whole rat brain during the post-natal development. Each experimental point represents the mean of at least three determinations

Table 1. PERCENTAGE MEAN VALUES AND STANDARD DEVIATIONS OF LDH ISOZYMES IN THE WHOLE BRAIN OF THE ADULT RAT*

Isozyme *A*	3·95 ± 0·75
Isozyme *B*	19·45 ± 2·90
Isozyme *C*	19·20 ± 2·80
Isozyme *D*	19·80 ± 2·60
Isozyme *E*	37·60 ± 3·34

* These data have been calculated from the electrophoretic patterns of 12 brain extracts.

amounts of isozyme *E* can be revealed by using the spectrophotometric technique described by Neilands[5] for pig heart enzyme. However, outstanding changes do occur also in the per cent distribution of other enzymatic components. Fig. 2 summarizes data on the quantitative changes of three LDH isozymes in rat brain as a function of the age. Fractions *C* and *D*, shown in Fig. 1, do exhibit only minor modifications with the age of the animals.

The gradual changes in the per cent distribution of LDH isozymes from the developing brain and the developing retina[6] may invite speculation on a possible correlation between morphological and biochemical maturation. It is obvious, however, that such a parallelism may be only approximate. LDH reaches its definitive isozymatic composition only after the twentieth day, that is, when the cortex is already fully organized[1], and when the electrical activity of the brain has been for a long time similar to that of the adult[7,8].

Transamination of Aromatic Amino-Acids in Nervous Tissue

THE metabolic significance of transaminases in nervous tissues has recently been reviewed by Bonavita[1]. His paper reveals that interest in transaminations of amino-acids in nervous tissues solely comprised the aliphatic compounds. In this communication evidence is presented of transamination of aromatic amino-acids in the nervous tissues, that is, rat brain extracts.

Table 1. PURIFICATION OF RAT BRAIN TRANSAMINASE BY ACETONE PRECIPITATION

3·2 mg protein, 0·5 mM pyridoxalphosphate in each cuvette. Amino acceptor: α-ketoglutaric acid

		Increase in optical density per 30 min		
	Wave-length (mμ)	Brain extract	Purified brain extract	Purification factor
d-*l*-5-OH-tryptophan	328	0 420	0·865	2·0
d-*l*-Tryptophan	328	0·317	0 989	2·7
d-*l*-Dihydroxyphenylalanine	340	0 384	0·174	0 45
d-*l*-Tyrosine	330	0·280	0·837	3·0
d-*l*-Phenylalanine	325	0·174	0·450	2·6
d-*l*-Histidine	293	0 000	0·000	

The enzymatic assay was carried out as follows: rat cerebra were homogenized (20 per cent w/v) in ice-cold 0·57 M borate buffer *p*H 8·2, and afterwards centrifuged at 25,000*g* for 40 min in a refrigerated centrifuge. The clear supernatant was used for enzymatic assay. The assay is based on the ability of the enol tautomer of the aromatic α-keto-acid, which is produced in the transaminase reaction, to combine instantaneously with borate to form a mixed ester-anhydride structure[2,3]. This complex-formation displaces the keto-enol equilibrium in favour of the enol tautomer, which absorbs strongly in the 300 mμ region. The transaminations were read at wavelengths stated in Table 1, using a Beckman *DU* spectrophotometer, fitted with thermospacers at 37° C. Each semimicro cuvette (light path 1 cm) contained 0·4 ml. of the brain extract in the borate buffered reaction mixture of total volume 1·3 ml. Pyridoxalphosphate (Hoffmann–La Roche) was added as stated here. The final concentrations of the amino- and keto-acid were $1·75 \times 10^{-2}$ M and 1×10^{-2} M, respectively. The reaction was started by addition of the keto-acid after a 5 min pre-incubation period.

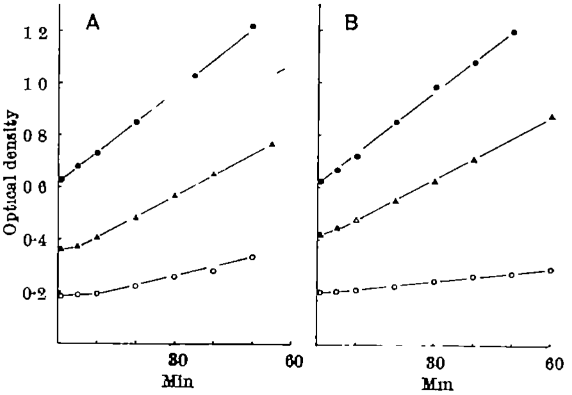

Fig. 1. Transamination of 5-hydroxytryptophan. *A*, α-Ketoglutaric acid as amino acceptor; *B*, pyruvic acid as amino acceptor. ○, 0 00 mM; △, 0 25 mM; ●, 0·5 mM pyridoxal phosphate added

Fig. 1*A* shows typical examples of the data obtained by transamination of 5-hydroxytryptophan with α-ketoglutaric acid. The data demonstrate the pyridoxalphosphate dependency of the transaminase reaction. It can be seen that, providing a sufficient pyridoxalphosphate supply (0·5 mM), a curve is obtained where the increment in optical density is a linear function of time. In Table 1 this increment per 30 min is taken as a measure of enzyme activity. When substituted for α-ketoglutaric acid, pyruvic acid was found to be almost equally effective in the transaminase reaction (Fig. 1*B*). This finding probably reflects low specificity of the enzyme for the keto-acid.

Table 1 reports experiments on the specificity and purification of the enzyme system. It can be seen that both brain extract and a partly purified enzyme preparation transaminated all aromatic amino-acids but histidine. The purified enzyme preparation was obtained as follows: a 20 per cent (w/v) rat cerebra homogenate in 0·15 M phosphate buffer *p*H 7·4 was centrifuged as described here. The clear supernatant was carefully decanted and afterwards

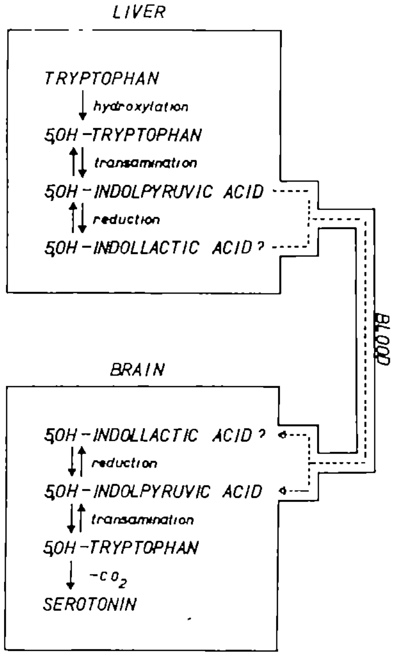

Fig. 2 A hypothetical scheme for the formation of serotonin in brain

precipitated by an equal volume of ice-cold acetone. The precipitate was collected by centrifugation at 25,000*g* for 15 min. The acetone–buffer supernatant was discarded, and the precipitate was extracted with a small volume of the phosphate buffer. Undissolved protein was removed by centrifugation. The protein concentration in the final supernatant was determined by the biuret method, and an aliquot used for enzymatic assay. It appears from Table 1 that the purification procedure gave increased activity for all amino-acids previously transaminated by the brain extract, except dihydroxyphenylalanine, which was transaminated at a significantly slower rate. This reveals that at least two enzymes must be present. However, a higher degree of purification is needed to state the exact number.

Preliminary experiments have shown that the transaminases described here are specific for the *l*-isomer, and further that the catalysis is reversible like other transaminases described[4].

The reactions demonstrated are considered to be of physiological significance for the metabolism of the biological amines. Support for this view is found in the *in vivo* experiments by Pogrund and collaborators[5], who obtained the same pressor response on systemic blood pressure from injection of 3-hydroxy- and 3,4-dihydroxy-phenylpyruvic acid, as from the corresponding amines: *m*-tyramine and dopamine. These findings may well be explained by a transamination and subsequent decarboxylation of the keto-acid directly in the peripheral nervous system. Also in the central nervous system the keto-acids evidently play a prominent part, since patients with phenylketonuria, besides the mental defects, have lowered amine-levels and disturbed amine metabolism[6,7].

The necessary enzymes being present, it seems permissible to postulate that the aromatic keto-acids may act as precursors of the corresponding biological amines. As an example a hypothetical scheme for the formation of serotonin in brain is presented in Fig. 2. This scheme is based on the formation of the appropriate keto (or lactic) derivative in the liver[8,9]. As seen from Fig. 2 a reduced transamination will influence the subsequent steps in the reaction sequence. It would therefore be of interest to investigate the metabolic position of the transaminases described here, in patients with phenylketonuria and other conditions associated with mental defects.

Effects of Atractyloside and Oligomycin on Magnesium-stimulated Adenosine Triphosphatase and on Adenosine Triphosphate-induced Contraction of Swollen Mitochondria

IN previous reports[1] it was shown that atractyloside inhibits the energy-transfer reactions of oxidative phosphorylation in a manner similar to that of the antibiotic oligomycin[2-4].

From these investigations it appeared that the only difference between the two substances concerned the effect on the magnesium-stimulated adenosine triphosphatase (ATPase). In fact, the magnesium-stimulated ATPase is inhibited by oligomycin and atractyloside using rat-liver mitochondria treated with low concentration of sodium deoxycholate (DOC), but it is not inhibited by atractyloside if the concentration of DOC is increased.

Since the effect of oligomycin on magnesium-stimulated ATPase was not tested on rat-liver mitochondria treated with high concentration of DOC, it was considered of interest to compare the effects of oligomycin and atractyloside under identical experimental conditions. The action of atractyloside on the terminal step of the energy-transfer reactions was also tested by experiments on adenosine triphosphate (ATP)–adenosine diphosphate (ADP) exchange reaction.

Table 1 shows that the effects of atractyloside and oligomycin on magnesium-stimulated ATPase are different: atractyloside strongly inhibits the magnesium-stimulated hydrolysis of ATP when the activity is elicited by a partial damage of the mitochondrial structure (0·1 mM DOC, short-time pre-incubation), while the inhibition is not present, or it is insignificant, when a strong damage is produced by various treatments (1·0 mM DOC, water treatment, mitochondria stored for 72 h); no inhibition was found when the concentration of atractyloside was increased 5- or 10-fold.

In order to explain the difference in the effects of atractyloside and oligomycin, the following possibilities were considered: (*a*) With low concentration

Table 1. Effects of atractyloside and oligomycin on Mg^{++}-stimulated ATPase. Each tube contained 50 mM potassium chloride, 50 mM *tris* buffer, *p*H 7 5, 2·5 mM ATP, 62 mM sucrose, 1 mM $MgSO_4$, atractyloside or oligomycin as indicated, 0·16–0·20 mg of nitrogen rat-liver mitochondria treated as follows: (*a*) 0 1 mM sodium deoxycholate (DOC) added in the medium; (*b*) 10 min of pre-incubation at 25° in 73 mM sucrose, 59 mM potassium chloride, 59 mM *tris* buffer, *p*H 7·5; (*c*) 1·0 mM sodium deoxycholate added in the medium; (*d*) 180 min of pre-treatment at 0° with distilled water; (*e*) ageing 72 h at 4° in 0 25 M sucrose. Final volume, 2 ml.; temperature, 25°; time of incubation, 20 min. Rat-liver mitochondria isolated in 0·25 M sucrose, according to Hogeboom (ref. 5)

	Treatment of mitochondria	μmoles inorganic phosphate liberated		
		Control	Atractyloside 0 05 mM	Oligomycin 0 5 μg/ml.
	—	0·5	0·5	—
(*a*)	0·1 mM DOC	2·6	0·5	0·5
(*b*)	Aged 10 min	2·6	0·6	0·4
(*c*)	1·0 mM DOC	2·4	2·3	0 8
(*d*)	Water at 0°	2 6	2 2	0 8
(*e*)	Aged 72 h	1·8	1·4	0·8

of DOC or with short-time pre-incubation, addition of atractyloside might result in an inhibition of the ageing-process. This hypothesis was in contrast with the observation that the atractyloside-induced inhibition of the magnesium-stimulated ATPase (elicited by pre-incubation in a potassium chloride-*tris*-sucrose medium) was the same when atractyloside was added before or after the preincubation. Furthermore, in Fig. 1 it is seen that atractyloside, as well as oligomycin, does not inhibit the spontaneous or the DOC-induced swelling of mitochondria.

(*b*) The site of hydrolysis or of utilization of the high-energy intermediate during the operation of the magnesium-stimulated ATPase is different in the case of partially and of completely damaged mitochondria. This difference offers a means of distinguishing between the site of action of oligomycin and that of atractyloside.

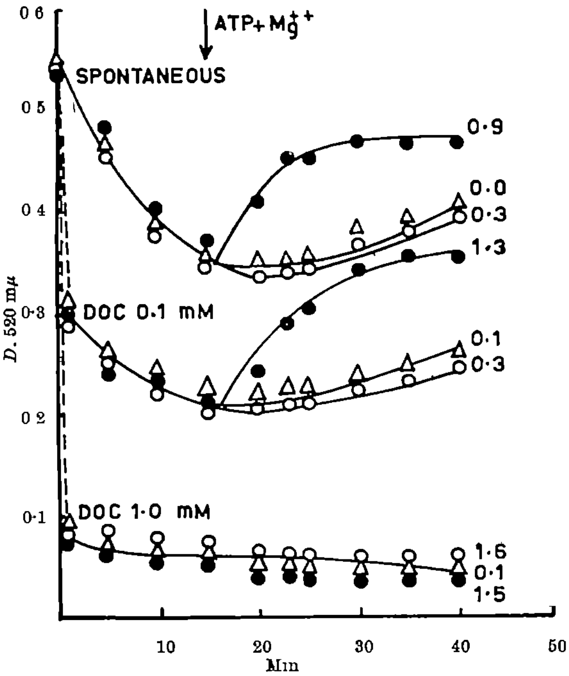

Fig. 1. Effects of atractyloside and oligomycin on ATP-induced contraction of swollen mitochondria and on the accompanying formation of inorganic phosphate. ATP-induced contraction of mitochondria was measured according to Lehninger (ref. 6), using a model *DU* Beckman spectrophotometer and 10 mm × 45 mm cuvettes. Each cuvette contained, in a final volume of 3 ml., 125 mM potassium chloride, 20 mM *tris* buffer, *p*H 7·5, 8·3 mM sucrose, 0 09 mg of nitrogen rat-liver mitochondria and, where indicated, 0·1 or 1·0 mM sodium deoxycholate. Additions: ●, nil; ○, 0 05 mM atractyloside; Δ, 1 0 μg/ml. oligomycin. 2·5 mM ATP and 1 0 mM $MgSO_4$ were added at the time indicated by the arrow. Temperature, 22°. The numbers refer to the μmoles of inorganic phosphate measured at the end of the experimental period

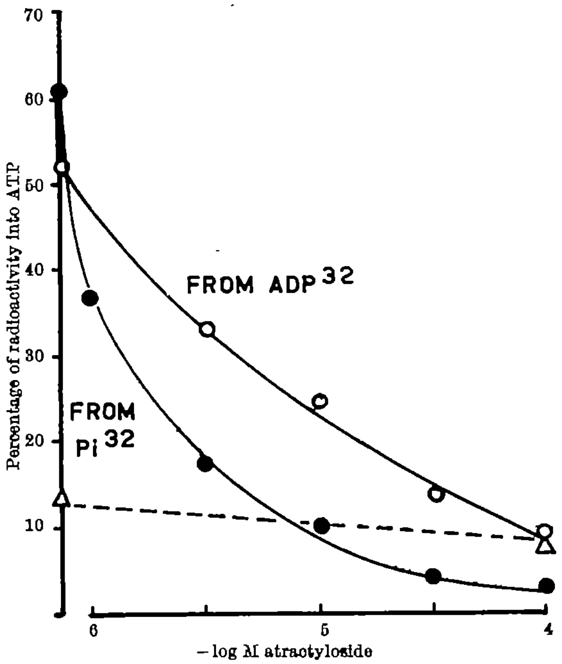

Fig. 2. Effects of atractyloside on ATP–ADP and ATP–inorganic phosphate exchange reactions. Conditions for ATP–ADP exchange: 50 mM *tris* buffer, *p*H 7·5, 4 mM ATP, 1·85 mM ADP (^{32}P) (5 × 10^4 c.p.m.), prepared as described by Cooper and Lehninger (ref. 7), 1 mM EDTA, *p*H 7·2, 62 mM sucrose, 0·08 mg of nitrogen rat-liver mitochondria, atractyloside as indicated. Final volume, 0·4 ml. Δ, per cent of the radioactivity detectable as ATP (^{32}P) in the absence of the ATP addition (adenylate kinase activity). Conditions for ATP–Pi exchange: 50 mM potassium chloride, 40 mM *tris* buffer, *p*H 7·5, 2 5 mM ATP, 1 mM EDTA, *p*H 7·2, 0·7 mM inorganic phosphate (^{32}P) (2 × 10^6 c.p.m.), 0 09 mg of nitrogen rat-liver mitochondria, 50 mM sucrose, atractyloside as indicated. Final volume, 1·0 ml. The samples were chromographed by the methods of Krebs and Hems (ATP–ADP exchange) (ref. 8) and of Cerletti *et al.* (ATP–inorganic phosphate exchange) (ref. 9), following deproteinization with trichloroacetic acid. Temperature, 25°; time of incubation, 20 min

This possibility is strengthened by the results plotted in Fig. 1, showing the effects of atractyloside and oligomycin on ATP-induced contraction of swollen mitochondria in the conditions described by Lehninger[6]. In agreement with the findings of Table 1, it is seen that:

(*a*) When a little damage of mitochondrial structure was produced by 0·1 mM DOC or by pre-incubation in a potassium chloride–*tris* medium, the addition of ATP and magnesium produced a contraction accompanied by formation of inorganic phosphate; both contraction and formation of inorganic phosphate were inhibited by atractyloside or by oligomycin.

(*b*) When a strong damage of mitochondrial structure was produced by 1·0 mM DOC the addition of ATP and magnesium resulted in a release of inorganic phosphate not accompanied by contraction of mitochondria; the release of inorganic phosphate was inhibited by oligomycin, but not by atractyloside.

In Fig. 2 it is seen that atractyloside inhibits both ATP-inorganic phosphate and ATP–ADP exchange reactions, catalysed by fresh liver mitochondria. By omitting ATP from the incubation medium and measuring the ATP formed, it was observed that the adenylate kinase activity of mitochondrial preparation, which was not affected by atractyloside, interfered with the effect of atractyloside on ATP–ADP exchange; ethylenediamine tetraacetate (EDTA) addition strongly reduced the adenylate kinase activity and rendered possible the observation of the atractyloside-induced inhibition of ATP–ADP exchange reaction.

Disruption of mitochondria with 1·0 mM DOC, ageing at 37° or at 4° resulted in an almost complete loss of the part of the ATP–ADP exchange activity that is not to be ascribed to the adenylate kinase. These results are in agreement with those of Cooper and Kulka[10], which also showed that oligomycin inhibits the ATP–ADP exchange activity of digitonin particles of mitochondria.

The atractyloside and oligomycin-induced inhibitions of mitochondrial contraction, together with the high sensitivity of the energy-transfer reactions to these agents, appear to be a convincing proof that the enzyme responsible for contraction is part of, or strictly related to, the coupling system. Furthermore, the findings reported in the present communication indicate that the mechanism or the site of action of atractyloside and oligomycin on the terminal step of energy-transfer reactions is not identical: atractyloside does not inhibit the magnesium-stimulated ATPase when the activity can be ascribed to a splitting of $X \sim P$ and, consequently, it does not interfere with the formation of $X \sim P$ at the expense of ATP; on the other hand, the strong inhibition by oligomycin of the magnesium-stimulated ATPase, in conditions where high concentrations of atractyloside are ineffective, can be explained by assuming that oligomycin inhibits under all conditions the formation of $X \sim P$ at the expense of ATP. In this regard it is interesting to note that atractyloside effect on magnesium-stimulated ATPase is more similar to that of the antibiotic aurovertin[4] than to that of oligomycin.
